The prognosis for AION varies but is often grim. Although there is no recognized treatment for AION, Williams *et al*¹⁵⁰ have reviewed the various therapies that may be instituted. These include iv acetazolamide, furosemide, mannitol, and steroids. Maintaining the head-up position could be helpful if increased ocular venous pressure is operative. Surgical optic nerve sheath fenestration or decompression is not only ineffective, but may actually be harmful.¹⁵¹

Posterior Ischemic Optic Neuropathy

Posterior ischemic optic neuropathy is less common than AION despite the fact that the posterior optic nerve has a less luxuriant blood supply than the anterior optic nerve. In contrast to AION, relatively few cases have been reported after CABG, and PION appears to be less related to coexisting cardiovascular disease. As with AION, male patients outnumber female patient four to one. Many cases have been associated with surgery involving the neck, nose, sinuses, or spine. In approximately one third of cases reported, facial edema has been noted.¹⁴⁵

Posterior ischemic optic neuropathy is produced by reduced oxygen delivery to the retrolaminar part of the optic nerve. Probably compression of the pial vessels (supplied by small collaterals from the ophthalmic artery) or embolic phenomena produce ischemia.¹⁵² However, severe systemic hypotension, anemia, or venous stasis may also be contributory.¹⁴⁵

A hypoxic insult in this region results in a slower development of ischemic damage, so a symptom-free period often precedes the loss of vision. In some patients, the onset of symptoms may be delayed several days. Typical findings include an afferent pupillary defect or nonreactive pupil. Disc edema is not a feature of PION owing to its retro-orbital position. CT scan in the early postoperative period may reveal enlargement of the intraorbital portion of the optic nerve. Bilateral blindness is more common with PION than AION, possibly indicating involvement of the optic chiasm. Concomitant disease of the eye or ocular blood supply may be related to PION.¹⁴⁵ Some cases may improve spontaneously, but usually no improvement is noted. Steroids may be considered for treatment. Preventative strategies are as outlined for AION.

Cortical Blindness

Brain injury rostral to the optic nerve may cause cortical blindness. The impairment is produced by damage to the visual path beyond the lateral geniculate nucleus or the visual cortex in the occipital lobe. Similar to AION, cortical blindness is a significant concern in patients undergoing CABG, and systemic disease is often present. Emboli and sustained, profound hypotension are common causes. Other events implicated in the pathophysiology include cardiac arrest, hypoxemia, intracranial hypertension, exsanguinating hemorrhage, vascular occlusion, thrombosis, and vasospasm.

Differential diagnostic features include a normal optic disc on fundoscopy and normal pupillary responses. There is, however, loss of optokinetic nystagmus with normal eye motility. CT and MRI are helpful to delineate the extent of brain infarction associated with cortical blindness. Occipital lesions are frequently bilateral and CT findings typically indicate posterior cerebral artery thrombosis, basilar artery occlusion, posterior cerebral artery branch occlusion, or watershed infarction. Lesions after CABG often include the parieto-occipital area.

Whereas most cases of ION do not improve significantly, visual recovery from cortical blindness in previously healthy patients may be considerable but prolonged. Preventive strategies include maintenance of adequate systemic perfusion pressure and, in cardiac surgery, minimizing manipulation of the aorta, meticulous removal of air and particulate matter during valvular procedures, and use of an arterial line filter in selected patients during bypass.

Visual Symptoms After Transurethral Resection of the Prostate

Visual disturbances associated with transurethral resection of the prostate (TURP) are transient and often the result of the TURP syndrome, wherein excessive absorption of irrigating fluid can produce cardiac failure, hyponatremia, serious dysrhythmias, seizures, and coma. Visual disturbances can extend the gamut from subtle changes, such as seeing halos or a bluish hue, to complete absence of light perception.

Liberal bladder irrigation is required during TURP to remove clots and other detritus to enhance visibility for the surgeon. Factors postulated to influence the volume of irrigant absorbed include the extent of opening of the prostatic venous sinuses, the hydrostatic pressure of the irrigation fluid, the venous pressure at the irrigant–blood interface, and, arguably, the duration of the resection.

Glycine 1.5%, although slightly hypo-osmolar, does not cause clinically significant hemolysis and is one of the most commonly used irrigating solutions. Glycine toxicity is probably the most important mechanism resulting in TURP-associated visual dysfunction, although the disturbance may be multifactorial. An inhibitory neurotransmitter in the CNS, glycine freely crosses the blood–brain barrier and depresses the spontaneous and evoked activity of retinal neurons.¹⁵³ Additionally, glycine is metabolized to serine and ammonia, both of which have been linked to CNS disturbances after TURP.¹⁵⁴ Serine is known to have inhibitory effects on the retina similar to those produced by glycine.¹⁵⁵

Hyponatremia can occur independently of glycine toxicity and produce hypo-osmolality-induced CNS dysfunction. The degree of brain dysfunction is determined by the rapidity as well as the severity of the reduction in sodium concentration. Symptoms include hallucinations, psychosis, focal neurologic signs, seizures, and coma. It has been suggested that TURP-associated hypo-osmolality produces occipital cortical edema, but this has not been definitively established.

Preventive strategy should focus on taking all possible measures to avoid excessive absorption of irrigating solution. Moreover, a high index of suspicion is necessary because significant amounts of irrigant may be absorbed even if the surgeon does not see any open venous sinuses. Thus, it is difficult, if not impossible, to estimate the degree of fluid absorption without confirmatory laboratory data.

Acute Glaucoma

Although topical application of such mydriatic drugs as atropine and scopolamine is contraindicated in patients with known, chronic glaucoma, the systemic use of anticholinergics in usual premedicating doses is safe for glaucomatous eyes.¹³⁰ The use of an atropine–neostigmine combination for reversal of neuromuscular blockade is also safe in patients with glaucoma.¹³¹ Topical ophthalmic medications that are being administered to control glaucoma should be continued through the perioperative period.

Acute angle-closure glaucoma typically occurs spontaneously but has been reported rarely after spinal anesthesia as well as general anesthesia. Acute angle-closure glaucoma caused by pupillary block is a serious, multifactorial disease. Risk factors include genetic predisposition,¹⁵⁶ shallow anterior chamber depth,¹⁵⁷ increased lens thickness,¹⁵⁷ small corneal diameter,¹⁵⁷ female sex,¹⁵⁷ and advanced age.¹⁵⁶ One study¹⁵⁸ explored possible precipitating events in at-risk patients and found no evidence that the type of anesthetic agent, the duration of surgery, the volume of parenteral fluids, or the intraoperative blood pressure were related to the development of acute angle-closure glaucoma.

Despite its seriousness, acute angle-closure glaucoma may be difficult to recognize. However, physicians should be knowledgeable about this potential complication because diagnostic delay may detrimentally affect visual outcome and cause permanent optic nerve damage. Fazio *et al*¹⁵⁸ recommend that the preoperative evaluation include a thorough ocular history as well as a penlight examination to detect a shallow anterior chamber. Those patients considered at risk should then undergo a preoperative ophthalmic evaluation as well as perioperative miotic therapy. After surgery, these patients should be scrupulously watched for red eye or for complaints of pain and blurred vision. Acute glaucoma is a true emergency, and ophthalmologic consultation should be secured immediately to acutely decrease IOP with systemic and topical therapy. The intense periorbital pain typically described by these patients is an important aid in differential diagnosis.

Postcataract Ptosis

Ptosis after cataract surgery is not uncommon, and multiple factors have been implicated in its etiology.^{159,160} These include the presence of a pre-existing ptosis, injection of anesthetic solution into the upper lid when performing facial nerve block, retrobulbar injection, injection of peribulbar anesthesia through the upper eyelid at the 12 o'clock position, ocular compression or massage, the eyelid speculum, placement of a superior rectus bridle suture with traction on the superior rectus–levator complex, creation of a large conjunctival flap, prolonged or tight patching in the postoperative period, and postoperative eyelid edema. Feibel and colleagues¹⁵⁹ believe that the development of postcataract ptosis is multifactorial, and no single aspect of cataract surgery is the sole contributor. Although local anesthetics clearly are myotoxic, that the local anesthetic injection cannot be isolated as the primary factor is underscored by the observation that postsurgical ptosis is seen in patients undergoing surgery with general anesthesia.

The anesthetic management of a patient undergoing surgery of the head, neck, ear, nose, and throat challenges the anesthesiologist to devise an anesthetic plan that will accommodate the needs of the surgeon, anesthesiologist, and patient. Among the problems that must be solved are the following:

1. Diagnosing alterations in a patient's airway created by infection, tumor, trauma, or congenital defect
2. Establishing and maintaining the airway in a patient whose anatomy has been distorted
3. Creating a shared operative field that enables the anesthesiologist to ventilate the patient's lungs and monitor the patient safely and the surgeon to perform his or her tasks
4. Selecting appropriate anesthetic drugs compatible with the surgical procedure
5. Defining the appropriate moment for extubating the trachea of the postoperative patient

EVALUATING THE AIRWAY

In the healthy human, air flow through the upper respiratory passages, and into the trachea, bronchi, bronchioles, and in and out of the alveoli occurs seemingly without either thought or effort, and the actual work of respiration in the unobstructed airway is minimal. However, airway obstruction due to tumor, infection, or trauma may significantly alter the clinical presentation and make gas exchange a laborious, energy-consuming process, leaving the patient exhausted, eventually incapable of maintaining adequate gas exchange, and finally succumbing to asphyxiation. Clinically evident upper airway obstruction is a late sign, whatever the causative process may be, and significant obstruction and anatomic distortion may be present in a patient with minimal evidence of disease. It is a most unwelcome experience for the anesthesiologist to discover a large, unexpected, and obstructing upper airway tumor at the time of attempted tracheal intubation.

In the presence of tumor or infection in the airway it may be useful to obtain radiologic evaluation of the airway via plain films of the tracheal and laryngeal air columns or computerized tomographic studies of the airway. Significant anatomic distortion is usually readily evident and may help the anesthesiologist to determine the most appropriate technique for securing the airway.

ANESTHESIA FOR PEDIATRIC EAR NOSE AND THROAT SURGERY

Particularly challenging to the anesthesiologist is the safe management of the pediatric patient undergoing surgery of the ear, nose, and throat (ENT). The restricted spaces in the airway of the child mandate an understanding and cooperative relationship between surgeon and anesthesiologist, and the use of specially adapted equipment suitable to these cramped areas. Tonsillectomy, adenoidectomy, myringotomy, and tube insertion (flexible and rigid bronchoscopy) are commonly performed on pediatric patients.

Tonsillectomy and Adenoidectomy

Untreated adenoidal hyperplasia may lead to nasopharyngeal obstruction, causing failure to thrive, speech disorders, obligate mouth breathing, sleep disturbances, orofacial abnormalities with a narrowing of the upper airway, and dental abnormalities. Surgical removal of the adenoids is usually accompanied by tonsillectomy; however, purulent adenitis, despite adequate medical therapy, and recurrent otitis media with effusion secondary to adenoidal hyperplasia are improved with adenoidectomy alone.

Tonsillectomy is one of the more commonly performed pediatric surgical procedures today.¹ Chronic or recurrent acute tonsillitis, peritonsillar abscess, and obstructive tonsillar hyperplasia are the major indications for surgery.^{2,3} Patients with cardiac valvular disease are at risk for endocarditis from recurrent streptococcal bacteremia secondary to infected tonsils, and tonsillar hyperplasia may lead to chronic airway obstruction resulting in sleep apnea, CO₂ retention, cor pulmonale, failure to thrive, swallowing disorders, and speech abnormalities. These risks are eliminated with removal of the tonsils.

Obstruction of the oropharyngeal airway by hypertrophied tonsils leading to apnea during sleep is an important clinical syndrome referred to as *obstructive sleep apnea syndrome*. Despite only mild to moderate tonsillar enlargement on physical examination, these patients have upper airway obstruction while awake and apnea during sleep. The goals of treatment are to relieve airway obstruction and increase the cross-sectional area of the pharynx, which is successful in two thirds of cases. Some patients require the use of nasal constant positive airway pressure during sleep, whereas others may require a tracheostomy to bypass the chronic upper airway obstruction that is present. The two most frequent levels of obstruction during sleep are at the soft palate and the base of the tongue.⁴ Most children will have tremendous improvement in their symptoms after tonsillectomy.

In children with long-standing hypoxemia and hypercarbia, increased airway resistance can lead to cor pulmonale [Fig. 35-1](#). Patients have electrocardiographic evidence of right ventricular hypertrophy and one third have chest radiographs consistent with cardiomegaly. Each apneic episode causes progressively increasing pulmonary artery pressure with significant systemic and pulmonary artery hypertension leading to ventricular dysfunction and cardiac dysrhythmias. Often, these patients have dysfunction in the medulla or hypothalamic areas of the central nervous system causing persistently elevated CO₂ despite relief of airway obstruction. This group of patients has a hyper-reactive pulmonary vascular bed and the increased pulmonary vascular resistance and myocardial depression in response to hypoxia, hypercarbia, and acidosis are far greater than what is expected for that degree of physiologic alteration in the normal population. Cardiac enlargement is frequently reversible with digitalization and surgical removal of the tonsils and adenoids.

Figure 35-1. Events leading to cor pulmonale.

Preoperative Evaluation

A thorough history is the basis for the preoperative evaluation. Because patients requiring tonsillectomy and adenoidectomy have frequent infections, the parent should be questioned for current use of antibiotics, antihistamines, or other medicines. A history of sleep apnea should be sought. The physical examination should begin with observation of the patient. The presence of audible respirations, mouth breathing, nasal quality of the speech, and chest retractions should be noted. Mouth breathing may be the result of chronic nasopharyngeal obstruction. A longer face, retrognathic mandible, and a high-arched palate may be present.⁵ The oropharynx should be inspected for evaluation of tonsillar size for determining the ease of mask ventilation and tracheal intubation (Fig. 35-2). The presence of wheezing or rales on auscultation of the chest may be a result of lower respiratory manifestation of pharyngitis or tonsillitis. The presence of inspiratory stridor or prolonged expiration may indicate partial airway obstruction from hypertrophied tonsils or adenoids.

Figure 35-2. Classification of tonsil size, including percentage of oropharyngeal area occupied by hypertrophied tonsils.

Measurement of hematocrit and coagulation parameters may be suggested. Many nonprescription cold medications and antihistamines contain aspirin, which may affect platelet function, and this should be taken into consideration. Chest radiographs and electrocardiograms (ECG) are not required unless specific history of abnormalities in these areas is elicited, such as recent pneumonia, bronchitis, upper respiratory infection (URI), or history consistent with cor pulmonale. In those children with a history of cardiac abnormalities, an echocardiogram may be indicated.

Anesthetic Management

The goals of the anesthesia for tonsillectomy and adenoidectomy are to render the child unconscious in the most atraumatic manner possible, provide the surgeon with optimal operating conditions, establish intravenous (iv) access to provide a route for volume expansion and medications should they be necessary, and to provide rapid emergence so that the patient is awake and able to protect the recently manipulated airway. Premedication may be used as determined by the anesthesiologist during the preanesthetic visit. Sedative premedication may be avoided in children with obstructive sleep apnea, intermittent obstruction, or very large tonsils. An antisialagogue is often included to minimize secretions in the operative field.

Anesthesia is usually induced with a volatile drug, oxygen and nitrous oxide (N₂O) by mask. Parental presence in the operating room during mask induction is often helpful in the anxious unpremedicated child. Tracheal intubation is best accomplished under deep inhalation anesthesia or aided by a short-acting nondepolarizing muscle relaxant. The possibility exists for blood in the pharynx to enter the trachea during the surgical procedure. For this reason, the supraglottic area may be packed with petroleum gauze, or a cuffed endotracheal tube may be used provided an appropriate leak around the endotracheal tube is obtained. Monitoring consists of precordial stethoscope, ECG, automated blood pressure, pulse oximetry, and end-tidal CO₂.

Emergence from anesthesia should be rapid and the child should be alert before transfer to the recovery area. The child should be awake and able to clear blood or secretions in the oropharynx as efficiently as possible before removal of the endotracheal tube. Maintenance of airway and pharyngeal reflexes is of utmost importance in the prevention of aspiration, laryngospasm, and airway obstruction. Emergence airway complications have not been shown to be different in patients extubated deep or awake.⁶

The use of the laryngeal mask airway (LMA) for adenotonsillectomy was described in 1990; however, it was not until the widespread availability of a streamlined flexible model that it was widely used.^{7,8} The wide, rigid tube of the original model did not fit under the mouth gag and was easily compressed or dislodged during full mouth opening. The newer, flexible model has a soft, reinforced shaft which easily fits under the mouth gag without becoming dislodged or compressed. Adequate surgical access can be achieved and the lower airway is protected from exposure to blood during the procedure.^{9,10}

Insertion is possible after either the intravenous administration of 3.5 mg · kg⁻¹ propofol or when sufficient depth of anesthesia is achieved using a volatile agent administered by mask. The same depth of anesthesia should be obtained during insertion of the LMA as would be required for performing laryngoscopy and endotracheal intubation. Positive-pressure ventilation should be avoided, although gentle assisted ventilation is both safe and effective if peak inspiratory pressure is kept below 20 cm H₂O.¹¹

Tonsillar enlargement can make LMA insertion difficult, so care in placement is essential.¹² Maneuvers to overcome this difficulty include increased head extension, lateral insertion of the mask, anterior displacement of the tongue, pressure on the tip of the LMA using the index finger as it negotiates the pharyngeal curve, or use of the laryngoscope if all else fails. Dislodgement of the device does not occur during extreme head extension, assuming that good position and ventilation were obtained before to changes in head position.¹³

Advantages of the LMA over traditional endotracheal intubation are a decrease in the incidence of postoperative stridor and laryngospasm and an increase in immediate postoperative oxygen saturation. The LMA should be viewed as a useful adjunct to airway management, never a substitute for endotracheal intubation. If the child is breathing spontaneously at a regular rate and depth, the LMA may be removed before emergence from anesthesia. The oropharynx should be gently suctioned with a soft, flexible catheter, the LMA deflated and removed, an oral airway inserted, and the respirations assisted with 100% oxygen delivered by mask. It is often distressing for young children to awaken with the LMA still in place, and although the device is an appropriate substitute for oral airway in the adult population, the same is not so in children. If the practitioner wishes to remove the LMA when the child has emerged from anesthesia, it should be deflated and removed as soon as possible after the return to consciousness.

Complications

The incidence of emesis after tonsillectomy ranges from 30% to 65%.¹⁴ Whether this is due to irritant blood in the stomach or interference with the gag reflex by

inflammation and edema at the surgical site remains unclear. Central nervous system stimulation from the gastrointestinal tract, as may be seen with gastric distention from the introduction of swallowed or insufflated air, may trigger the emetic center.¹⁵ Decompressing the stomach with an orogastric tube may be helpful in preventing this response. The nasal route of insertion should not be used because unremoved adenoidal tissue may become dislodged or bleeding may be induced at the surgical site if adenoidectomy has been performed. Postoperative administration of meperidine increases the probability of emesis, and other analgesic agents should be administered. Dehydration secondary to poor oral intake as a result of nausea, vomiting, or pain can occur after tonsillectomy.¹⁶ Postoperative dehydration occurs at a frequency of 1.1%.¹⁷ Vigorous iv hydration during surgery to restore intravascular volume can offset the physiologic effects of later decreases in fluid intake.

The most serious complication of tonsillectomy is postoperative hemorrhage, which occurs at a frequency of 0.1–8.1%.^{17,18} and ¹⁹ Approximately 75% of postoperative tonsillar hemorrhage occurs within 6 hours of surgery. Most of the remaining 25% occurs within the first 24 hours of surgery, although bleeding may be noted until the sixth postoperative day.²⁰ Sixty-seven percent of postoperative bleeding originates from the tonsillar fossa, 27% in the nasopharynx, and 7% in both. Initial attempts to control bleeding may be made using pharyngeal packs and cautery. If this fails, patients must return to the OR for exploration and surgical hemostasis.

Unappreciated large volumes of blood originating from the tonsillar bed may be swallowed. These patients must be considered to have a full stomach, and anesthetic precautions addressing this situation must be taken. A rapid sequence induction accompanied by cricoid pressure and a stylet endotracheal tube are often recommended. Because the amount of blood swallowed can be considerable, blood pressure must be checked in both the erect and supine positions to look for orthostatic changes resulting from decreases in vascular volume. Intravenous access and hydration must be established before the induction of anesthesia. A variety of laryngoscope blades and endotracheal tubes as well as functioning suction apparatus should be prepared in duplicate because blood in the airway may impair visualization of the vocal cords and cause plugging of the endotracheal tube.

Pain after adenoidectomy is usually minimal but is severe after tonsillectomy. This contributes to poor fluid intake and overall discomfort of patients. An increase in postoperative pain medication requirements has been noted in patients having laser or electrocautery as part of the operative tonsillectomy compared with those having had sharp surgical dissection and ligation of blood vessels to achieve hemostasis.²¹ Intraoperative administration of corticosteroids may decrease edema formation and subsequent patient discomfort.²² Although infiltration of the peritonsillar space with local anesthetic and epinephrine has been shown to be effective in reducing intraoperative blood loss, it does not decrease postoperative pain.²³

Peritonsillar abscess, or quinsy tonsil, is a condition that may require immediate surgical intervention to relieve potential or existing airway obstruction. An acutely infected tonsil may undergo abscess formation, producing a large mass in the lateral pharynx that can interfere with swallowing and breathing (Fig. 35-3, Fig. 35-4 and Fig. 35-5). Fever, pain, and trismus are frequent symptoms. Treatment consists of surgical drainage of the abscess either with or without tonsillectomy and iv antibiotic therapy. Although the airway seems compromised, the peritonsillar abscess is usually in a fixed location in the lateral pharynx and does not interfere with ventilation of the patient by mask after induction of general anesthesia. Visualization of the vocal cords should not be impaired because the pathologic process is supraglottic and well above the laryngeal inlet. Laryngoscopy must be carefully performed, avoiding manipulation of the larynx and surrounding structures. Intubation should be gentle because the tonsillar area is tense and friable and inadvertent rupture of the abscess can occur, leading to spillage of purulent material into the trachea.

Figure 35-3. (A) Patient with a peritonsillar abscess on the left side. (B) Note the displacement of the uvula. (Courtesy of Michael Cunningham, M.D., Boston, Massachusetts.)

Figure 35-4. Neck radiograph of a patient with a peritonsillar abscess

Figure 35-5. Computed tomography scan of a patient with a peritonsillar abscess.

Acute postoperative pulmonary edema is an infrequent but potentially life-threatening complication encountered when airway obstruction is suddenly relieved. One proposed mechanism is that during inspiration before adenotonsillectomy, the negative intrapleural pressure that is generated causes an increase in venous return, enhancing pulmonary blood volume. In the healthy child without airway obstruction, pleural pressure ranges from -2.5 cm to -10.0 cm H₂O during inspiration. Intrapleural pressure generated in the child with airway obstruction can be as much as -30 cm H₂O which, when transmitted to the interstitial peribronchial and perivascular spaces, causes disruption of the capillary walls of the pulmonary microvasculature. Concurrent with a negative transpulmonary gradient is an increase in venous return to the right side of the heart, thus increasing preload, which, in the setting of "leaky capillaries," facilitates transudation of fluid into the alveolar space. To counterbalance this, positive intrapleural and alveolar pressure is generated during exhalation, which decreases pulmonary venous return and blood volume. This is similar to an expiratory "grunt" mechanism in which the transpleural pressures generated are similar to those present during a Valsalva maneuver.

The rapid relief of airway obstruction results in decreased airway pressure, an increase in venous return, an increase in pulmonary hydrostatic pressure, hyperemia, and finally pulmonary edema. The all-important counterbalance of the expiratory "grunt" in limiting pulmonary venous return is lost when the obstruction is relieved.

Contributing factors are the increased volume load on both ventricles as well as the inability of the pulmonary lymphatic system to remove acutely large amounts of fluid. The anesthesiologist may attempt to prevent this situation during induction of anesthesia by applying moderate amounts of continuous positive pressure to the airway, thus allowing time for circulatory adaptation to take place. This physiologic sequence is similar to that seen in patients with severe acute airway obstruction secondary to epiglottitis or laryngospasm.

Negative-pressure pulmonary edema is signaled by the appearance of frothy pink fluid in the endotracheal tube of an intubated patient or the presence of a decreased oxygen saturation, wheezing, dyspnea, and increased respiratory rate in the immediate postoperative period in a previously extubated patient. Mild cases may present with minimal symptoms. The differential diagnosis of negative-pressure pulmonary edema includes aspiration of gastric contents, adult respiratory distress syndrome, congestive heart failure, volume overload, and anaphylaxis. A chest radiograph illustrating diffuse, usually bilateral interstitial pulmonary infiltrates combined with an appropriate clinical history will confirm the diagnosis.²⁴

Treatment is usually supportive, with maintenance of a patent airway, oxygen administration, and diuretic therapy in some cases. Endotracheal intubation and mechanical ventilation with positive end-expiratory pressure may be necessary in severe cases. Resolution is usually rapid and may occur within hours of surgery. Most cases resolve without treatment within 24 hours. There is currently no reliable method for predicting which children will experience this clinical syndrome after their airway obstruction has been resolved.²⁵

Adenoidectomy patients may be safely discharged on the same day after recovering from anesthesia. Tonsillectomy has been a procedure that warranted postoperative admission of the patient to the hospital for observation, administration of analgesics, and hydration. Many centers are discharging tonsillectomy patients on the day of surgery without adverse outcome, and this trend will likely continue.^{17,20,21,26} It is recommended that patients be observed for early hemorrhage for a minimum of 6 hours and be free from significant nausea, vomiting, and pain prior to discharge. Ability to take fluid by mouth is not a requirement for discharge home. However, iv hydration must be adequate to prevent dehydration. Excessive somnolence and severe vomiting are indications for hospital admission. There is a set of patients in whom early discharge is not advised, and those patients should be admitted to the hospital after tonsillectomy. The characteristics of such patients are listed in [Table 35-1](#).²⁷

| |
|---|
| <p>Patients shall be admitted to the hospital after adenotonsillectomy if they meet any of the following criteria:</p> <ul style="list-style-type: none"> Age \leq 3 y Abnormal coagulation values with or without an identified bleeding disorder in the patient or family Evidence of obstructive sleep disorder or apnea due to tonsillar or adenoidal hypertrophy Systemic disorders that put the patient at increased preoperative cardiopulmonary, metabolic, or general medical risk Child with craniofacial or other airway abnormalities including, but not limited to, syndromic disorders such as Treacher Collins syndrome, Crouzon's syndrome, Goldenhar syndrome, Pierre Robin anomaly, C1A, R, G, E, associations, achondroplasia, and, most prominently, Down's syndrome, as well as isolated airway abnormalities such as choanal atresia and laryngotracheal stenosis When the procedure is being done for acute peritonsillar abscess When extended travel time, weather conditions, and home social conditions are not consistent with close observation, cooperation, and ability to return to the hospital quickly at the discretion of the attending physician |

Table 35-1. TONSILLECTOMY AND ADENOIDECTOMY INPATIENT GUIDELINES: RECOMMENDATION OF THE AMERICAN ACADEMY OF OTOLARYNGOLOGY–HEAD AND NECK SURGERY PEDIATRIC OTOLARYNGOLOGY COMMITTEE

Ear Surgery

The ear and its associated structures are target organs for many pathologic conditions. General anesthesia for surgery of the ear has its own set of unique considerations that must be addressed.

Myringotomy and Tube Insertion

Chronic serous otitis in children can lead to hearing loss, and drainage of accumulated fluid in the middle ear is effective treatment for this condition. Myringotomy, which creates an opening in the tympanic membrane for fluid drainage, may be performed alone. During healing, the drainage path may become occluded. Therefore, tube placement is usually included. The insertion of a small plastic tube in the tympanic membrane serves as a vent for the ostium and allows for continued drainage of the middle ear until the tubes are naturally extruded in 6 months to a year or surgically removed at an appropriate time ([Fig. 35-6](#)).

Figure 35-6. Two types of myringotomy tubes. Both are 2.5 mm in internal diameter. Both the ventilating T-tube and the beveled-button ventilating tube (large and small) are shown in full and cross-sectional views. (Courtesy of Michael Cunningham, M.D., Boston, Massachusetts.)

Myringotomy and tube insertion is a relatively short procedure and anesthesia may be effectively accomplished with a potent inhalation drug, oxygen, and N₂O administered by mask. Premedication is not recommended because most sedative drugs used for premedication will far outlast the duration of the surgical procedure. Patients with chronic otitis frequently have accompanying recurrent URIs. It is often the eradication of middle ear fluid that resolves the concomitant URI. Because tracheal intubation is not required for routine patients, the criteria for cancellation of surgery and anesthesia may be different for this procedure. No significant difference in perioperative morbidity between asymptomatic patients and those fulfilling URI criteria has been demonstrated.^{28,29} It is recommended that patients with URI symptoms receive supplemental postoperative oxygen.³⁰

Middle Ear and Mastoid

Tympanoplasty and mastoidectomy are two of the most common procedures performed on the middle ear and accessory structures. To gain access to the surgical site, the head is positioned on a head rest, which may be lower than the operative table, and extreme degrees of lateral rotation may be required. Extreme tension on the heads of the sternocleidomastoid muscles must be avoided. The laxity of the ligaments of the cervical spine as well as immaturity of odontoid process in children make them especially prone to C1–C2 subluxation. Up to 31% of patients with Down's syndrome and achondroplasia may have atlantoaxial instability.³¹

Ear surgery often involves surgical identification and preservation of the facial nerve, which requires isolation of the nerve by the surgeon and verification of its function by means of electrical stimulation ([Fig. 35-7](#) and [Fig. 35-8](#)). This is accomplished by brainstem auditory evoked potential and electrocochleogram monitoring, and this is safest if profound skeletal muscle relaxation is avoided and a volatile drug is the primary anesthetic.³² If an opioid-relaxant technique is chosen, however, at least 30% of the muscle response, as determined by a twitch monitor, should be preserved. There is evidence, however, that electrically induced facial muscle activity persists and is easily visible even when neuromuscular blockade prevents a visible response to electrical stimulation of the thenar muscles.³³ This suggests that it is not mandatory to avoid skeletal muscle relaxants in the anesthetic management of patients undergoing surgical procedures when monitoring of facial nerve function is

necessary.

Figure 35-7. Anesthetized patient with facial nerve monitoring electrodes in place.

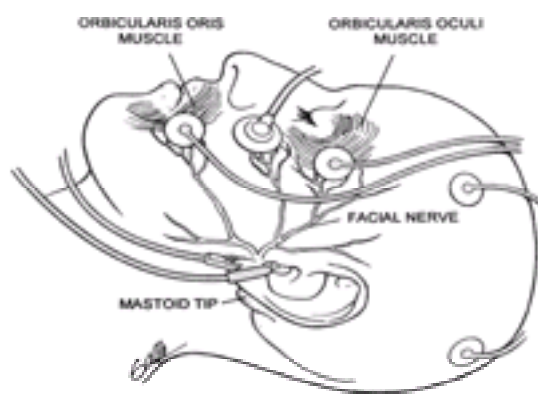

Figure 35-8. Illustration of facial nerve and monitoring electrodes. (Courtesy of Steve Ronner, Ph.D., Boston, Massachusetts.)

Bleeding must be kept to a minimum during surgery of the small structures of the middle ear. Relative hypotension, keeping the mean arterial pressure 25% below baseline, is effective. Concentrated epinephrine solution, often 1:1000, can be injected in the area of the tympanic vessels to produce vasoconstriction. Close attention should be paid to the volume of injected epinephrine to avoid dysrhythmias and wide swings in blood pressure.

The middle ear and sinuses are air-filled, nondistensible cavities. An increase in the volume of gas in these structures results in an increase in pressure. N_2O diffuses along a concentration gradient into the air-filled middle ear spaces more rapidly than nitrogen moves out. Passive venting occurs at 20–30 cm H_2O pressure, and it has been shown that use of N_2O results in pressures that exceed the ability of the eustachian tube to vent the middle ear within 5 minutes, leading to pressure buildup.³⁴ Intermittent venting of the middle ear leads to constant changes in middle ear pressure, which in turn cause movement of the tympanic membrane.³⁵ During procedures in which the ear drum is replaced or perforation is patched, N_2O should be discontinued or, if this is not possible, limited to a maximum of 50% the application of the tympanic membrane graft to avoid pressure-related displacement.

After N_2O is discontinued, it is quickly reabsorbed, creating a void in the middle ear with resulting negative pressure. This negative pressure may result in serous otitis, disarticulation of the ossicles in the middle ear, especially the stapes, and hearing impairment, which may last up to 6 weeks after surgery. The use of N_2O may cause a high incidence of postoperative nausea and vomiting, which is a direct result of negative middle ear pressure during recovery. The vestibular system is stimulated by traction placed on the round window by the negative pressure that is created. Although all patients have the potential for nausea and vomiting after surgery, children younger than 8 years of age seem to be most affected. If the use of N_2O cannot be avoided, vigorous use of antiemetics is warranted.

Special Considerations

Postoperative Nausea and Vomiting. Nausea and vomiting are among the most common postoperative problems. Although all are at risk, ENT procedures are associated with the highest incidence of postoperative emesis. Not only are patients uncomfortable after surgery, but delayed discharge from the postanesthesia care unit or unscheduled hospital admission is becoming an economic concern.

The act of vomiting is under the control of both the dorsal aspect of the lateral reticular formation and the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle. Although the control of emesis is central in origin, the afferent stimuli originate primarily in the periphery from the gastrointestinal tract, the labyrinthine apparatus, or the oculomotor center. The anesthetic technique and drugs used can have an impact on the incidence of nausea and vomiting through effects on both central and peripheral structures. There are, however, some nonanesthetic factors that contribute to the incidence of nausea and vomiting, including a positive correlation with both obesity and prior history of motion sickness.

Both the conduct of the anesthetic and the use of specific drugs can help to prevent postoperative emesis, if not eliminate it completely. Decompressing the stomach after induction of general anesthesia empties the stomach of gas and fluid, thereby diminishing gastric distention. Limiting the use of opioids is helpful in those patients who fall into a high-risk category. The use of meperidine is known to cause emesis in children more frequently than adults, and other analgesics should be substituted. Ketamine, etomidate, and anticholinesterase inhibitors may promote emesis. Ketorolac is a nonsteroidal anti-inflammatory cyclo-oxygenase inhibitor analgesic that is effective as an adjuvant to volatile anesthetic drugs. It has been shown to provide excellent postoperative analgesia and less emesis compared with equipotent doses of morphine. Propofol has been widely used for both induction and maintenance of general anesthesia and has been associated with a dramatic decrease in postoperative nausea and vomiting. In one series of children undergoing strabismus repair, postoperative emesis occurred in only 24% of patients receiving propofol, compared with 71% receiving halothane. Butyrophenones such as droperidol are often given but are minimally effective and cause excessive somnolence. Metoclopramide, a benzamide that blocks central nervous system dopaminergic receptors, is a more effective prophylactic antiemetic that does not result in sedation and drowsiness, but in the recommended dose may cause extrapyramidal side effects. Postoperative pain, dizziness, and sudden changes in movement increase the frequency of nausea and vomiting and should be minimized in the postanesthesia care unit.

When postoperative emesis cannot be prevented, there are many effective treatments available. Metoclopramide is effective for treatment as well as prevention of nausea and vomiting. Ondansetron, a serotonin inhibitor, antagonizes central and peripheral 5-hydroxytryptamine type 3 receptors to prevent emesis. It is an effective antiemetic when administered iv. In children undergoing tonsillectomy, the iv administration of ondansetron ($0.15 \text{ mg} \cdot \text{kg}^{-1}$) after inhalational induction of anesthesia decreased but did not abolish the incidence of postoperative emesis.³⁶ In the same report, droperidol and metoclopramide had no significant effect on postoperative vomiting.

Airway Surgery

Stridor

Noisy breathing due to obstructed airflow is known as *stridor*. Inspiratory stridor results from upper airway obstruction; expiratory stridor results from lower airway obstruction; and biphasic stridor is present with midtracheal lesions. The evaluation of a patient with stridor begins with taking a thorough history. The age of onset suggests a cause because laryngotracheomalacia and vocal cord paralysis are usually present at or shortly after birth, whereas cysts or mass lesions develop later in life (Table 35-2). Information indicating positions that make the stridor better or worse should be obtained, and placing a patient in a position that allows gravity to aid in reducing obstruction can be of benefit during anesthetic induction.

| Supraglottic Airway | Larynx | Subglottic Airway |
|----------------------|--|---------------------------------|
| Laryngomalacia | Laryngocele | Tracheomalacia |
| Vocal cord paralysis | Infection (tonsillitis, peritonsillar abscess) | Vascular ring |
| Subglottic stenosis | Foreign body | Foreign body |
| Hemangiomas | Choanal atresia | Infection (croup, epiglottitis) |
| Cysts | Cyst | |
| | Mass | |
| | Large tonsils | |
| | Large adenoids | |
| | Craniofacial abnormalities | |

Table 35-2. CAUSES OF STRIDOR

Physical examination reveals the general condition of a patient as well as the degree of the airway compromise. Laboratory examination may include assessment of hemoglobin, a chest radiograph, and barium swallow, which can aid in identifying lesions that may be compressing the trachea. Computed tomography scan and tomograms may be indicated in isolated instances but are not routinely ordered. Specific note of the signs and symptoms listed in [Table 35-3](#) should be made.

Respiratory rate
Heart rate
Wheezing
Cyanosis
Chest retractions
Nasal flaring
Level of consciousness

Table 35-3. SIGNS AND SYMPTOMS SPECIFICALLY EXAMINED IN PATIENTS WITH STRIDOR

Laryngomalacia is the most common cause of stridor in infants. It is most often due to a long epiglottis that prolapses posteriorly, and prominent arytenoid cartilages with redundant aryepiglottic folds, that obstruct the glottic opening during inspiration.³⁷ The definitive diagnosis is obtained by direct laryngoscopy and rigid or flexible bronchoscopy. Preliminary examination is usually carried out in the surgeon's office. A small, flexible fiberoptic bronchoscope is inserted through the nares into the oropharynx, and the movement of the vocal cords is observed. Alternatively, it may be accomplished in the OR before anesthetic induction in an awake patient or in a lightly anesthetized patient during spontaneous respiration. Patients must be spontaneously breathing so that the vocal cords move freely. After deepening anesthesia, a rigid bronchoscope is inserted through the vocal cords and the subglottic area is inspected; the lower trachea and bronchi are evaluated with a rigid or flexible fiberoptic bronchoscope.

Bronchoscopy

Small infants may be brought into the operating room unpremedicated. Older children and adults may experience respiratory depression and worsening of airway obstruction if heavy premedication is administered, so light sedation is suggested. The airway must be protected from aspiration of gastric contents during prolonged airway manipulation; therefore, premedication with the full regimen of acid aspiration prophylaxis may be indicated.

The goals of anesthesia are analgesia, an unconscious patient, and a "quiet" surgical field.³⁸ Coughing, bucking, or straining during instrumentation with the rigid bronchoscope may cause difficulty for the surgeon and result in damage to the patient's airway. At the conclusion of the procedure, patients should be returned to consciousness quickly with airway reflexes intact. For most patients, a pulse oximeter, blood pressure cuff, ECG, and precordial stethoscope are applied before induction of anesthesia. Inhalation induction by mask is accompanied by oxygen and a volatile drug (usually halothane) administered in increasing concentrations in children, and iv drugs in adults. Patients should be placed in the position that produces the least adverse effect on airway symptoms (often the sitting position). An antisialagogue (atropine or glycopyrrolate) is often administered iv to decrease secretions that may obscure the view through the bronchoscope.

The size of a bronchoscope refers to the internal diameter. Because the external diameter may be significantly greater than in an endotracheal tube of similar size ([Table 35-4](#)), care must be taken to select a bronchoscope of proper external diameter to avoid damage to the laryngeal structures.

| Endotracheal Tube | | |
|------------------------|------------------------|---|
| Internal Diameter (mm) | External Diameter (mm) | Rigid Bronchoscope External Diameter (mm) |
| 2.5 | 3.5 | 4.2 |
| 3.0 | 4.3 | 5.0 |
| 3.5 | 4.9 | 5.7 |
| 4.0 | 5.5 | 6.7 |
| 5.0 | 6.8 | 7.8 |
| 6.0 | 8.2 | 8.2 |

Table 35-4. COMPARISON OF EXTERNAL DIAMETER OF STANDARD ENDOTRACHEAL TUBES VERSUS RIGID BRONCHOSCOPE

A rigid bronchoscope can be used for ventilation of the lungs during examination of the airway. It is inserted through the vocal cords and ventilation is accomplished through a side port, which can be attached to the anesthesia circuit. During ventilation with the viewing telescope in place, high resistance may be encountered as a result of partial occlusion of the lumen. High fresh gas flow rates, large tidal volumes, and high inspired volatile anesthetic concentrations are often necessary to compensate for leaks around the ventilating bronchoscope and the high resistance encountered when the viewing telescope is in place. Manual ventilation at higher-than-normal rates is most effective in achieving adequate ventilation. Adequate time for exhalation must be provided for passive recoil of the chest.

An alternative method of ventilation is the Sander's jet ventilation technique. The principle of jet ventilation involves intermittent bursts of oxygen delivered under a pressure of 50 psi through a 16-gauge catheter attached to a rigid bronchoscope.³⁹ Intermittent flow is accomplished by depressing the lever of an on-off valve. The use of jet ventilation techniques is associated with the additional risks of pneumothorax or pneumomediastinum due to rupture of alveolar blebs or a bronchus.⁴⁰

Because ventilation may be intermittent and at times suboptimal, it is recommended that oxygen be used as the carrier gas during bronchoscopic examination. Intravenous drugs that cause excessive respiratory depression should be avoided. It is wise to ask the surgeon if movement of the vocal cords will be observed at the conclusion of the procedure or if tracheal or bronchial dynamics will be evaluated during the procedure so that the anesthetic may be planned accordingly (*i.e.*, spontaneous respirations preserved during light levels of anesthesia versus no respiratory efforts and the use of short-acting muscle relaxants).

Maintenance of anesthesia is usually accomplished with a volatile anesthetic. Intravenous anesthetics combined with muscle relaxation best maintain a constant level of anesthesia because the delivery of volatile anesthetics through the bronchoscope may be interrupted and anesthetic depth can vary. At the conclusion of rigid bronchoscopy, an endotracheal tube is usually placed in the trachea to control the airway during recovery of anesthesia; this tube is particularly important if muscle relaxants have been used because passive regurgitation of gastric contents may be more likely to occur in paralyzed patients. An additional advantage of placing an endotracheal tube is that if the surgeon should wish to examine the distal airways, a small, flexible fiberoptic bronchoscope can be passed through the endotracheal tube.

Pediatric Airway Emergencies

Upper airway emergencies may be life-threatening and demand immediate treatment. Rapid respiratory failure can occur in patients with croup, epiglottitis, or foreign body aspiration, and few clinical situations are more challenging to the anesthesiologist.

Epiglottitis

Acute epiglottitis is one of the most feared infectious diseases in children and adults and is the result of *Haemophilus influenzae* type B. It can progress with extreme rapidity from sore throat to airway obstruction to respiratory failure and death if proper diagnosis and intervention are not rapidly effected. Patients are usually between 2 and 7 years of age, although epiglottitis has been reported in younger children and adults. Vaccination against *H. influenzae* type B polysaccharide is now recommended before 2 years of age to provide immunity before the greatest period of vulnerability in pediatric patients.

Characteristic signs and symptoms of acute epiglottitis include sudden onset of fever, dysphagia, drooling, thick, muffled voice, and preference for the sitting position with the head extended and leaning forward. Retractions, labored breathing, and cyanosis may be observed in cases where respiratory obstruction is present. However, in the early stages, the patient may be pale and toxic without respiratory distress. *Supraglottitis* may be a more appropriate designation because it is the tissues of the supraglottic structures, from the vallecula to the arytenoids, that are involved in the infectious process. At no time (in the emergency room or radiography suite) should direct visualization of the epiglottis be attempted in the unanesthetized patient. The differential resulting from negative pressure inside and atmospheric pressure outside the extrathoracic airway results in slight narrowing during normal inspiration. The pressure differential on inspiration is exaggerated in the patient with airway obstruction. This dynamic collapse of the airway may become life-threatening in the struggling, agitated patient, and every attempt should be made in keeping him or her calm. Blood drawing, iv insertion, and excessive manipulation of the patient as well as sedation should be avoided before securing the airway to avoid the possibility of total obstruction.

If the clinical situation allows, oxygen should be administered by mask and lateral radiographs of the soft tissues in the neck may be obtained. Thickening of the aryepiglottic folds as well as swelling of the epiglottis may be noted. Radiologic examination should only be carried out if skilled personnel and adequate equipment accompany the patient at all times. The patient with severe airway compromise should proceed from the emergency department directly to the operating suite accompanied by the anesthesiologist and surgeon. Parental presence in this situation may calm an anxious and frightened child.

In all cases of epiglottitis, an artificial airway is established by means of tracheal intubation. In some centers where personnel experienced in the management of the compromised airway are not available, tracheostomy is a less favored alternative. In the OR, the child is kept in the sitting position while monitors are placed. A pulse oximeter and precordial stethoscope are essential. If it is thought to be helpful, one parent may accompany the child and remain in the OR during the induction of general anesthesia. The OR must be prepared with equipment and personnel for laryngoscopy, rigid bronchoscopy, and tracheostomy. Anesthetic induction is accomplished by inhalation of oxygen and increasing concentrations of halothane or sevoflurane. After loss of consciousness occurs, iv access should be secured and the child lowered into the supine position. Laryngoscopy followed by oral tracheal intubation is then accomplished without the use of muscle relaxants. The endotracheal tube chosen should be at least one size (0.5 mm) smaller than would normally be chosen, and a stylette is often useful. Once the surgeon has examined the larynx, noting the appearance of the epiglottis, aryepiglottic folds, and surrounding tissues, the endotracheal tube may be changed to a nasotracheal tube and secured. Tissue and blood cultures are taken and antibiotic therapy is initiated. The child is then transferred to the intensive care unit for continued observation and radiographic confirmation of tube placement. Sedation is appropriate at this time. Tracheal extubation is usually attempted 48–72 hours later in the OR, when a significant leak around the nasotracheal tube is present and visual inspection of the larynx by flexible fiberoptic bronchoscopy confirms reduction in swelling of the epiglottis and surrounding tissues.

Laryngotracheobronchitis

Laryngotracheobronchitis (LTB), or croup, occurs in children from 6 months to 6 years of age but is primarily seen in children less than 3 years of age. It is usually viral in etiology and its onset is more insidious than that of epiglottitis. The child presents with low-grade fever, inspiratory stridor, and a “barking” cough. Radiologic examination confirms the diagnosis, and subglottic narrowing of the airway column secondary to circumferential soft tissue edema produces the “steeple” sign characteristic of LTB. Approximately 6% of patients with LTB require admission to the hospital. Treatment includes cool, humidified mist and oxygen therapy, usually administered in a tent for mild to moderate cases. More severe cases of LTB are accompanied by tachypnea, tachycardia, and cyanosis. Racemic epinephrine administered by nebulizer is beneficial. The use of steroids has been surrounded by a great deal of controversy, but current opinion is that a short course of steroids may be beneficial. In rare circumstances, thick secretions are present in the airway and the child requires intubation to allow pulmonary toilet and suctioning to be carried out. Management in the intensive care unit and extubation are carried out in the same fashion as for epiglottitis.

Foreign Body Aspiration

A major cause of morbidity and mortality in children as well as adults is aspiration of a foreign body. Any history of coughing, choking, or cyanosis while eating (peanuts, popcorn, jelly beans, hot dogs) should suggest the possibility of foreign body aspiration. Any patient who presents to the emergency room with refractory wheezing should be suspected of this diagnosis. Physical findings include decreased breath sounds, tachypnea, stridor, wheezing, and fever. These signs indicate an obstructive–inflammatory process in the airway. Some foreign bodies are identifiable on radiologic examination; however, 90% are radiolucent and air trapping, infiltrate, and atelectasis are all that is noted. The most common site of foreign body aspiration is the mainstem bronchus, the right being more frequent than the left. Food particles comprise the majority of aspirated items; however, beads, pins, and small toys are not unusual. Each type of aspirated item has potential complications associated with it. Vegetable items expand with moisture encountered in the respiratory tract and can fragment into multiple pieces, thus creating a situation where the original foreign body is in one bronchus and with coughing a fragment is dislodged and transported to the other bronchus. Oil-containing objects, such as peanuts, cause a chemical inflammation and sharp objects cause bleeding in addition to the obstruction.

All aspirated foreign bodies in the airway should be removed in the OR and considered to be emergency situations. No sedation should be administered to patients before removal of the foreign body. If the patient has recently eaten, full stomach precautions must be taken and anesthesia should be induced iv (topical EMLA cream may be applied to the skin before iv insertion in small children) by rapid sequence and gentle cricoid pressure maintained during intubation of the trachea. If the child has not recently eaten, anesthesia may be induced by inhalation of halothane in oxygen by mask. Inhalation induction can be prolonged secondary to obstruction of the airway and N₂O should be avoided to reduce air trapping distal to the obstruction. After evacuation of the stomach by orogastric tube, the airway may be given over to the surgeon, who replaces the endotracheal tube with a rigid bronchoscope and removes the aspirated object.

Spontaneous ventilation should be preserved until the location and nature of the foreign body have been determined. Ventilation via the bronchoscope requires careful attention. Hypoxia and hypercarbia may occur because of inadequate ventilation caused by an excessively large leak around the bronchoscope or, more commonly, inability to provide adequate gas exchange through a narrow-lumen bronchoscope fitted with an internal telescope. These conditions are remedied by frequent removal of the telescope and withdrawal of the bronchoscope to the midtrachea, allowing effective ventilation. Bronchospasm may occur during examination of the respiratory tract and should be treated with increasing depths of anesthesia, nebulized albuterol, or iv bronchodilators. Although rare, pneumothorax should be suspected if acute deterioration occurs during the procedure.

Once the foreign body has been removed, examination of the entire tracheobronchial tree is carried out to detect any additional objects or fragments. Often, vigorous irrigation and suctioning distal to the obstruction are required to remove secretions and prevent the possibility of postobstructive pneumonia. Steroids are administered if inflammation of the airway mucosa is observed. Close postoperative observation of the patient is required so that early intervention may be instituted in the event of respiratory compromise secondary to airway edema or infection.

ANESTHESIA FOR PEDIATRIC AND ADULT SURGERY

Certain surgical procedures are commonly performed in both adults and children, including nasal surgery and laser surgery of the airway. Surgery for maxillofacial trauma and upper airway tumors or infection, as well as temporomandibular joint (TMJ) arthroscopy, are procedures done more commonly in adults.

Laser Surgery of the Airway

One of the greatest advances in airway surgery has been the use of the laser (*light amplification by stimulated emission of radiation*). For use in the airway, the laser provides precision in targeting lesions, minimal bleeding and edema, preservation of surrounding structures, and rapid healing. The laser consists of a tube with reflective mirrors at either end and an amplifying medium between them to generate electron activity, resulting in the production of light.⁴¹ The CO₂ laser is the most widely used in medical practice, having particular application in the treatment of laryngeal or vocal cord papillomas, laryngeal webs, resection of redundant subglottic tissue, and coagulation of hemangiomas. The laser is an especially useful modality for the surgeon because the invisible beam of light affords an unobstructed view of the lesion during resection. The energy emitted by a CO₂ laser is absorbed by water contained in blood and tissues. Human tissue is approximately 80% water, and laser energy absorbed by tissue water rapidly increases the temperature, denaturing protein and vaporizing the target tissue. The thermal energy of the laser beam cauterizes capillaries as it vaporizes tissues; thus, bleeding and postoperative edema are minimized.

The properties that give the laser a high degree of specificity also supply the route by which a misdirected laser beam may cause injury to a patient or to unprotected OR personnel.⁴² The eyes are especially vulnerable, and all OR personnel should wear laser-specific eye goggles with side protectors to prevent injury. Due to the limited penetration (0.01 mm) of the CO₂ laser, it may cause injury only to the cornea. Other lasers, such as the neodymium–yttrium–aluminum–garnet (Nd-YAG), have deeper penetration and may cause retinal injury and scarring. The eyes of a patient undergoing laser treatment must be protected by taping them shut, followed by the application of wet gauze pads and a metal shield. Any stray laser beam is absorbed by the wet gauze, preventing penetration of the eyes. Laser radiation increases the temperature of absorbent material, and flammable objects such as surgical drapes must be kept away from the path of the laser beam. Wet towels should be applied to exposed skin of the face and neck when the laser is being used in the airway to avoid cutaneous burns from deflected beams. Laser smoke plumes may cause damage to the lungs, and interstitial pneumonia has been reported with long-term exposure. In addition, it has been postulated that, during laser application, cancer cells and virus particles, including human immunodeficiency virus, are vaporized and the resultant smoke plume, if inhaled, may be a vehicle for spread. The use of specially designed surgical masks for filtering laser smoke is recommended.

Most anesthetic techniques are suitable for laser surgery provided that patients are immobile and the laser beam can be directed at a target that is entirely still and in full view. Both N₂O and oxygen support combustion. The primary gas for anesthetic maintenance should consist of blended air and oxygen or helium and oxygen. A pulse oximeter should be used at all times.

Anesthesia during laser surgery may be administered with or without an endotracheal tube. The choice of endotracheal tube used during laser surgery can affect the safety of the technique. All standard polyvinyl chloride (PVC) endotracheal tubes are flammable and can ignite and vaporize when in contact with the laser beam. Red rubber endotracheal tubes wrapped with reflective metallic tape do not vaporize but instead deflect the laser beam. The unwrapped cuff below the vocal cords is still vulnerable to laser injury. Cuffed endotracheal tubes should be inflated with sterile saline to which methylene blue has been added so that a cuff rupture from a misdirected laser spark is readily detected by the blue dye and extinguished by the saline.⁴³ Endotracheal tubes have been manufactured specifically for use during laser surgery. Some have a double cuff to ensure protection of the airway in the event of a cuff rupture, whereas others have a special matte finish that is effective in deflecting the laser beam throughout the entire length. Nonreflective flexible metal endotracheal tubes are also specifically manufactured for use during laser surgery. The outer diameter of each size of metal laser tube is considerably greater than the PVC counterpart, especially in the small sizes used for pediatric anesthesia (Fig. 35-9 and Fig. 35-10, Table 35-5).

| 5.0 (cuffed) | 6.8 | 7.5 |
| 5.5 (cuffed) | 7.5 | 7.9 |
| 6.0 (cuffed) | 8.2 | 8.5 |

Table 35-5. COMPARISON OF STANDARD PLASTIC VERSUS METAL ENDOTRACHEAL TUBES

An apneic technique is preferred by some surgeons, especially when working on the airway of small infants and children. The advantage of this technique is the absence of an endotracheal tube, which may obscure the surgical field. In this circumstance, a child is anesthetized and rendered immobile by use of a muscle relaxant or deep inhalation of a volatile anesthetic. The patient's trachea is not intubated and the airway is given over to the surgeon, who uses the laser for brief periods. Between laser applications, the patient's lungs are ventilated by mask. Because apnea is a component of this technique, it is prudent to ventilate the lungs with oxygen.

Although this technique has been widely used with safety, there is a greater potential for debris and resected material to enter the trachea.

A modification of the apneic technique that does not require tracheal intubation but does provide for oxygenation during laser surgery uses a jet ventilator. The operating laryngoscope is fitted with a catheter through which oxygen is delivered under pressure through a variable reducing valve (see [Fig. 35-10](#)). Additional room air is entrained and the patient's lungs are ventilated with this combination of gases. This technique produces a quiet surgical field because large chest excursions of the diaphragm are eliminated and ventilation of the patient is uninterrupted. In morbidly obese patients and those with severe small airway disease, effective ventilation is not accomplished with this technique, and an alternate technique should be used.

The final technique that may be used without the aid of an endotracheal tube is spontaneous ventilation with the "oxiscope." In this technique, a surgical laryngoscope fitted with an oxygen insufflation port is inserted into the larynx. The volatile anesthetic gas is mixed with oxygen and administered through the side port. Anesthesia is maintained without muscle relaxant in the spontaneously breathing patient in this manner. Propofol may be infused to decrease the concentration of inhaled volatile anesthetic, and the vocal cords may be sprayed with 4% lidocaine to decrease reactivity. This technique is advantageous in that longer periods of uninterrupted laser application may be provided. Disadvantages include the absence of complete control of the airway, no protection from laryngospasm, no protection from debris entering the airway, motion of the vocal cords is present, and adequate scavenging is difficult.

Nasal Surgery

Nasal surgery may be successfully accomplished under either general anesthesia or conscious sedation. Whichever method is selected, profound vasoconstriction is required. Cocaine packs, local anesthetics, and epinephrine infiltration are often used simultaneously. All three of these agents can cause cardiac irritability, and both epinephrine and cocaine are known to produce varying degrees of hypertension. The simultaneous use of these medications causes cumulative and often dangerous side effects. Young, healthy patients may be able to tolerate these effects. The older patient or one who has known cardiovascular compromise may benefit from slow, sequential administration of these medications guided by heart rate, cardiac rhythm, and blood pressure. The potent inhalation anesthetics do have varying degrees of dysrhythmogenic potential and should be used with caution in the face of pharmacologically induced alterations in cardiac rhythm.

A moderate degree of controlled hypotension combined with head elevation decreases bleeding in the surgical site, but some blood may passively enter the stomach. The placement of an oropharyngeal pack or suctioning of the stomach at the conclusion of surgery may attenuate postoperative retching and vomiting.

Maxillofacial Trauma

Traumatic disruption of the bony, cartilaginous, and soft tissue components of the face and upper airway challenge the anesthesiologist to recognize the nature and extent of the injury and consequent anatomic alteration, create a plan for securing the airway safely, implement the plan without doing further damage, maintain the airway during the administration of an anesthetic, and determine when and how to extubate the patient's trachea, all the while creating an environment in which both surgeon and anesthesiologist can comfortably work together in the same cramped space.

Anatomy

It is conventional to divide the facial skeleton into thirds. The lower third consists of the mandible, with its subdivisions of midline symphysis, body, angle, ramus, condyle, and coronoid process. The middle third contains the zygomatic arch of the temporal bone, blending into the zygomaticomaxillary complex, the maxillae, nasal bones, and orbits. The superior third consists of the frontal bone. Actually, there are two skeletons, facial and cranial, each one in contiguity with the other. Great forces are generated within the facial skeleton during the normal physiologic process of mastication. To prevent injury of one skeleton against the other, there is a series of bony buttresses built into the relationship between the two skeletons. Horizontal posterior displacement of the facial skeleton is limited by the zygomatic process of the temporal bone, oblique posterior displacement by the pterygoid process of the sphenoid bone, and vertical posterior displacement by the greater wing of the sphenoid bone. Upward displacement is held in check by the zygomatic process of the frontal bone, the nasal part of the frontal bone, and the roof of the mandibular fossa.

In addition to the buttresses, there are two arches lending stability to the craniofacial skeleton. An arch extends from the mandibular condyle to the coronoid process, and another arch is created by the zygomatic arch of the temporal bone extending into the zygomaticomaxillary complex.

This combination of bony buttresses and arches creates a normal vector of force dispersion and distribution.⁴⁴ Thus, a blow to the mandible may be of sufficient magnitude to fracture the mandible at the point of impact, or elsewhere, but does not extend the fracture line into the base of the skull. However, a blow to the midface, especially from in front and above, does not follow a normal vector of force dispersion and redistribution and tends to create an abnormal shearing force, which may tear the facial skeleton from the cranial skeleton and extend the fracture into the base of the skull. In any patient with severe midfacial trauma, a fracture of the base of the skull must be considered.

The mandible is a tubular bone and, as such, derives its strength from the cortices and is least vulnerable to fracture where the cortex is thickest (*i.e.*, at the anteroinferior margin).⁴⁵ Moving posteriorly, the cortex thins and a greater incidence of fractures found at the angle of the mandible, the ramus, and the condyle.^{46,47,48} and ⁴⁹ Another common point of fracture is in the body of the mandible at the level of the first or second molar. These are laboratory observations, but clinical experience indicates that this distribution occurs after high-velocity, high-impact trauma, such as in an automobile accident. After personal trauma, such as inflicted by a fist, a blunt weapon, or a fall, there is a greater tendency for a fracture of the symphysis, parasymphysis, and body to occur. This may result from lesser versus greater energy impact and redistribution but also results from the person's tendency to turn the head away from an impending blow and thus take the force of impact on the side of the face and the body of the mandible rather than on the symphysis.⁵⁰

The mandible has a unique, horseshoe shape that causes forces to gather at points of vulnerability, often distant from the point of impact.⁴⁸ If this phenomenon is unrecognized, it can create serious problems in diagnosis. It may be known, for example, that the patient was struck on the symphysis, but it must also be recognized that he may have a fracture of the condyle, perhaps with involvement of the TMJ and limitation of jaw mobility.

LeFort Classification of Fractures

In 1901 Rene LeFort of Lille, France, published the results of a series of rather bizarre experiments.⁵¹ He attempted to determine if there is a reliable means of detecting facial fractures by examining the facial soft tissue injuries and using the nature and extent of these injuries as indicators of bony disruption. This relationship does not exist. Extensive soft tissue injury does not necessarily indicate bony trauma, and conversely, serious fractures may exist with relatively little soft tissue disruption. In the course of his studies LeFort determined the common lines of fracture of the midface, which are thus eponymous and called LeFort I, LeFort II, and LeFort III fractures.

The LeFort I fracture is a horizontal fracture of the maxilla, passing above the floor of the nose but involving the lower third of the septum, mobilizing the palate, maxillary alveolar process, and the lower third of the pterygoid plates and parts of the palatine bones. The fracture segment may be displaced posteriorly or laterally, rotated about a vertical axis, or any combination.

The LeFort II fracture is pyramidal, beginning at the junction of the thick upper part of the nasal bone and the thinner portion forming the upper margin of the anterior nasal aperture. The fracture crosses the medial wall of the orbit, including the lacrimal bone, beneath the zygomaticomaxillary suture, crosses the lateral wall of the antrum, and passes posteriorly through the pterygoid plates. The fracture segment may be displaced posteriorly or rotated about an axis.

In a LeFort III fracture, the line of fracture parallels the base of the skull, separating the midfacial skeleton from the base of the cranium. The line of fracture passes through the base of the nose and the ethmoid bone in its depth, and through the orbital plates. The cribriform plate of the ethmoid may or may not be fractured. The fracture line crosses the lesser wing of the sphenoid, then downward to the pterygomaxillary fissure and sphenopalatine fossa. From the base of the inferior orbital fissure, the fracture extends laterally and upward to the frontozygomatic suture and downward and backward to the root of the pterygoid plates. A LeFort III fracture results from massive force applied to the mid-face. The zygomata are displaced and rotational force applied to the zygomatic arches. The arches are usually fractured as a result.

With this fracture, the midface is mobilized and often distracted posteriorly. The normal convexity of the face may be replaced by a concavity, giving rise to the characteristic "dish face deformity" of a LeFort III fracture. Even if this facial concavity is not clinically evident, the presence of a LeFort III fracture should be suspected if the incisive edges of the maxillary and mandibular teeth are apposed, instead of the normal position in which the maxillary incisors shingle over the mandibular incisors. This apposition serves as a subtle clue to minimal posterior displacement of the midface.

Tumors

Neoplastic growths can occur anywhere within the upper airway and may achieve significant size with little evidence of airway obstruction. These tumors are often friable and bleed readily. Attempted tracheal intubation can induce significant hemorrhage and edema and cause severe compromise of the airway. Prior radiation therapy may cause extensive fibrosis, increased intraoperative bleeding, and ankylosis of the TMJ, making tracheal intubation under direct vision difficult or impossible. Consultation with a surgeon as to the nature and extent of the tumor its potential to bleed, together with review of appropriate radiographs and prior therapy, are important in determining techniques for airway management. Tumors of the head and neck are usually associated with abuse of both cigarettes and alcohol, with consequent abnormalities of both pulmonary and hepatic function.

Upper Airway Infection

Infectious processes in the upper airway may be of sufficient size to mimic neoplasms and present the same problems of airway distortion, compression, and compromise. The same precautions must be taken in dealing with airway abscesses as with tumors. An added problem is the ability of an abscess to leak spontaneously, dribbling pus into the lungs, contaminating and infecting them, and producing scattered areas of pneumonitis; or to rupture during tracheal intubation, flooding the lungs with purulent material.

Ludwig's Angina

Ludwig's angina is an overwhelming generalized septic cellulitis of the submandibular region.^{52,53} It generally occurs after dental extraction, especially of the second or third mandibular molars, whose roots lie below the attachment of the mylohyoid muscle. The infection is bilateral and involves three fascial spaces: submandibular, submental, and sublingual.⁵⁴ Ludwig's angina is characterized by brawny induration of the upper neck, usually without obvious fluctuation, and the patient has a typical open-mouthed appearance. Involvement of the sublingual space pushes the tongue upward and backward, and it usually protrudes from the open mouth. Soft tissue swelling in the suprahyoid region, coupled with upward and posterior displacement of the tongue, and the frequent presence of laryngeal edema can close the airway and asphyxiate the patient.

Early signs and symptoms include chills, fever, drooling of saliva, inability to open the mouth, and difficulty in speaking. The cause is often hemolytic streptococci but may be a mixture of aerobic and anaerobic organisms, including gas-forming bacteria.⁵⁵ Although fluctuation is rarely appreciated, abscesses may be present but their presence hidden by the thick, indurated tissue of the neck. The infectious process may spread into the thorax, causing empyema, pericarditis, pericardial effusion, and pulmonary infiltrates.^{56,57} Patients with Ludwig's angina often require incision and drainage of whatever purulent material is present, coupled with airway decompression. Airway management may be extremely difficult. While inhalation anesthesia and intubation have been advocated,⁵⁸ preliminary tracheostomy using local anesthesia in the awake patient is the safest course. The patient with Ludwig's angina is commonly septic and extremely ill, and often poorly hydrated.

Temporomandibular Joint Arthroscopy

Open surgery of the human TMJ was first described in 1887 in a discussion of operative repair of displaced interarticular cartilage of the joint.⁵⁹ Although open surgery of the joint is still sometimes considered necessary, the development of small-gauge arthroscopes and lasers has made arthroscopic surgery of the TMJ an increasingly popular technique, frequently performed on an ambulatory basis.^{60,61} Common indications for arthroscopic correction of TMJ lesions include the following:⁶¹ (1) internal joint derangement with closed lock, (2) internal joint derangement with painful clicking, (3) osteoarthritis, (4) hypermobility, (5) fibrous ankylosis, and (6) arthralgia. Other less common indicators include chondromalacia and synovitis.

Temporomandibular joint disease is usually caused by spasm of the muscles of mastication secondary to chronic tensing of these muscles as an involuntary mental tension-relieving mechanism.⁶² The patient population is unique in that 86% of patients with chronic TMJ dysfunction have significant psychopathology, with major depression in 74% and somatoform disorder in 50%.⁶³ A total of 40% of the patients are preoccupied with facial pain yet have no physical findings accounting for the pain. Many of these patients habitually use mood-altering or tension-abating drugs such as benzodiazepines, phenothiazines, or lithium.

Nasotracheal intubation is usually preferred, allowing the surgeon the option of intraoral manipulation during surgery. Complications of TMJ arthroscopy are rare but include partial or total hearing loss, infection, hemorrhage requiring open arthrotomy, and temporary or permanent deficits of the fifth and eighth cranial nerves and temporary seventh nerve paresis.^{61,64}

Of particular importance to the anesthesiologist is partial or even complete closure of the airway due to extracapsular extravasation of the fluid used to irrigate the joint during arthroscopy.⁶⁵ Significant amounts of fluid can leak into the soft tissues of the neck and compromise the airway. After TMJ arthroscopy, the patient's trachea should not be extubated until the oral cavity, especially on the affected side, and neck have been examined carefully and there is no evidence of unusual swelling that might indicate extravasated fluid.

Patient Evaluation

The patient who has sustained facial trauma or whose airway is clearly distorted by tumor or infection may present with an obvious pathologic process that can distract the physician from completing a total evaluation of the patient. In the patient with facial trauma, other injuries may not be as apparent but may represent a greater threat to the patient's well-being. In patients with maxillofacial injury due to low-velocity, low-impact blows (as from a fist), 4% had major (life-threatening) other injuries, and 10% had minor (non-life-threatening) injuries. With high-velocity, high-impact (motor vehicle) accidents, 32% had major and 31% minor other injuries.⁶⁶ Of great importance, cervical spine fractures occurred in 1.2% of high-velocity injuries. Other studies have reported a 5.5% incidence of cervical spine injury in patients with facial skeletal trauma.⁶⁷ Any level of the cervical spine may be involved, but injuries at C2 (31%) and C6–7 (50%) predominate. Cranial fractures and intracranial injury are also not uncommon.

SECURING THE AIRWAY

In most instances of anesthesia for head and neck surgery, tracheal intubation is effected without significant problems. Grave difficulties can arise in patients with tumor or infection or other facial trauma. If any of these processes has so altered the airway that attempted tracheal intubation risks airway compromise and an inability to ventilate the lungs, then awake tracheal intubation or preliminary tracheostomy is mandated. History, physical examination, appropriate radiographs, and surgical consultation are the foundation of airway evaluation and choice of intubating technique. The technique of an "awake look" before a decision to anesthetize and paralyze a patient is particularly hazardous and misleading. Muscle tone and labored respiration in the awake patient help to identify the rima glottis or some seemingly familiar anatomic structure but disappear once anesthesia and paralysis have been induced, and it may be impossible to identify the entrance to the airway and intubate the trachea.

For the anesthesiologist to be able to intubate the trachea of a patient under direct vision, the patient must be able, at a minimum, to open the mouth and extend the tongue beyond the incisors. After maxillofacial trauma, there may be serious limitation in mobility owing to one or more factors, including pain, trismus, edema, and mechanical dysfunction of the TMJ. Pain yields to an anesthetic and muscle relaxant and presents no problem.

Trismus is spasm of the masseter muscles, binding the jaw closed, secondary to trauma or infection. Trismus, too, succumbs to an anesthetic and muscle relaxant, but with an important caveat. If the trismus has been present for 2 weeks or if the jaw has been closed for some other reason for 2 weeks, the masseters acquire a degree of fibrosis that limits their response to an anesthetic and relaxant. A jaw closed for 2 weeks for whatever cause merits consideration for awake tracheal intubation. Edema varies in severity and consequences from mild to extreme and may occasionally cause serious limitation in jaw mobility.

Mechanical dysfunction in the jaw arises from several causes. A fracture of the condyle in its articulation in the TMJ may create a situation in which the jaw is locked closed and unresponsive to an anesthetic and muscle relaxant. A fracture of the zygomatic arch of the temporal bone will always cause some decrease in jaw mobility. This bone is well protected, enveloped in the tough temporal fascia. Nonetheless, a severe blow to the side of the head may fracture the bone, pushing bony segments down onto the coronoid process of the mandible. There is a biphasic motion in the mandible, rotation about an axis passing through the condyles, and anterior motion (translation). This anterior motion is limited by the bony impingement on the coronoid process, and TMJ function is thus limited by the limitation in translation. Usually, the decrease in function is not severe enough to make tracheal intubation impossible, but it may be, and the decision whether to anesthetize and paralyze the patient or perform awake tracheal intubation may be difficult. The anesthesiologist in doubt is cautioned to err on the side of conservatism.

Patients with TMJ dysfunction undergoing arthroscopic surgery may present with either closed or open lock and be unsuitable for intubation of the trachea after induction of anesthesia. Patients with large cervical abscesses may require awake intubation or tracheostomy. If the abscess has caused anatomic distortion or respiratory difficulty, awake intubation or tracheostomy is usually mandatory. Early tracheostomy in Ludwig's angina is preferred, and no patient should ever be observed to the point of airway compromise.⁶⁸ In any instance in which awake intubation is elected in the infected patient provision must be available for immediate

tracheostomy.

Awake Intubation

Passing an endotracheal tube through the mouth or nose and into the larynx and trachea of an awake patient is a formidable procedure that the patient resists fiercely, stimulated by the protestations of highly sensitive airway reflexes. To overcome these reflexes, the airway must be anesthetized using a combination of topical local anesthetic and superior laryngeal nerve block.

The *superior laryngeal nerve* is a branch of the vagus arising from the nodose ganglion and coursing with the main trunk of the vagus until it reaches the level of the larynx, where it springs forward and terminates in two branches, internal and external. The external branch of the superior laryngeal nerve penetrates and innervates the cricothyroid muscle, a tensor of the vocal cords. The internal branch penetrates the thyrohyoid membrane, ramifies, and provides sensory innervation from the base of the tongue to the vocal cords.⁶⁹ Once it has penetrated the thyrohyoid membrane, it lies in a closed space, bounded medially by the laryngeal mucosa, laterally by the thyrohyoid membrane, superiorly by the inferior border of the hyoid bone, and inferiorly by the superior surface of the thyroid cartilage. The anatomic landmarks for superior laryngeal nerve block are as follows:

1. The hyoid bone, a freely movable bone in the upper part of the neck, articulating with no other bone
2. The thyroid cartilage, the largest component of the larynx, usually easily identified
3. The thyrohyoid membrane binding the two together

With the patient lying supine, a 22-gauge needle attached to a syringe containing 2 ml of 2% lidocaine is aimed directly at the hyoid, traveling parallel to the operating table. When the needle strikes the hyoid, the operator can appreciate the characteristic gritty feeling of a needle on bone, similar to striking the rib while doing an intercostal block. The needle is then walked caudad until it just slips off the bone, penetrating the thyrohyoid membrane. After negative aspiration, lidocaine may be injected and the block repeated on the other side.^{70,71}

Contraindications to a superior laryngeal nerve block are relative, not absolute, and include the following:

1. A full stomach, because of the possibility of vomiting and aspiration into an airway whose protective reflexes have been partially obtunded
2. Tumor at the site of block
3. Infection at the site of block

Tumor and infection are considered to be relative contraindications because of the possibility of dissemination of either tumor or infection secondary to the manipulation associated with the block. Risks must be weighed against benefit, and very often benefit wins. Protection against aspiration can be increased by the presence of knowledgeable help, an operating table that can swing quickly into the Trendelenburg position, and efficient suction apparatus.

Local anesthetic may be instilled into the nose for nasotracheal intubation and into the mouth and oropharynx for either nasal or oral intubation. A vasoconstrictor, such as 0.5% phenylephrine hydrochloride or 0.05% oxymetazoline, should also be instilled in the nose to shrink the nasal mucosa, decrease the risk of trauma, and create a larger passage for tracheal intubation. Topical anesthetic may be applied to the trachea below the level of the vocal cords by introducing a 22-gauge needle attached to a syringe containing 4 ml of 2% lidocaine and injecting the drug rapidly into the trachea at the end of the maximal expiration. The injection of the drug excites a vigorous cough reflex, spraying the local anesthetic along the tracheal side walls and inferior surface of the vocal cords. As a supplement to direct tracheal instillation of local anesthetic and bilateral superior laryngeal nerve block, local anesthetic (e.g., 2% lidocaine) may be nebulized in a hand-held nebulizer and inhaled by the patient. This is a tedious process, demanding long, slow breaths and inhalation of the nebulized anesthetic over the course of at least 20 minutes. The endotracheal tube may then be passed into the anesthetized airway using a guided, fiberoptic technique or blindly. Complications of superior laryngeal nerve block include intravascular injection of local anesthetic. The carotid sheath lies just posterior to the site of block and, if the needle is angled posteriorly, the sheath may be entered and the anesthetic injected directly into the carotid artery or internal jugular vein.

The role of the LMA in head and neck surgery awaits clarification. The LMA may be useful in temporarily securing a compromised airway. In any situation, however, where the airway is jeopardized by blood or pus, or the anatomy distorted by trauma, the airway must be secured with a cuffed endotracheal or tracheostomy tube. The intubating LMA may facilitate awake intubation.⁷² The flexible LMA is unsafe in head and neck surgery in the presence of foreign material such as blood, bone fragments, or pus.⁷³

LeFort III Fractures

A LeFort III fracture may involve the cribriform plate of the ethmoid bone, thus violating the separation of nasopharynx and base of the skull and allowing entrance into the intracranial subarachnoid space. Nasotracheal intubation risks the introduction of foreign material from the nasopharynx into the subarachnoid space and the consequent development of meningitis. More importantly, it risks the introduction of the endotracheal tube into the substance of the brain, with direct mechanical damage. Even positive-pressure bag and mask ventilation is contraindicated because the increase in volume and pressure within the nasopharynx can force foreign material⁷⁴ or air into the skull.⁷⁵

The problems of securing the airway in a patient with a LeFort III fracture are ordinarily obviated by doing a preliminary tracheostomy using local anesthetic in an awake patient. This has the added advantage of separating surgeon and anesthesiologist and allowing each an adequate working space. Nasotracheal intubation can be performed in a patient with a LeFort III fracture provided three criteria are met: (1) absence of clinical signs of basal skull fracture, (2) absence of radiographic evidence of basal skull fracture, and (3) a compelling reason for doing so. Occasionally (rarely) these three criteria are fulfilled.

Anesthetic Management of the Traumatized Upper Airway

After tracheal intubation has been achieved or tracheostomy performed, general or iv anesthetics may be used. The use of ketamine as a sole anesthetic in an attempt to obviate the necessity of performing a difficult tracheal intubation is perilous and should be avoided. Ketamine is a potent respiratory depressant⁷⁶ in bolus doses, increases intracranial pressure⁷⁷ (ICP), and causes focal alterations in the cerebral metabolic rate.⁷⁸ Because there is a significant incidence of intracranial trauma associated with maxillofacial trauma, the brain must be protected and alterations in ICP avoided. Opioids have little effect on ICP and are useful in anesthetic management. However, the dose may be difficult to determine because of the high incidence of drug abuse associated with trauma. Inhalation anesthetics are safe and effective and ICP can be moderated by altering the PaCO₂. The halogenated ethers are particularly useful, but the halogenated alkane halothane should be avoided because of the high incidence of cardiac arrhythmias associated with its use.⁷⁹

Extubation

When tracheostomy has been incorporated into the anesthetic-surgical plan, it is maintained at the termination of the procedure and the only decision facing the anesthesiologist is whether to allow spontaneous respiration or to create suitable conditions for continued mechanical ventilation by maintaining the patient anesthetized and paralyzed. This decision is contingent on such factors as the nature and duration of surgery, the patient's prior physical condition, and concurrent respiratory disease, a frequent concomitant of head and neck tumors.

After trauma, infection, or extensive oral resection for tumor, the endotracheal tube must not be removed until there is clearly subsidence of any edema that might compromise the unprotected airway. Particular attention must be given to the submandibular area, where extensive edema pushes the tongue upward and posteriorly and risk the airway. An edematous tongue protruding past the incisors is an ominous warning of dangerous edema. If substantial edema is present, a waiting period of 24–36 hours is usually indicated. Serious infection may require a longer period of time to resolve. An oral endotracheal tube may be removed over a tube changer. When removing a nasotracheal tube, a useful technique is to place a fiberoptic bronchoscope through the tube and into the airway and remove the tube over the bronchoscope, so that it can be replaced immediately if need demands.

The kidney plays a central role in the implementation and control of a variety of homeostatic functions. Most important are the complementary tasks of excreting metabolic waste products in the form of urine and maintaining extracellular fluid volume and composition constant. Renal dysfunction may occur perioperatively as a direct result of surgical or medical disease, prolonged reduction in renal oxygen delivery, nephrotoxin insult, or, frequently, a combination of the three. Postoperative renal failure, although infrequent, is a serious complication that carries a high mortality rate. The first part of this chapter reviews renal physiology and pathophysiologic states as they relate to anesthetic practice, and then discusses strategies for recognizing and managing patients at risk for renal failure.

Since 1980, many exciting advances have occurred in urologic surgery. Lithotripsy and endoscopic surgery have replaced open surgical procedures for the treatment of urinary tract calculi. Laparoscopy is now used for numerous surgical procedures, and improved diagnostic tests for urologic cancers have dramatically increased the number of radical surgical procedures. These surgical advances have presented the anesthesiologist with enormous challenges. For example, minimally invasive surgical techniques have made it possible to treat patients who were once considered too sick to undergo open surgical procedures. The creation of a pneumoperitoneum during laparoscopic surgery produces unique physiologic alterations and increases the potential for complications. The second part of this chapter familiarizes the anesthesiologist with current surgical techniques in urology and their attendant anesthetic management issues.

RENAL ANATOMY AND PHYSIOLOGY

Anatomy and Innervation of the Genitourinary System

The kidneys are located in the retroperitoneal space, with their center at the L2 vertebral body. Renal pain sensation is conveyed back to spinal cord segments T10–L1 by sympathetic fibers. Sympathetic innervation is supplied by preganglionic fibers from T8–L1 whereas the vagus nerve provides parasympathetic innervation to the kidney ([Fig. 36-1](#)).

Figure 36-1. (A) Anatomy and innervation of the kidney and ureters. (B) Schematic illustration of the autonomic and sensory nerve pathways supplying the kidney and ureters. (Reprinted with permission from Ansell JS, Gee WF: Diseases of the kidney and ureter. In Bonica JJ [ed]: The Management of Pain, p 1233. Philadelphia, Lea & Febiger, 1990.)

The ureters are also retroperitoneal structures and have sympathetic innervation and nociceptive projection to the spinal cord that is nearly identical to that of the kidneys. These spinal segments also provide somatic innervation to the lumbar area, flank, ilioinguinal area, and scrotum or labia. Accordingly, pain from the kidney and ureter is referred to those areas. Parasympathetic fibers from S2–4 spinal segments supply the ureters ([Fig. 36-1](#)).

The bladder is located in the retroperitoneal space and receives its innervation from sympathetic nerves originating from T11–L2, which conduct pain, touch, and temperature sensations, whereas bladder stretch sensation is transmitted via parasympathetic fibers from segments S2–4. Parasympathetics also provide the bladder with most of its motor innervation ([Fig. 36-2](#)).

Figure 36-2. (A) Anatomy and innervation of the urinary bladder and prostate. (B) Schematic illustration of the innervation of the bladder, penis, and scrotum. *Solid lines* = preganglionic fibers; *dashed lines* = postganglionic fibers; *dotted lines* = sensory fibers. (Reprinted with permission from Gee WF, Ansell JS: Pelvic and peritoneal pain of urologic origin. In Bonica JJ [ed]: The Management of Pain, p 1369. Philadelphia, Lea & Febiger, 1990.)

The prostate, penile urethra, and penis also receive sympathetic and parasympathetic fibers from the T11–L2 and S2–4 segments, respectively. The pudendal nerve provides pain sensation to the penis *via* the dorsal nerve of the penis. The sensory innervation of the scrotum is *via* cutaneous nerves, which project to lumbosacral segments, whereas testicular sensation is conducted to lower thoracic and upper lumbar segments (Fig. 36-2).

Anatomy of the Nephron

The *nephron* is the microscopic functional unit of the kidney and is elegantly designed to carry out its excretory and regulatory roles (Fig. 36-3). The *glomerulus* is a capillary network that serves as the basic filtering unit of the nephron and is situated in the outer cortex of the kidney. Blood to be filtered enters the glomerular tuft through the afferent arteriole and eventually exits the glomerulus through the efferent arteriole. The initial segment of the renal tubular system, called *Bowman's capsule*, envelops the glomerulus. The glomerular filtrate passes from Bowman's capsule into the proximal tubule and then into the descending loop of Henle, which dips deep into the medullary portion of the kidney. The ascending limb of the loop is made up of an initial thin segment, which gives rise to a thick-walled segment as it approaches the cortex. Once back in the cortex, the distal tubule comes in contact with both the afferent and efferent arterioles to form the juxtaglomerular apparatus. The distal tubule then proceeds through the cortex to join with other tubules to form cortical collecting ducts. These collecting ducts again plunge into the medulla, coalesce, and eventually empty urine into the renal pelvis, which is drained by the ureters. Blood supply to the entire tubular system comes from the glomerular efferent arteriole, which branches into an extensive capillary network. Some of these peritubular capillaries, the *vasa recta*, descend deep into the medulla to parallel the loops of Henle. The vasa recta then return in a cortical direction with the loops, join other peritubular capillaries, and empty into the cortical veins.

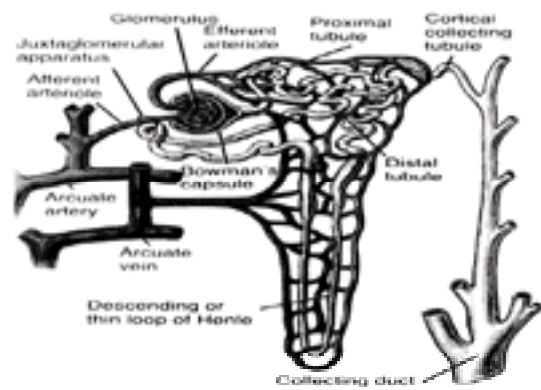

Figure 36-3. Anatomy of the nephron. (Reprinted with permission from Guyton AC: Formation of urine by the kidney: Renal blood flow, glomerular filtration, and their control. In Guyton AC [ed]: Textbook of Medical Physiology, 8th ed, p 287. Philadelphia, WB Saunders, 1991.)

Renal Physiology

The kidney fulfills its dual roles of waste excretion and body fluid management by filtering large amounts of fluid and solutes from the blood, reabsorbing needed components of this filtrate, and secreting waste products into the tubular fluid.¹ Filtration and reabsorption are most susceptible to alterations by surgical illness and anesthesia and are the focus of discussion.

Glomerular Filtration

Urine production begins with the filtration of water and solutes from blood flowing through the afferent arteriole. The glomerular membrane serves as the filter, whereas Bowman's capsule acts as the initial receptacle for the filtrate. The kidneys receive ~20% of the systemic cardiac output and are able to filter 10% of this volume to produce 180 l · day⁻¹ of glomerular filtrate. More than 99% of the filtered fluid is reabsorbed and returned to the circulation, resulting in 1–2 l of urine output per day in the healthy adult.

The *glomerular filtration rate* (GFR) is a measure of glomerular function expressed as milliliters of filtrate produced per minute. GFR can be thought of as the product of the tendency of the glomerular membrane to allow filtration to occur (*i.e.*, glomerular permeability and surface area) and the pressure inside the glomerular capillary that forces fluid through the filter. Thus, the GFR can be expressed simply as:

$$\text{GFR} = K_f [\text{Filtration pressure}]$$

where K_f is the ultrafiltration constant of the glomerulus. The glomerular filtration pressure is a complex value that can be calculated by subtracting oncotic forces from opposing hydrostatic forces:

$$\text{Filtration pressure} = (P_{GC} - P_{BC}) - (\pi_{GC} - \pi_{BC})$$

where P_{GC} is the glomerular capillary pressure, P_{BC} is the pressure inside Bowman's capsule, π_{GC} is the glomerular capillary oncotic pressure (plasma oncotic pressure), and π_{BC} is Bowman's capsule oncotic pressure.

The *ultrafiltration constant* (K_f) is directly related to glomerular capillary permeability and glomerular surface area. Glomerular capillary permeability is relatively constant, but the glomerular surface area can be reduced by intense sympathetic or angiotensin II stimulation, which, in turn, decreases GFR.

Changes in glomerular filtration pressure exercise the greatest influence on GFR in both normal and pathologic states. The two major determinants of filtration pressure are glomerular capillary pressure (P_{GC}) and glomerular oncotic pressure (π_{GC}), changes in Bowman's capsule hydrostatic and oncotic pressures are of less importance. P_{GC} is directly related to the renal artery pressure but is heavily influenced by arteriolar tone at points upstream (afferent) and downstream (efferent) from the glomerulus. An increase in afferent arteriolar tone, as occurs with intense sympathetic or angiotensin II stimulation, causes filtration pressure and GFR to fall. Milder degrees of sympathetic or angiotensin activity cause a selective increase in efferent arteriolar tone, which tends to increase the filtration pressure and GFR. The π_{GC} is directly dependent on the plasma oncotic pressure but is also related to the rate of blood flow through the glomerulus. The capillary oncotic pressure tends to increase as fluid is filtered into Bowman's capsule, and this would inhibit further filtration but for fresh blood flowing through the glomerulus and diluting the "left-over" plasma proteins. Therefore, high renal (glomerular) blood flow keeps the π_{GC} lower, which promotes filtration. Afferent arteriolar dilation enhances GFR by increasing glomerular flow, which, in turn, elevates glomerular capillary pressure and keeps π_{GC} low. Efferent arteriolar constriction intense enough to slow glomerular blood flow produces opposing effects on the GFR. This occurs because any increase in capillary pressure is partially offset by an increase in capillary oncotic pressure.

Autoregulation of Renal Blood Flow and Glomerular Filtration Rate

From the preceding discussion, it is apparent that renal blood flow (RBF) and perfusion pressure, in large part, determine GFR. To maintain relatively constant rates of RBF and glomerular filtration over a wide range of physiologic demands, the kidney must exercise some control over its own performance. Renal autoregulation of blood flow and filtration is accomplished by local feedback signals that modulate glomerular arteriolar tone.

Autoregulation of RBF is effective over a wide range of arterial pressure (Fig. 36-4). Two separate mechanisms for regulating blood flow to the glomerulus have been

proposed, and both involve the modulation of afferent arteriolar tone. A myogenic reflex has been postulated in which an increase in arterial pressure causes the afferent arteriolar wall to stretch and then reflexly constrict, whereas a decrease in arterial pressure causes arteriolar dilation. The other mechanism of RBF autoregulation is a phenomenon called *tubuloglomerular feedback*, which is also responsible for the autoregulation of GFR.

Figure 36-4. Autoregulation of glomerular filtration rate (GFR) and renal blood flow (RBF) over a wide range of arterial pressures. Note that urine output is not subject to autoregulation. (Reprinted with permission from Guyton AC: Formation of urine by the kidney: Renal blood flow, glomerular filtration, and their control. In Guyton AC [ed]: Textbook of Medical Physiology, 8th ed, p 293. Philadelphia, WB Saunders, 1991.)

Tubuloglomerular feedback control of RBF and GFR works by using the composition of distal tubular fluid to influence glomerular function through the *juxtaglomerular apparatus*. When RBF falls, the concomitant decrease in GFR results in less chloride ion delivery to the juxtaglomerular apparatus, which then signals the afferent arteriole to dilate. Glomerular flow and pressure then increase and the GFR returns to previous levels. Chloride ion also acts as the feedback signal for control of efferent arteriolar tone. When GFR falls, declining chloride ion delivery to the juxtaglomerular apparatus triggers release of *renin*, which causes the formation of *angiotensin II*. In response to angiotensin, efferent arteriolar constriction increases glomerular pressure, which increases glomerular filtration. Simultaneous afferent arteriolar dilation and efferent arteriolar constriction allow glomerular flow and filtration to increase.

Note from [Figure 36-4](#) that autoregulation of urine flow does not occur and that there is a linear relationship between mean arterial pressure above 50 mm Hg and urine output.

Tubular Reabsorption of Sodium and Water

The renal tubular system is responsible for selectively reabsorbing the vast quantities of fluid and solutes filtered by the glomeruli. Waste materials are thereby separated from essential solutes and excreted in the minimum volume of water possible. Sodium and water conservation by the kidney are closely related to the homeostatic mechanisms involved in the mammalian response to physiologic stress. The neurohumoral response to surgical stress and critical illness is primarily directed at maintaining blood pressure, circulating blood volume, and essential organ blood flow. Sodium and water reabsorption will be examined in the context of their roles as markers of the stress response.

The active, energy-dependent reabsorption of sodium begins almost immediately as filtrate enters the proximal tubule. Here, an adenosine triphosphatase pump drives the sodium into tubular cells while chloride ion passively follows. Glucose, amino acid, and other organic compound reabsorption is strongly coupled to sodium in the proximal tubule. Normally, the proximal tubule reabsorbs ~65% of the filtered sodium, but no active sodium transport occurs in the loop of Henle until the medullary thick ascending limb (mTAL) is reached. The cells of the mTAL are metabolically active in their role of reabsorbing sodium and chloride and have a high oxygen consumption compared with the thin portions of the descending and ascending limbs. Sodium pumps in the distal tubule and collecting duct are unique in that they are under the control of the adrenal hormone aldosterone.

The reabsorption of water is a passive, osmotically driven process that is tied to sodium and other solute reabsorption. Water reabsorption also depends on peritubular capillary pressure; high capillary pressure opposes water reabsorption in the proximal tubule and tends to increase urine output. The proximal tubule reabsorbs ~65% of filtered water in an isosmotic fashion with sodium and chloride. The descending limb of the loop of Henle allows water to follow osmotic gradients into the renal interstitium. However, the thin ascending limb and mTAL are relatively impermeable to water and play a key role in the production of concentrated urine. Only approximately 15% of filtered water is reabsorbed by the loop of Henle, and the remaining 20% of the filtrate volume flows into the distal tubule. There, and in the collecting duct, water reabsorption is controlled entirely by antidiuretic hormone (ADH) secreted by the pituitary gland.

The conservation of water and excretion of excess solute by the kidneys would become untenable without the ability to produce concentrated urine. This is accomplished by establishing a hyperosmotic medullary interstitium and regulating the water permeability of the distal tubule and collecting duct with ADH.

Medullary interstitial fluid hyperosmolarity is achieved primarily through the activity of nephrons whose glomeruli are located at the border of the cortex and medulla. These juxtamedullary nephrons send their loops of Henle very deep into the medulla and are able to produce an increasingly hyperosmolar interstitium by three mechanisms: (1) vigorous transport of ions by the mTAL into the interstitium while water is retained in the tubule, (2) active transport of ions into the medullary interstitium by the collecting ducts, and (3) passive diffusion of large quantities of urea from the collecting ducts into the interstitium. The medullary interstitium would eventually lose its hyperosmolarity by washout of solutes were it not for the unique role of the vasa recta. The vasa recta prevents medullary solute washout by providing for a countercurrent exchange of ions, which continually "recycles" solutes between its descending and ascending arms. The countercurrent exchange mechanism works because the vasa recta is extremely permeable to solutes and water, which allows for their rapid, passive movement between the two arms. The other important characteristic of the vasa recta is that its blood flow is sluggish (the inner medulla receives 2% of total RBF) and therefore, does not contribute to washout of solutes from the medulla. Low medullary blood flow is essential to renal concentrating ability but may render the metabolically active mTAL vulnerable to ischemic injury during times of reduced RBF.²

All that is now necessary to produce a concentrated urine is to alter the water permeability of the distal tubule and collecting duct in response to bodily needs. ADH increases the water permeability of these structures and allows for passive diffusion of water (under considerable osmotic pressure) back into the circulation. The posterior pituitary releases ADH in response to an increase in either the extracellular sodium concentration or the extracellular osmolality. In addition, ADH release can be triggered by a perceived reduction in intravascular fluid volume. The arterial baroreceptors are activated when hypovolemia leads to a decrease in blood pressure, whereas atrial receptors are stimulated by a decline in atrial filling pressure. Both of these circulatory reflex systems stimulate release of ADH from the pituitary and cause retention of water by the kidney in an effort to return the intravascular volume toward normal. ADH also causes renal cortical vasoconstriction when it is released in large amounts, as during the physiologic stress response to trauma, surgery, or other critical illness. This induces a shift of RBF to the hypoxia-prone renal medulla.

The neurohumoral regulation of sodium reabsorption by the kidney is another important component of the physiologic response to stress. The hormonal messengers involved in sodium management also have potent vasoactive effects on both the renal and systemic vasculature.

Renin-Angiotensin-Aldosterone System. As discussed earlier, renin-angiotensin activity plays an important role in regulating RBF and GFR. Renin release by the renal afferent arteriole may be triggered by hypotension, increased tubular fluid chloride ion concentration, or sympathetic stimulation. Renin enhances angiotensin II production, which induces renal efferent arteriolar vasoconstriction. Angiotensin II also promotes ADH release from the posterior pituitary, sodium reabsorption by the proximal tubule, and aldosterone release by the adrenal medulla. Aldosterone, in turn, stimulates the distal tubule and collecting duct actively to reabsorb sodium (and water), resulting in intravascular volume expansion. Sympathetic nervous system stimulation may also directly cause the release of aldosterone. Thus, the response of the body to surgical stress uses existing mechanisms for sodium and water conservation. This results in renal cortical vasoconstriction, a shift in RBF to salt-and-water-conserving juxtamedullary nephrons, a decrease in GFR, and salt and water retention. Clinically, this tendency toward oliguria and edema formation may persist for several days into the postoperative period due to ongoing stress (pain, sepsis, hypovolemia).

Renal Vasodilator Mechanisms. Opposing the salt and water retention and vasoconstriction observed in stress states and mediated by the sympathetic nervous system, ADH, and the renin-angiotensin-aldosterone system are the actions of *atrial natriuretic peptide* (ANP), *nitric oxide*, and the renal *prostaglandin* system. ANP is released by the cardiac atria in response to increased stretch under conditions of relative hypervolemia. Both salt and water excretion increase as ANP blocks reabsorption of sodium in the distal tubule and collecting duct. ANP also increases GFR, causes systemic vasodilation, inhibits the release of renin, opposes the production and action of angiotensin II, and decreases aldosterone secretion.^{3,4 and 5} Nitric oxide produced by the kidney opposes the renal vasoconstrictor effects of angiotensin II and the adrenergic nervous system, increases sodium and water excretion, and participates in the tubuloglomerular feedback system.⁶

Prostaglandins are produced by the kidney as part of a complex system that modulates RBF and opposes the actions of ADH, norepinephrine, and the renin-angiotensin-aldosterone system.⁷ Stress states, renal ischemia, and hypotension stimulate the production of renal prostaglandins through the enzymes phospholipase A₂ and cyclo-oxygenase. The prostaglandins produced by cyclo-oxygenase activity cause dilation of renal arterioles (anti-angiotensin II), whereas their distal tubular effects result in an increase in sodium and water excretion (anti-ADH and aldosterone). The renal prostaglandin system is important in maintaining RBF and sodium and water excretion during times of high physiologic stress and poor renal perfusion.⁷ This defensive role for the prostaglandins has been confirmed by experiments that demonstrate that cyclo-oxygenase inhibition has damaging effects in the ischemic kidney, but not in the unstressed state.⁸ Conversely, the stimulation of prostaglandin synthesis or the administration of exogenous prostaglandin E₂ protects the kidney from hypoxic injury.⁹

RENAL DYSFUNCTION AND ANESTHESIA

Altered renal function can be represented as a clinical continuum that ranges from normal compensatory changes in renal function during stress to frank renal failure. Clinically, there is considerable overlap between compensated and decompensated renal dysfunctional states. For the anesthesiologist, there is little time or opportunity to make such a distinction in the operating room using laboratory tests. Nevertheless, it is worthwhile here to review the clinical spectrum of renal dysfunction-failure and comment on the implications for anesthesia practice.

The kidney under stress reacts in a predictable manner to help restore intravascular volume and maintain blood pressure. The sympathetic nervous system reacts to trauma, shock, or pain by releasing norepinephrine, which acts much like angiotensin II on the renal arterioles. Norepinephrine also activates the renin-angiotensin-aldosterone system and causes ADH release. The net result of modest activity of the stress response system is characterized by a shift of blood flow from the renal cortex to the medulla, avid sodium and water reabsorption, and decreased urine output. A more intense stress response may induce a decrease in RBF and GFR by causing afferent arteriolar constriction. If this extreme situation is not reversed, ischemic damage to the kidney may result and acute renal failure (ARF) may become clinically manifest. More often, some other insult contributes to renal failure in the “stressed” patient with co-existing renal vasoconstriction.¹⁰

With the exception of methoxyflurane and possibly enflurane, anesthetic agents do not directly cause renal dysfunction or interfere with normal compensatory mechanisms activated by the stress response. Nephrotoxicity of methoxyflurane appears to be due to its metabolism, which results in the release of fluoride ion thought to be responsible for the renal injury.¹¹ It has been suggested that renal, not hepatic, metabolism of methoxyflurane may be responsible for generating fluoride ions locally that contribute to nephrotoxicity.¹² Enflurane nephrotoxicity may occur,¹³ but seems to be of minor clinical importance even in patients with pre-existing renal dysfunction.¹⁴ Controversy over sevoflurane-induced nephrotoxicity appears to be waning and is discussed in [Chapter 15](#). Anesthetic-induced reductions in RBF have been described for many agents but are clinically insignificant and reversible.^{15,16} Likewise, anesthetic agents have not been shown to interfere with renal neurohumoral responses to physiologic stress.

Although direct anesthetic effects on the kidney are usually not harmful, indirect effects of anesthesia may combine with hypovolemia, shock, nephrotoxin exposure, or other renal vasoconstrictive states to produce renal dysfunction. If the chosen anesthetic technique causes a protracted reduction in cardiac output or sustained hypotension that coincides with a period of intense renal vasoconstriction, renal dysfunction or failure could result. This is true for either general or regional anesthesia. There are no comparative studies demonstrating superior renal protection or improved renal outcome with general versus regional anesthesia.

Acute Renal Failure

Acute renal failure is a sudden decrease in renal function resulting in the inability of the kidneys to excrete nitrogenous and other wastes. This is manifest by the accumulation of creatinine and urea in the blood (uremia) and is often accompanied by reduced urine production, although nonoliguric forms of postoperative ARF are common.¹⁷ In surgical patients, (1) acute tubular necrosis (ATN) is the etiology for ARF in most patients; (2) ARF frequently occurs in the setting of critical surgical illness with multiple organ failure (MOF) /dysfunction—it is rarely an isolated event; and (3) the mortality rate is alarmingly high (up to 90%) and may be higher than for medical patients with renal failure.¹⁸

One explanation for the high death rate is that ARF is often part of an MOF–sepsis syndrome.^{19,20} Major trauma, burns, and other critical events predispose surgical patients to sepsis, MOF, and ARF.¹⁹ Nonseptic triggers of MOF have also been identified in seriously ill trauma patients.²¹ The mortality rate in MOF is directly related to the number of organ systems involved.^{22,23} To ascribe these deaths solely to failure of the kidneys overestimates the contribution that ARF makes to the overall syndrome, especially because isolated ARF carries a mortality rate of <10%.²³ A contributing factor to the poor outcome is the fact that extracorporeal renal support appears to have had little success in altering the course of ARF in critically ill surgical patients.^{22,24} Even studies that advocate the use of extra-corporeal technology report mortality rates of between 50% and 70%.^{25,26,27} and [28](#)

Active renal failure can be classified as arising from *prerenal* factors causing renal hypoperfusion, numerous *intrinsic* renal etiologies, or *postrenal* causes (obstructive uropathy). There are many pathophysiologic similarities between the various causes of renal failure that ultimately lead to a common syndrome referred to as organic ARF ([Fig. 36-5](#)).

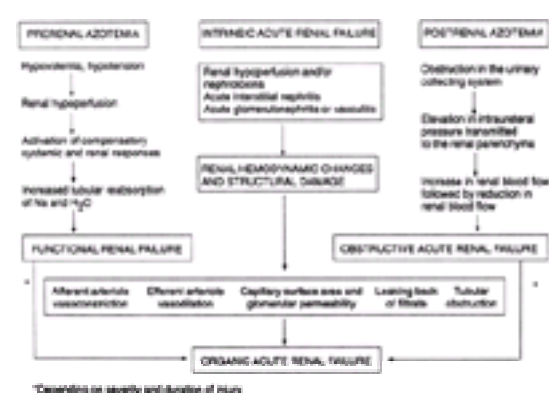

Figure 36-5. Mechanisms of acute renal failure. (Reprinted with permission from Pellanda MV, Fabris A, Ronco C: Etiology and pathophysiology of acute renal failure. In Pinsky MR, Dhainaut JFA [eds]: Pathophysiologic Foundations of Critical Care, p 575. Baltimore, Williams & Wilkins, 1993.)

Prerenal Azotemia and Acute Tubular Necrosis

Prerenal azotemia is defined as the increase in blood urea nitrogen (BUN) associated with renal hypoperfusion or ischemia that has not caused renal parenchymal damage. As such, prerenal azotemia forms a continuum with ATN. As normal renal compensatory mechanisms are maximized to maintain RBF and GFR and conserve salt and water, increasing sympathetic activity and circulating blood levels of angiotensin II and ADH cause the afferent arteriole and mesangium to constrict and the efferent arteriole to paradoxically dilate. Global RBF decreases and the renal medulla is subjected to profound hypoxia. The metabolically active cells of the mTAL of Henle are especially vulnerable to hypoxic damage because of their relatively high oxygen consumption-to-delivery ratio.² The necrosis of tubular cells releases debris into the tubules, causing obstruction to flow, increased tubular pressure, and back leak of tubular fluid ([Fig. 36-5](#)). Often prerenal failure is precipitated in patients with pre-existing renal vasoconstriction (e.g., volume depletion, congestive heart failure, sepsis), by nephrotoxin exposure, or a reduction in cardiac output.²⁹

Intrinsic Acute Renal Failure

The term “intrinsic” implies a primary renal etiology of ARF but also includes ischemia and toxins as well as renal parenchymal diseases. ATN remains the most common ischemic lesion and represents an extension of prerenal azotemia, whereas cortical necrosis may follow a massive renovascular insult such as prolonged suprarenal aortic cross-clamping or renal artery embolism. Nephrotoxins often act in concert with hypoperfusion or underlying renal vasoconstrictive states to damage renal tubules or microvasculature. Several common nephrotoxins, some of which are difficult to avoid in a hospitalized patient population, are listed in [Table 36-1](#). Renal parenchymal diseases may affect either the glomerulus or the interstitium and are frequently immune mediated or part of a more systemic disorder that targets the kidney.

| Exogenous | Endogenous |
|---|--|
| Antibiotics Aminoglycosides, cephalosporins, amphotericin B, sulfonamide, tetracyclines, vancomycin | Calcium (hypercalcemia) Uric acid (hyperuricemia and hyperuricosuria) Myoglobin (rhabdomyolysis) |
| Anesthetic agents Methoxyflurane, enflurane | Hemoglobin (hemolysis) Bilirubin (obstructive jaundice) |
| Nonsteroidal anti-inflammatory drugs (NSAIDs) Aspirin, ibuprofen, naproxen, indomethacin, ketorolac | Oxalate crystals Porphyrins |
| Chemotherapeutic-immunosuppressive agents Cisplatin, cyclosporin A, methotrexate, mitomycin, nitrosoureas, taxolimus | |
| Contrast media | |

Table 36-1. NEPHROTOXINS COMMONLY FOUND IN THE HOSPITAL SETTING

Postrenal Azotemia: Obstructive Uropathy

Downstream obstruction of the urinary collecting system is the least common pathway to organic ARF, accounting for <5% of cases.²⁹ The obstructing lesion may occur at any level of the collecting system, from the renal pelvis to the distal urethra. Intraluminal pressure then rises and is eventually transmitted back to the glomerulus, thereby reducing its filtration pressure. RBF transiently increases but soon falls as angiotensin II and thromboxane A₂ are generated and produce ischemic renal damage and ARF.

Intraoperative Oliguria: Prerenal Azotemia or Acute Tubular Necrosis

Several real-time RBF monitors are being developed for intraoperative and critical care use (see [Perioperative Assessment of Renal Function](#)). However, urine flow rate has traditionally been used as a measure of renal “well-being,” a job for which it is ill suited.³⁰ Nevertheless, oliguria (a urine flow rate of <0.5 ml · kg⁻¹ · h⁻¹) may be a useful sign of renal hypoperfusion when other objective signs of reduced systemic blood flow are present and the overall clinical scenario is appropriate. The presumption should be that intraoperative oliguria is a normal response to the stress of surgery and ongoing blood and fluid losses. If a fluid bolus improves the urine flow rate, or heart rate and blood pressure indicate hypovolemia, further fluid administration is indicated. Isolated hypovolemia can usually be corrected relatively quickly as long as ongoing loss of blood and intravascular fluid is also replaced. If oliguria persists and signs of congestive heart failure or volume overload appear, the patient's hemodynamic profile should be further assessed with a pulmonary artery catheter. The goal of pulmonary artery catheterization in this setting is to optimize cardiac output and systemic oxygen delivery and, in so doing, improve renal perfusion.

When sepsis is responsible for poor urine output, hypotension is a common finding and is usually secondary to systemic vasodilation, hypovolemia, and depressed myocardial contractility. Hypovolemia should be corrected with vigorous fluid resuscitation while combinations of inotropic-vasopressor agents, such as dopamine, norepinephrine, phenylephrine, and dobutamine, are used to increase cardiac output, systemic vascular resistance, and renal perfusion pressure.^{31,32 and 33}

Chronic Renal Failure

Chronic renal failure (CRF) or end-stage renal disease (ESRD) are the terms used to describe a clinical syndrome that is characterized by multiple organ dysfunction that would prove fatal without dialysis. These patients have GFRs <25% of normal. Lesser degrees of renal dysfunction are categorized as renal insufficiency (25–40% of normal GFR) or decreased renal reserve (60–75% of normal GFR). Patients with decreased renal reserve are asymptomatic and frequently do not have abnormally elevated blood levels of creatinine or urea ([Fig. 36-6](#)). Renal insufficiency results in clearly abnormal creatinine and BUN values, but nocturia (due to decreased concentrating ability) may be the patient's only symptom.

Figure 36-6. Relationship of serum creatinine concentration and blood urea nitrogen levels to glomerular filtration rate (GFR). (Reprinted with permission from Valtin H: *Renal Dysfunction: Mechanisms Involved in Fluid and Solute Imbalance*, p. 206, Boston, Little, Brown, 1979.)

The *uremic syndrome* represents the most extreme form of CRF that occurs as the surviving nephron population and GFR decrease below 10% of normal. The uremic syndrome results in the inability of the kidney to perform its two major duties: the regulation of the volume and composition of extracellular fluid and the excretion of waste products. The loss of homeostasis and the accumulation of cellular toxins cause the multiple organ system dysfunction seen in the uremic syndrome³⁴ ([Table 36-2](#)). Patients with the uremic syndrome usually require frequent or continuous dialysis. Dialytic therapy in the perioperative period is discussed in [Chapter 52](#).

Table 36-2. THE UREMIC SYNDROME

Water balance in ESRD becomes difficult to manage because the number of functioning nephrons is too small either to concentrate or fully dilute the urine. This results in the inability to conserve water as well as to excrete excess water. Eventually, as GFR continues to decline, the urine flow rate falls below a threshold that prevents water accumulation, and expansion of the extracellular fluid volume takes place. This has implications for sodium homeostasis, the cardiovascular system, and the respiratory system.

Electrolyte and acid-base disturbances associated with the uremic syndrome are listed in [Table 36-2](#). Hyponatremia occurs, in part, because extracellular fluid expansion triggers natriuresis and results in an obligatory sodium loss that is characteristic of the end-stage kidney. Sodium restriction or overhydration of the patient

with CRF may also precipitate hyponatremia. Potassium homeostasis is maintained in renal failure until the GFR is <10% of normal through increased distal tubule secretion, decreased reabsorption, and enhanced fecal potassium loss. Nevertheless, life-threatening hyperkalemia may occur in CRF because of slower potassium clearance than normal. Situations predisposing patients with renal failure to hyperkalemia are presented in [Table 36-3](#). Derangements in calcium, magnesium, and phosphorus metabolism are also commonly seen in CRF (see [Table 36-2](#)).

Table 36-3. FACTORS CONTRIBUTING TO HYPERKALEMIA IN CHRONIC RENAL FAILURE

Metabolic acidosis occurs in two forms in ESRD: a hyperchloremic, normal-anion-gap acidosis and a high-gap acidosis due to an inability to excrete titratable acids. Both render patients susceptible to an endogenous acid load as may occur in shock states, hypovolemia, or an increase in catabolism.

Cardiovascular complications of the uremic syndrome are primarily due to volume overload, high renin-angiotensin activity, autonomic nervous system hyperactivity, acidosis, and electrolyte disturbances. Hypertension due to extracellular fluid volume expansion, autonomic factors, and hyper-reninemia is an almost universal finding in ESRD. Together with volume overload, acidemia, anemia, and high-flow arteriovenous fistulae created for dialysis access, hypertension contributes to the development of myocardial dysfunction and congestive heart failure. Pericarditis may occur secondary to uremia or dialysis, with pericardial tamponade developing in 20% of the latter group.³⁵ Fatal dysrhythmias may result from acute elevation in serum potassium.³⁶

The pulmonary problems associated with CRF are limited to changes in lung water and the control of ventilation. Pulmonary edema and restrictive pulmonary dysfunction are commonly seen in patients with renal failure and are responsive to dialysis. Hypervolemia, congestive heart failure, reduced serum oncotic pressure, and increased pulmonary capillary permeability are factors in the development of pulmonary edema. Chronic metabolic acidosis may be responsible, in part, for the hyperventilation seen in patients with ESRD, but increased lung water and poor pulmonary compliance also stimulate ventilation.

Gastrointestinal complaints, seen early in CRF, are almost universal in the uremic syndrome and consist of anorexia, nausea, vomiting, and hiccups. Delayed gastric emptying is of importance to the anesthesiologist and may improve with metoclopramide treatment or dialysis.

Uremic neuromuscular complications may take the form of central nervous system dysfunction, peripheral polyneuropathy, or autonomic dysfunction. The encephalopathy of uremia consists of alterations in the level of consciousness, tremors, myoclonus, and seizures. This picture can be mimicked or worsened by the accumulation of renally excreted, pharmacologically active metabolites of certain opioids and sedative-hypnotic drugs (see [Anesthetic Agents in Renal Failure](#), later). Autonomic dysfunction may be manifest by sympathetic hyperactivity or hypoactivity, decreased baroreceptor responsiveness, or dialysis-associated hypotension.

The anemia of CRF is due to reduced levels of erythropoietin, red cell damage, ongoing gastrointestinal blood loss, and iron or vitamin deficiencies. Recombinant human erythropoietin has improved the management of anemia in ESRD.³⁷ Platelet dysfunction may aggravate blood loss but is responsive to dialysis, cryoprecipitate, and desmopressin (DDAVP). Acquired defects in both cellular and humoral immunity probably account for the high rate of serious infections (60%) and the high mortality rate due to sepsis in CRF (30%).

Anesthetic Agents in Renal Failure

Significant renal impairment may affect the disposition, metabolism, and excretion of commonly used anesthetic agents. The inhalational anesthetics are, of course, an exception to the rule that drugs with central nervous system activity (which generally are lipid soluble) must be converted to more hydrophilic compounds by the liver before being excreted by the kidney. Water-soluble metabolites of agents that are not inhaled may accumulate in renal failure and contribute to a prolongation of clinical effects if they possess even a small percentage of the pharmacologic activity of the parent drug. Drugs that are eliminated unchanged by the kidneys (e.g., certain nondepolarizing muscle relaxants, the cholinesterase inhibitors, many antibiotics, and digoxin) may have a prolonged elimination half-life when given to patients with renal failure. Many drugs used in the practice of anesthesia are highly protein bound and may demonstrate exaggerated clinical effects when protein binding is reduced by uremia. Renal failure may also increase the volume of distribution of certain agents, thereby prolonging their elimination half-life. There is a paucity of data concerning the effects of renal failure on anesthetic drug metabolism,^{38,39} and suspected pharmacodynamic changes in patients with renal failure have proved difficult to document for most drugs.⁴⁰ Renal disease has a minimal effect on the pharmacokinetics of the inhaled anesthetics; therefore, the following discussion focuses on anesthetic agents that are not inhaled.

Induction Agents and Sedatives

Thiopental serves as an example of how reduced protein binding in CRF may affect the clinical use of an anesthetic agent. Burch and Stanski⁴¹ have shown that the free fraction of a thiopental induction dose is nearly doubled in patients with renal failure. This accounts for the exaggerated clinical effects of thiopental in these patients and explains the need for a decreased induction dose in uremic patients compared with normal patients.

Ketamine is less extensively protein bound than thiopental, and renal failure appears to have minimal influence on its free fraction. Redistribution and hepatic metabolism are largely responsible for termination of the anesthetic effects, with <3% of the drug excreted unchanged in the urine. Norketamine, the major metabolite, has one third of the pharmacologic activity of the parent drug and is further metabolized before it is excreted by the kidney.⁴² Poor renal function is not known to alter the pharmacokinetics or clinical profile of ketamine.⁴³ However, caution must be used when it is administered to patients with renal failure with hypertension because it may induce a dramatic increase in blood pressure.⁴⁴

Etomidate, although only 75% protein bound in normal patients, has a larger free fraction in ESRD.⁴⁵ The decrease in protein binding does not seem to alter the clinical effects of an etomidate anesthetic induction in patients with renal failure. This may be due to its relative lack of cardiovascular-depressant effects.

Propofol undergoes extensive, rapid hepatic biotransformation to inactive metabolites that are renally excreted. Its pharmacokinetics appear to be unchanged in patients with renal failure,^{46,47} and there are no reports of prolongation of its effects in ESRD. Use of the standard induction dose of propofol and a propofol infusion has been shown to be safe for patients with renal failure.^{47,48}

The benzodiazepines, as a group, are extensively protein bound. CRF increases the free fraction of benzodiazepines in plasma, which may potentiate their clinical effect. Certain benzodiazepine metabolites are pharmacologically active and have the potential to accumulate with repeated administration of the parent drug to anephric patients. For example, 60–80% of midazolam is excreted as its (active) *a*-hydroxy metabolite,⁴⁹ which accumulates during long-term infusions in patients with renal failure.⁵⁰ ARF appears to slow the plasma clearance of midazolam itself,⁵⁰ while repeated diazepam or lorazepam administration in CRF may carry a risk of active metabolite-induced sedation.³⁹ Alprazolam is one of the few drugs related to anesthesia practice that has undergone pharmacodynamic studies in patients with CRF. Schmith *et al*⁵¹ found that when decreased protein binding and increased free fraction of alprazolam are taken into account, patients with CRF are actually more sensitive to its sedative effects than normal people. It would seem that a single dose of benzodiazepine should be well tolerated but that the dose should be reduced because of the possibility of increased free fraction and increased patient sensitivity.

Opioids

Single-dose studies of morphine pharmacokinetics in renal failure do not demonstrate any alteration in its disposition. However, chronic administration results in the accumulation of its 6-glucuronide metabolite, which has potent analgesic and sedative effects.⁵² There is also a decrease in protein binding of morphine in ESRD,

which mandates a reduction in its initial dose. Meperidine is remarkable for its neurotoxic, renally excreted metabolite (normeperidine) and is not recommended for use in patients with poor renal function. Hydromorphone is metabolized to hydromorphone-3-glucuronide, which is excreted by the kidneys. This active metabolite accumulates in patients with renal failure and may cause cognitive dysfunction and myoclonus.⁵³ Oxycodone elimination was found to be prolonged in a single-dose study of patients with CRF.⁵⁴ Repeated dosing of oxycodone should result in prolonged opioid effects. Codeine also has the potential for causing prolonged narcosis in patients with renal failure and cannot be recommended for long-term use.⁵²

Fentanyl appears to be an excellent opioid for use in ESRD because of its lack of active metabolites, unchanged free fraction, and short redistribution phase.³⁹ Small to moderate doses of fentanyl, titrated to effect, are well tolerated by uremic patients. However, a dose of $25 \mu\text{g} \cdot \text{kg}^{-1}$ given to patients undergoing renal transplantation resulted in prolonged opioid effect that correlated with preoperative BUN.⁵⁵ Alfentanil has been shown to have reduced protein binding but no change in its elimination half-life or clearance in ESRD, and is extensively metabolized to inactive compounds.^{56,57} Therefore, caution should be exercised in administering the loading dose of alfentanil, but the total dose and infusion dose should be similar to those for patients with normal renal function. The free fraction of sufentanil is unchanged in ESRD, but its pharmacokinetics are variable and it has been reported to cause prolonged narcosis.⁵⁸ Remifentanil is rapidly metabolized by blood and tissue esterases to a weakly active, renally excreted metabolite, GR90291. Renal failure has no effect on the clearance of remifentanil but GR90291 elimination is markedly reduced.⁵⁹ The long-term administration of remifentanil to anephric patients has not been studied to determine if accumulation of GR90291 has any clinical implications.

Muscle Relaxants

The muscle relaxants are the most likely group of drugs used in anesthetic practice to produce prolonged effects in ESRD because of their reliance on renal excretion (Table 36-4). (See also Chapter 16). Only succinylcholine, atracurium, *cis*-atracurium, and mivacurium appear to have minimal renal excretion of the unchanged parent compound. Most nondepolarizing muscle relaxants must either be hepatically excreted or metabolized to inactive forms to terminate their activity in the absence of renal function. Some muscle relaxants have renally excreted, active metabolites that may contribute to their prolonged duration of action in patients with ESRD. Although the following discussion focuses on the pharmacology of individual muscle relaxants, coexisting acidosis and electrolyte disturbances, as well as drug therapy (e.g., aminoglycosides, diuretics, immunosuppressants, and magnesium-containing antacids), may alter the pharmacodynamics of muscle relaxants in patients with renal failure.⁶⁰

| Drug | % Renal Excretion | Half-life (hr) Normal/ESRD | Renally Excreted Active Metabolite | Use in ESRD |
|-------------------------|-------------------|----------------------------|------------------------------------|--|
| Atracurium | 46 | 14-22 | - | Avoid |
| Metocurium | 46-49 | 4/13.4 | - | Avoid |
| Pancuronium | 38 | 23/44 | + | Avoid |
| Gallamine | >46 | 25/40 | + | Avoid |
| Pipecuronium | 37 | 18-23/64 | + | Avoid |
| Doxacurium | 38 | 17/32 | - | Avoid |
| Vecuronium | 38 | 19/34 | - | Normal single smaller repeat doses avoid prolonged CI |
| Rocuronium | 38 | 12-18/19-17 | - | Normal single repeat doses, increased variability |
| Neostigmine/edrophonium | <1 | 13/16 | - | Normal single repeat, CI doses |
| Mivacurium | <1 | 2 min/2 min | - | Duration 1/3 normal, lower CI dose |
| Rapacuronium | <1 | 15/15 | ++ | Normal single dose, much smaller repeat doses avoid CI |

CI = continuous infusion; ESRD = end-stage renal disease.

Table 36-4. NONDEPOLARIZING MUSCLE RELAXANTS IN RENAL FAILURE^{60,64,65,68,69,70 and 71,78,80,81,82,83 and 84,86,87}

Succinylcholine has a long history of use in CRF that has been somewhat confused by conflicting reports of plasma cholinesterase activity in renal failure.^{61,62,63,64 and 65} Its use can be justified as part of a rapid-sequence intubation because its duration of action in ESRD is not significantly prolonged. The use of a continuous infusion of succinylcholine, however, is more problematic because the major metabolite, succinylmonocholine, is weakly active and excreted by the kidney. Concern over the increase in serum potassium levels after succinylcholine administration ($0.5 \text{ mEq} \cdot \text{l}^{-1}$ in normal subjects) dictates that a recent, normal potassium level be demonstrated in patients with renal failure. Recent dialysis (<24 hours before surgery) also lessens the risk of hyperkalemia in this population.^{66,67}

The older nondepolarizing muscle relaxants (*i.e.*, *c*-tubocurarine, metocurine, pancuronium, and gallamine) all have prolonged elimination half-lives in renal failure (see Table 36-4). A single small dose of these drugs should be well tolerated, but larger doses or repeated small doses may result in the accumulation of the parent drug and prolonged clinical effect. More recently introduced intermediate- and short-acting muscle relaxants are less likely to have a clinically significant prolongation of duration in ESRD.

The use of the long-acting muscle relaxants, doxacurium and pipecuronium, also might be questioned in patients with known renal insufficiency. In a single-dose study of doxacurium, Cook *et al*⁶⁸ demonstrated an increased elimination half-life, reduced plasma clearance, and prolonged duration of effect in patients with renal failure. These data support the observations of Cashman *et al*,⁶⁹ that renal failure nearly doubles the clinical duration of doxacurium. Similar findings have been reported for the pharmacokinetics of pipecuronium. Although the mean duration of action was not different between control subjects and patients with renal failure, the latter group had an unpredictable response to pipecuronium with a wide variability in duration of action of the drug.^{70,71}

The intermediate-acting muscle relaxants (atracurium, *cis*-atracurium, vecuronium, and rocuronium) have a distinct advantage in ESRD precisely because of their shorter duration; the risk of a clinically significant, prolonged block is reduced. Atracurium and its derivative, *cis*-atracurium, undergo enzymatic ester hydrolysis and spontaneous nonenzymatic (Hoffman) degradation with minimal renal excretion of the parent compound. Their elimination half-life, clearance, and duration of action are not affected by renal failure,^{72,73} nor have they been reported to cause prolonged clinical effect in ESRD. These characteristics strongly recommend atracurium and *cis*-atracurium for use in patients with renal disease. One potential concern is that an atracurium metabolite, laudanosine, causes seizures in experimental animals and may accumulate with repeated dosing or continuous infusion.⁷⁴ This concern, however, has not been realized in intensive care patients with renal failure receiving prolonged infusions of atracurium.⁷⁵ Consistent with its greater potency and lower dosing requirements, *cis*-atracurium metabolism results in lower laudanosine blood levels than atracurium in ESRD.⁷⁶

The pharmacokinetics of vecuronium were initially reported as unchanged in renal failure,⁷⁷ but it was later demonstrated that its duration of action was prolonged as a result of reduced plasma clearance and increased elimination half-life.⁷⁸ In addition, the active metabolite, 3-desmethylvecuronium, was shown to accumulate in anephric patients receiving a continuous vecuronium infusion who subsequently had prolonged neuromuscular blockade.⁷⁹ Vecuronium is an acceptable muscle relaxant for patients with ESRD if it is not continuously infused for long periods and if maintenance doses are reduced and the dosing interval is increased. An intubating dose would be expected to last ~50% longer in patients with ESRD.⁷⁸

Rocuronium, a rapid-onset muscle relaxant, has a pharmacokinetic profile in normal subjects that is similar to that of vecuronium.⁸⁰ Single-dose pharmacokinetic studies in patients with renal failure have reported conflicting findings. Szenhradszky *et al*⁸¹ reported that renal failure increased the volume of distribution and elimination half-life of rocuronium, but had no effect on its clearance. Cooper *et al*⁸² found that clearance was reduced and the duration of block widely variable in patients with renal failure, although the mean duration of clinical relaxation and spontaneous recovery was not statistically different from that in controls subject. Wide variation in the duration of neuromuscular block has been reported by others, who also found that repeated maintenance doses of rocuronium were well tolerated in patients with ESRD.⁸³

The short-acting muscle relaxant mivacurium is enzymatically eliminated by plasma pseudocholinesterase at a somewhat slower rate than succinylcholine. Low pseudocholinesterase activity correlates with slower recovery from a bolus dose of mivacurium in anephric patients.^{64,65,84} The maintenance infusion dose has been reported to be both lower⁶⁵ and similar⁸⁴ to that in normal control subjects. A single case report of neuromuscular blockade lasting 3 hours after an intubating dose of mivacurium implies that ESRD may significantly alter the clinical response to this drug.⁸⁵

Rapacuronium is a rapid-onset, short-to-intermediate-acting muscle relaxant, that undergoes nonspecific hydrolysis to a very potent, renally excreted 3-hydroxy metabolite, Org9488.⁸⁶ The clearance of Org9488 is 85% slower in anephric patients compared with normal subjects.⁸⁷ Repeated dosing or continuous infusion of rapacuronium in this population should result in prolonged clinical effects.

The pharmacokinetics of the clinically available anticholinesterases (*i.e.*, neostigmine, pyridostigmine, and edrophonium) are significantly affected by renal failure.^{88,89 and 90} All three have a prolonged duration of action in ESRD due to their heavy reliance on renal excretion. The anticholinergic agents, atropine and glycopyrrrolate, which are used in conjunction with the anticholinesterases, are similarly excreted by the kidney.⁹¹ Therefore, no dosage alteration of the anticholinesterases is required

when antagonizing neuromuscular blockade in patients with reduced renal function.

PRESERVATION OF RENAL FUNCTION

Prevention of renal failure in the surgical patient is preferable to treatment of established ARF based on the previous discussion of poor outcome of these patients. To prevent ARF, the clinician must first identify those patients who are particularly at risk for perioperative renal damage and then focus on preserving renal function in that group. Patients may be at risk for postoperative renal failure because of an underlying condition or pre-existing renal insufficiency. Several well known nephrotoxins may contribute to renal damage in hospitalized patients and must be identified so that their use can be avoided or limited in high-risk patients. Finally, certain surgical procedures are known to increase the chances of development of postoperative ARF. All three factors (patient status, nephrotoxin exposure, and surgical procedure) can be recognized before surgery, affording the anesthesiologist an opportunity to devise an anesthetic plan emphasizing renal preservation. Risk factors for postoperative ARF are listed in [Table 36-5](#).

| PATIENT-BASED INDICATORS |
|--|
| Preoperative renal dysfunction |
| Perioperative cardiac dysfunction |
| Sepsis |
| Hepatic failure, obstructive jaundice, ascites |
| Hypovolemia |
| Advanced age? |
| NEPHROTOXIN EXPOSURE (SEE TABLE 36-1) |
| HIGH-RISK SURGICAL PROCEDURES |
| Cardiac: cardiopulmonary bypass |
| Aortic cross-clamping |
| Trauma/burn (? emergency) |
| Hepatic transplantation |
| Renal transplantation |

Table 36-5. RISK FACTORS FOR POSTOPERATIVE RENAL FAILURE

Patient-Based Risk Factors for Acute Renal Failure

Large, prospective studies of preoperative patient-based risk factors for ARF are lacking. Most often, retrospective reviews of ARF in surgical patients have revealed conflicting data that may be pertinent to a select patient population but cannot be generalized to a larger group of patients. Novis *et al*⁹² published a review of the available prospective and retrospective studies examining patient-based risk factors for postoperative renal failure. Their report serves as the basis for the following discussion on preoperative risk factors, which can be easily identified with history, physical examination, and appropriate laboratory screening tests.

The single most reliable predictor of postoperative renal dysfunction is preoperative renal dysfunction.⁹² Elevated BUN or creatinine levels, a history of renal dysfunction, or other evidence of pre-existing renal problems successfully predict postoperative ARF. It is likely that pre-existing renal disease predisposes patients to further renal insult, but it may also make further loss of function easier to recognize.⁹² The presumption, of course, is that it is essential to preserve what renal function the patient has. The alternative (frank renal failure) is potentially catastrophic. Identifying patients with pre-existing renal dysfunction requires appropriate screening of BUN and creatinine in those who have other renal risk factors (history of renal problems, cardiac disease, sepsis) or are facing high-risk surgical procedures.

Preoperative cardiac dysfunction is another important predictor of postoperative ARF.⁹² Shusterman *et al*⁹³ identified congestive heart failure as a risk factor in a mixed, surgical-medical population.⁹³ Specifically, evidence of left ventricular dysfunction or elevated pulmonary capillary wedge pressure (PCWP) has predictive value in identifying patients at risk for ARF. This is intuitively obvious when one considers that poor cardiac output reduces RBF and increases the potential for renal vasoconstriction and ischemic injury. Patients with a history and physical examination consistent with congestive heart failure should have a screening echocardiogram and chest radiograph. When the diagnosis of left ventricular dysfunction is confirmed, medical management should be optimized before surgery whenever possible. Intraoperative monitoring with a pulmonary artery catheter may be helpful in managing fluid administration, oliguria, respiratory dysfunction, or further deterioration in cardiac performance.

Sepsis poses a major threat to renal function in surgical patients.^{19,20,93,94} The pathophysiology of ARF in sepsis involves systemic hemodynamic derangements,⁹⁵ inflammatory mediator-induced renal vasoconstriction,⁹⁶ and, frequently, nephrotoxin exposure in the form of aminoglycoside antibiotics.⁹⁷ The sepsis syndrome, once recognized, is managed by eradication of the septic focus with antibiotics and surgical excision (where feasible), fluid and blood component therapy, and manipulation of cardiovascular performance with vasopressors.

Volume depletion has been reported to be an ARF risk factor in both medical and surgical patients.⁹³ As with heart failure and sepsis, hypovolemia may induce renal vasoconstriction and render the kidney vulnerable to nephrotoxin exposure or a further reduction in oxygen delivery. Patients with diabetes mellitus (and microangiopathy) are particularly prone to development of ARF when they become volume depleted.⁹³

Cholestatic jaundice has long been suspected to be a risk factor for postoperative ARF.^{98,99} Patients with severe cirrhosis and ascites or hepatic failure are clearly predisposed to renal dysfunction as a result of portal vein sepsis. In up to 75% of patients with hepatic failure, associated renal dysfunction-failure (hepatorenal syndrome) develops.¹⁰⁰

In patients presenting for liver transplantation surgery, 25% have some degree of renal dysfunction, and post-transplantation this percentage rises to almost 70%.¹⁰¹ Preoperative serum creatinine levels can predict short-term survival of liver transplant recipients.¹⁰²

Numerous investigators cite advanced age as a risk factor for postoperative ARF.⁹² Elderly patients are frequently found to have reduced GFR, RBF, and renal reserve, making them less able to withstand a renal insult.¹⁰³ The aged also have a high incidence of cardiovascular disease and flow-limiting renal arterial atherosclerosis, which may account for their apparent increased risk of ARF. One study has convincingly demonstrated that advanced age increases the risk of ARF due to aminoglycoside toxicity.⁹³ However, age as an isolated risk factor has not been shown to predict postoperative ARF.⁹²

Other risk factors for postoperative ARF were reviewed by Novis *et al*⁹² but could not be conclusively shown to be of significance. These included aortic aneurysm, acute bacterial endocarditis, decreased serum albumin, malignancy, emergency surgery, and previous cardiac surgery.

Perioperative Assessment of Renal Function

Preoperative renal function appears to be the most reliable predictor of postoperative renal failure.⁹² Although an accurate preoperative assessment of renal function is important in identifying the high-risk patient, it would be advantageous to be able to differentiate prerenal azotemia from early ATN and predict impending ARF. Kellen *et al*³⁰ examined the ability of commonly used measures of renal function to predict and diagnose early ARF in the critically ill patient. The findings of their meta-analysis of the specificity, sensitivity, and positive predictive value of renal function tests are summarized in [Table 36-6](#).

| Renal Function Test | Distinguish ATN vs. PRA | Predict Early ATN | Comments |
|--------------------------------------|-------------------------|-------------------|---------------------------|
| Urine flow rate | Poor | Poor | |
| Urine specific gravity | Poor | Poor | Many normal factors |
| Urine osmolality | Poor | Poor | Many normal factors |
| Serum creatinine, BUN | Poor | Late findings | Rapid preoperative screen |
| Urine/plasma creatinine, BUN | Poor | Poor | |
| Urine Na ⁺ | Poor | Poor | |
| Fractional excretion Na ⁺ | Good in late ATN | Poor | |
| Free water clearance | - | Good with Cr | Less sensitive than Cr |
| Cr | Good | Good | 24-h collection |

ATN = acute tubular necrosis; PRA = prerenal azotemia; BUN = blood urea nitrogen; Cr = creatinine clearance.

Table 36-6. CLINICAL USEFULNESS OF RENAL FUNCTION TESTS

Kellen *et al*³⁰ found that most of the standard renal function tests were unable to predict impending ATN and that many could not reliably differentiate between prerenal azotemia and early ATN. Urine flow rate, specific gravity, and osmolality are poor indicators of renal dysfunction because they are influenced by many nonrenal variables. Serum creatinine and BUN are good screening tools for preoperative renal dysfunction, but they are late warning signals of reduced GFR. A sizable loss of GFR may occur before serum creatinine and BUN values become abnormal (see Fig. 36-6). Unfortunately, creatinine and BUN are influenced by nonrenal variables such as catabolic rate and muscle mass, making isolated serum determinations unreliable in a rapidly changing scenario of critical illness. This is also true for tests based on creatinine and urea levels such as urine-to-plasma ratios of these compounds. Urine sodium excretion should increase when tubular injury results in a loss of reabsorptive ability, but isolated urine sodium (urine Na⁺) values more accurately reflect the composition of resuscitative fluids than tubular function in the acute setting. The fractional excretion of sodium (percentage of filtered sodium that is excreted) can reliably distinguish prerenal azotemia from established ATN, but Kellen *et al*³⁰ found it unable to serve as an early indicator or predictor of ARF.³⁰ Free water clearance (CH₂O) measures the diluting-concentrating ability of the kidney and should reflect tubular integrity. As a predictor of impending ARF, however, CH₂O cannot be used by itself and should be combined with a creatinine clearance (Ccr) determination.¹⁰⁴ It would appear that the Ccr, as a sole indicator of imminent ARF, is the best test available to the clinician.³⁰

The Ccr is a direct reflection of the GFR and may be either measured or calculated. The measured determination requires that urine and plasma creatinine (cr) levels be obtained and that the urine volume for 24 hours be collected and measured, such that:

$$\text{Ccr} = \frac{\text{Urine cr} \times \text{Urine volume}}{\text{Plasma cr}}$$

Traditionally, the need for a 24-hour urine collection has limited the usefulness of Ccr in the acute situation. However, a 2-hour Ccr correlates reasonably well with the standard 24-hour collection in critically ill surgical patients¹⁰⁵ and in nonoliguric intensive care patients.¹⁰⁶ Shin *et al*¹⁰⁴ used 1-hour Ccr determinations to predict the onset of renal dysfunction-failure in postoperative trauma patients. Despite normal blood pressure and urine flow rates in all patients studied, those with Ccr <25 ml · min⁻¹ within the first 6 postoperative hours went on to have renal dysfunction or frank ARF.¹⁰⁴ A major advantage of the abbreviated Ccr determination is that it facilitates sequential monitoring of renal function during periods of rapidly changing patient status. Therapeutic interventions directed at improving renal function may be quickly assessed in this way.

Measured Ccr remains the most reliable predictor of renal dysfunction in critically ill surgical patients regardless of the urine collection duration. The ideal renal function monitor would provide real-time data using noninvasive, easily transportable, and interpretable technology. Real-time monitoring of renal function is under development using ultrasonography^{107,108} and nuclear medicine^{109,110} and ¹¹¹ technology.

Nephrotoxins and Perioperative Acute Renal Failure

Nephrotoxin exposure is a common occurrence in hospitalized patients and frequently plays a role in the etiology of ARF in this population. Nephrotoxins may take the form of drugs, nontherapeutic chemicals, heavy metals, poisons, and endogenous compounds. A partial list is found in Table 36-1. The nephrotoxins most likely to contribute to renal dysfunction-failure in the perioperative period are certain antimicrobial and chemotherapeutic-immunosuppressive agents, radiocontrast media, nonsteroidal anti-inflammatory drugs (NSAIDs), and the endogenous heme pigments myoglobin and hemoglobin. These diverse groups of renal toxins share a common pathophysiologic characteristic: they disturb either renal oxygen delivery or oxygen utilization and thereby promote renal ischemia.

Antimicrobial and chemotherapeutic-immunosuppressive agents are effective for their designed purpose because they are cellular toxins. When these drugs are filtered, reabsorbed, secreted, and eventually excreted by the kidney, the potential for achieving toxic concentrations in renal cells can be realized.¹¹² The aminoglycoside antibiotics (neomycin, gentamicin, tobramycin, amikacin) and amphotericin B are particularly difficult to avoid because they are effective antimicrobials, with few available alternatives.¹¹³ Cyclosporin A and tacrolimus are similarly indispensable agents but, in combination with other nephrotoxins and clinical factors, cause both acute and chronic renal injury in transplant recipients.¹¹⁴

Radiocontrast media pose a threat to the renal function of patients with diabetic nephropathy, pre-existing renal vasoconstriction (congestive heart failure, hypovolemia), or renal insufficiency.¹¹⁵ Measures that can prevent ARF or lessen the severity of renal damage include prehydration, smaller contrast doses, and withholding other nephrotoxins, such as NSAIDs. Consideration should also be given to using an imaging technique that does not require contrast media. Future strategies to prevent radiocontrast-induced renal ischemia may include pretreatment with renal vasodilators such as fenoldopam, nifedipine, or ANP.

The NSAIDs produce reversible inhibition of prostaglandin synthesis and are well known nephrotoxins.¹¹⁶ Except in cases of massive overdose, the NSAIDs produce renal dysfunction only in patients with coexisting renal hypoperfusion or vasoconstriction. Advanced age, hypovolemia, end-stage hepatic disease, congestive heart failure, sepsis, renal insufficiency, and major surgery are risk factors for the development of NSAID-induced ARF.¹¹³ Of particular interest to anesthesiologists is *ketorolac*, a parenterally administered NSAID. Ketorolac may predispose the critically ill and elderly patient to ischemic ARF and acute, life-threatening hyperkalemia when given in the perioperative period.¹¹³ Oliguric ARF has been observed after a single dose of ketorolac.¹¹⁷ All NSAIDs must be used with caution in high-risk patients, and should be withheld before surgical procedures that carry a significant risk of renal dysfunction.

Myoglobin and hemoglobin are both capable of causing ARF in the context of critical surgical illness. Myoglobin seems to be a more potent nephrotoxin than hemoglobin because it is more readily filtered at the glomerulus and can be reabsorbed by the renal tubules, where it inhibits nitric oxide and induces medullary vasoconstriction and ischemia.^{2,118} Hypovolemia and acidemia potentiate the toxicity of both pigments. Reduced intravascular volume causes a decrease in RBF and GFR, which results in a smaller volume of tubular fluid with a relatively higher concentration of pigment. Myoglobin and hemoglobin dissociate more easily to ferriheme (a potent nephrotoxin) in acidic tubular fluid. There is also evidence to suggest that pigment precipitation inside the tubular lumen is enhanced under acidotic conditions and that tubular obstruction plays a role in the pathogenesis of ARF.^{118,119}

Myoglobinuric renal failure occurs in the clinical scenario of massive rhabdomyolysis that may follow from a number of insults. The most common causes of massive rhabdomyolysis in surgical patients are major crush, thermal, or electrical injuries, acute muscle ischemia due to arterial occlusion or compartment syndrome, malignant hyperpyrexia, the extreme lithotomy position, and hyperlordotic position.^{119,120,121,122} and ¹²³ Potassium, phosphorus, and creatinine are released in large quantities from the necrotic muscle. The clinical picture of myoglobinuric ARF is one of oligo-anuria, rapidly rising creatinine, and life-threatening hyperkalemia. Unfortunately, the diagnosis of rhabdomyolysis is not straightforward and a high index of suspicion is necessary to identify patients at risk for ARF. A creatine phosphokinase level >15,000 units · l⁻¹ is predictive of hyperkalemic ARF and a high risk of death.¹²⁴ A creatine phosphokinase level should be obtained and preventive treatment initiated in patients with suspected rhabdomyolysis.

Hemoglobinuric ARF is usually the result of massive hemolysis in association with renal hypoperfusion as is seen during exposure to extracorporeal circulation or cardiopulmonary bypass (CPB). Major transfusion reactions that occur in hypovolemic, acidemic, septic, or hemodynamically unstable patients may lead to renal injury, but rarely does isolated hemoglobinemia cause renal failure.¹¹⁹

Preventive treatment of pigmenturia-induced ARF is directed at increasing RBF and tubular (urine) flow while correcting any existing acidosis. These goals are accomplished by expanding the intravascular fluid volume with crystalloid infusion, stimulating an osmotic diuresis with mannitol, and increasing urine pH with alkali therapy.¹²⁵ Adequate systemic resuscitation from shock cannot be overemphasized as a prerequisite for prevention of ARF, especially in massive crush injuries and electrical burns. Forced mannitol-alkali diuresis is indicated as the second step in preventive treatment of myoglobinuric renal failure, with urine flow rates of up to 300 ml · hr⁻¹ and urine pH 6.5 advocated for patients with massive crush injuries.¹²⁵ This treatment regimen is effective for moderate hyperkalemia, but life-threatening potassium levels may require urgent dialysis. Occasionally, acetazolamide therapy may be used to counteract excessive systemic alkalosis and promote a further increase in urine pH.¹²⁵

High-Risk Surgical Procedures

Several common surgical procedures can place renal function at risk. These include surgery of the heart and aorta, trauma surgery, and hepatic transplantation. Renal transplantation poses other special problems for renal preservation and is discussed in more detail in Chapter 52.

Emergency surgery has been reported as a possible risk factor for ARF, with trauma surgery figuring as a prominent subgroup of emergency procedures.⁹² ATN is the pre-eminent renal lesion associated with trauma and may be produced by any number of ischemic mechanisms. Most often, hypovolemic shock, pigmenturia, MOF, or exogenous nephrotoxins are responsible for sequential or simultaneous insults to the kidney.¹²⁶ ARF that develops in the trauma patient may be characterized by either an early, oliguric picture related to inadequate volume resuscitation or a later, often nonoliguric, syndrome associated with MOF, nephrotoxin exposure, or sepsis.¹²⁷ The outcomes of these two post-traumatic ARF scenarios are dramatically different. The early form is associated with up to 90% mortality rate, whereas only 20–30% of patients die with nonoliguric ARF.⁹⁴ Not surprisingly, trauma victims with pre-existing renal insufficiency have a higher mortality rate than previously healthy patients.¹²⁸

Prevention of ARF in the patient presenting for emergency surgery begins with proper management of intravascular volume depletion and shock. The restoration of euolemia and maintenance of cardiac output, systemic oxygen delivery, and RBF obviate renal vasoconstriction. Urine flow, once established, is maintained at $\approx 0.5 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$. Invasive hemodynamic monitoring may be required to guide the intraoperative management of ongoing cardiovascular instability due to surgical manipulation, blood loss, fluid shifts, and anesthetic effects. Nephrotoxin exposure should be kept to a minimum in the unstable trauma victim. Radiocontrast media, NSAIDs, and myoglobin pose the greatest threat in this patient group. There is no place for either furosemide or mannitol therapy in the early, resuscitative phase of trauma management except in the case of head injury with elevated intracranial pressure or when massive rhabdomyolysis is suspected. After surgery, 1 or 2-hour Ccr determinations can help identify those patients with impending ARF.¹⁰⁴ It is not yet clear whether renal function in these patients can be normalized with renal vasodilators, diuretics, supraphysiologic oxygen delivery, or other maneuvers.

Vascular surgery requiring cross-clamping of the aorta has deleterious effects on renal function regardless of the level of cross-clamp placement. Suprarenal cross-clamping results in an attenuated ATN-like lesion.¹²⁹ Infrarenal cross-clamping causes a smaller, short-lived reduction in GFR and is associated with a lower risk of ARF, whereas surgery involving the thoracic aorta has an incidence of renal failure of 25%.¹³⁰ It is hoped that the use of endoluminal aortic stents, which do not require aortic cross-clamping, will reduce the incidence of ischemic renal injury.^{131,132} Two major predictors of ARF following aortic surgery appear to be pre-existing renal dysfunction and perioperative hemodynamic instability.¹³³ Olsen *et al*²⁴ reported that in a large series of patients undergoing abdominal aortic aneurysm repair, the overall incidence of ARF was 12%.²⁴ Those patients who had emergency surgery for ruptured aneurysm had a very high incidence of hemodynamic instability and ARF developed in 26%, whereas elective aortic surgery was associated with good hemodynamic control and a 4% incidence of renal failure.²⁴ Atheromatous renal artery emboli and prolonged cross-clamp time may contribute to the ischemic renal injury.

Efforts to improve renal outcome in aortic surgery should begin in the preoperative period by identifying patients with renal dysfunction. Ideally, these high-risk patients should not receive radiocontrast media or other nephrotoxins in the immediate preoperative period. The surgeon and anesthesiologist must also work together to provide as much hemodynamic stability as possible throughout the perioperative period.¹³⁴ Consideration should be given to using acute normovolemic hemodilution during infrarenal cross-clamping to improve systemic blood flow and RBF, thereby preserving renal function.¹³⁵

Most efforts to preserve renal function in aortic surgery have centered on the use of diuretic and renal vasodilator therapy. Unfortunately, there are few data to support the use of either mannitol or low-dose dopamine to prevent the renal injury associated with aortic surgery. Indeed, a clinical infrarenal cross-clamp study found that combined mannitol and low-dose dopamine treatment was no more effective in preventing renal dysfunction than volume expansion with saline.¹³⁶ Pass *et al*¹³⁷ could demonstrate no benefit of mannitol, low-dose dopamine, or a combination of the two in a canine suprarenal cross-clamp model. Baldwin *et al*¹³⁸ compared low-dose dopamine with crystalloid volume loading and strict maintenance of euolemia in patients undergoing infrarenal cross-clamping and found no difference in postoperative renal function between the two groups. Although other investigators have demonstrated an increase in urine flow rate with low-dose dopamine in sick postoperative patients,¹³⁹ evidence that low-dose dopamine preserves renal function during aortic surgery is lacking. Nifedipine prevented a postoperative decrease in GFR in a small, placebo-controlled study in aortic surgery patients.¹⁴⁰ Larger outcome trials are needed to confirm this preliminary finding. Insulin-like growth factor-1 has been shown to speed healing in experimental ischemic ARF¹⁴¹ and to improve renal function in patients with ESRD¹⁴² and those undergoing aortic or renal artery surgery.¹⁴³ A synthetic form of ANP may be useful in the management of established oliguric ARF,¹⁴⁴ but it has not been used prophylactically in high-risk surgical patients. Fenoldopam, a selective dopamine-1 receptor agonist, shows great promise as a renal protective agent and should be the subject of future perioperative studies.¹⁴⁵

Cardiac surgery requiring CPB can be expected to result in renal dysfunction or failure in up to 7% of patients.^{146,147,148,149} and ¹⁵⁰ Preoperative renal dysfunction is a major risk factor for postoperative ARF in this population,^{146,149,150} and ¹⁵¹ yet patients with preoperative CRF appear to tolerate surgery and CPB well.¹⁴⁷ Renal hypoperfusion is considered the primary pathogenic mechanism involved in precipitating ARF. Preoperative left ventricular dysfunction^{149,150,152} and the duration of CPB^{146,149,150} are associated with post-CPB renal failure. The type of CPB (pulsatile versus nonpulsatile) and bypass pressure are less important factors in the pathogenesis of ARF than is protracted hemodynamic instability due to poor overall cardiovascular performance.^{147,148,149} and ^{150,152,153}

Careful perioperative hemodynamic management is the basis of any strategy designed to promote renal perfusion in cardiac surgery. Early experience with non-CPB, “off pump”, coronary revascularization suggests that it offers better renal preservation than the traditional, on-pump technique.¹⁵⁴ When CPB is used, mannitol can be used to protect against hemoglobin-induced ARF, promote urine flow, and reduce renal cell swelling.¹⁵⁵ Dopamine has been used as a renal vasodilator in cardiac surgery with mixed success. Costa *et al*¹⁵⁶ administered low-dose dopamine during CPB to patients with preoperative renal dysfunction and were able to induce a saluresis without affecting GFR or protecting the kidney from ischemic injury. When perioperative low-dose dopamine was used in patients undergoing elective coronary artery bypass surgery, it had no beneficial effect on urine output, Ccr, free water clearance, or the incidence of renal dysfunction compared with placebo.¹⁵⁷ Other investigators have warned that low-dose dopamine can increase dysrhythmias in postoperative cardiac surgery patients.¹⁵⁸ Dopexamine has been shown to improve Ccr and systemic oxygen delivery in cardiac surgery patients,¹⁵⁹ but studies examining the renal protective effects of fenoldopam, ANP, and insulin-like growth factor-1 in this population are not yet available.

As previously discussed, patients with hepatic failure or cholestatic jaundice are particularly susceptible to renal dysfunction. This probably accounts for the high likelihood of ARF after liver transplantation and biliary surgery.^{98,99,160,161} Renal dysfunction-failure may occur in up to two thirds of liver transplant recipients.¹⁰¹ Many transplantation candidates have overt hepatorenal syndrome, asymptomatic renal dysfunction, or underlying renal vasoconstriction. When such patients are exposed to intraoperative hemodynamic instability, massive transfusion, and nephrotoxins, ARF frequently follows.^{160,161} Both preoperative and postoperative renal dysfunction contribute to early and long-term mortality.^{102,160,162,163} Maintenance of adequate intravascular volume and aggressive management of hypoperfusion are basic tenets of anesthetic care of the liver transplant recipient, but investigators have sought a role for low-dose dopamine as well. In a retrospective study of liver transplant recipients who also received mannitol, low-dose dopamine administration during the perioperative period was thought to increase urine flow and Ccr and prevent postoperative renal dysfunction.¹⁶⁴ Swygert *et al*¹⁶⁵ attempted to confirm this observation with a randomized, prospective, double-blind study using low-dose dopamine in liver transplant recipients with normal preoperative renal function.¹⁶⁵ In this study, low-dose dopamine did not increase urine production or GFR compared with placebo, and the incidence of ARF was similar in both groups. Low-dose dopamine has been shown to be no better than preoperative hydration at preserving renal function in patients with obstructive jaundice.¹⁶⁶

ANESTHESIA FOR ENDOUROLOGIC PROCEDURES

Since 1980, medical care has evolved toward nonoperative or minimally invasive surgical procedures. Incisional surgery in urology is being replaced by endoscopic procedures in which endoscopes are passed along natural pathways (*e.g.*, urethra, ureter) or through minimal incisions.¹⁶⁷ Economic considerations, patient convenience, and advances in instrumentation have all supported the trend toward endoscopy in urologic surgery. (Table 36-7)

Cystourethroscopy
 Internal optical urethrotomy
 Ureteroscopy
 Placement of ureteral stent
 Distal stone manipulation/laser lithotripsy
 Transurethral resection of prostate
 Transurethral incision of the prostate
 Balloon dilation of the prostate
 Transurethral resection of bladder tumors
 Extracorporeal shock wave lithotripsy
 Percutaneous nephrostomy, nephroscopy, and nephroolithotomy

Table 36-7. COMMON ENDOUROLOGIC PROCEDURES

Cystourethroscopy and Ureteral Procedures

Cystourethroscopy is commonly used to examine and treat lower urinary tract disease. This procedure provides direct visualization of the anterior and posterior urethra, bladder neck, and bladder. In the past, cystourethroscopy was performed with rigid endoscopes, and general or regional anesthesia was required for patient comfort. In 1973, the flexible endoscope was introduced, which can be gently passed over anatomic angles with less patient discomfort.¹⁶⁸ For brief cystoscopic procedures, 5–10 ml of lubricant anesthetic jelly (2% lidocaine hydrochloride jelly) can be instilled into the urethra prior to the procedure.¹⁶⁹ This local anesthetic technique provides adequate anesthesia for many patients undergoing simple cystoscopy. For longer or more extensive procedures, conscious sedation techniques utilizing a wide variety of sedative-hypnotic, anxiolytic, and analgesic drugs have been shown to combine excellent patient comfort and operating conditions with rapid patient recovery.^{170,171} If general anesthesia is required for cystoscopy or urethral procedures, laryngeal mask airways are an attractive alternative to the traditional face mask.¹⁷²

Numerous therapeutic procedures may also be performed using endoscopic techniques. Strictures of the bladder neck or urethra are treated with internal optical urethrotomy, which uses a “cold knife” to excise the scar. Ureteroscopy is an extension of cystoscopic techniques and provides access to the upper urinary tract and kidney for diagnostic endoscopy and biopsy, removal of ureteral and renal calculi, passage of a ureteral stent, dilation and incision of strictures, fulguration of tumors, and laser treatments.^{167,173,174} Ureteroscopy usually requires dilation of the ureteral orifice and intramural ureter, often necessitating regional or general anesthesia.

Transurethral Resection of the Prostate

Benign prostatic hyperplasia (BPH), the most common benign tumor in men, refers to the regional nodular growth that occurs in the prostate gland of men as they age.¹⁷⁵ The prostate is a pear-shaped gland that surrounds the urethra at the base of the bladder (Fig. 36-7). Because of the anatomic position of the prostate gland, hypertrophy of this organ compresses the proximal urethra. Thus, BPH is responsible for the majority of the urinary symptoms in men over the age of 50 years of age and results in the need for prostatectomy in approximately one third of all men who live to 80 years of age.¹⁷⁶

Figure 36-7. Anatomy of the normal and hypertrophic prostate gland. (Reprinted from Stoelting RK, Barash PG, Gallagher TJ: *Advances in Anesthesia*, p. 379, Chicago, Year Book Medical Publishers, 1986.)

Transurethral resection of the prostate (TURP) is the primary treatment for symptomatic BPH. This procedure commences with an initial cystoscopy to rule out concomitant disease and to evaluate the size of the prostate gland.¹⁷⁷ The resectoscope, a specialized instrument with an electrode capable of both coagulating and cutting tissue, is then introduced through a modified cystoscope into the bladder, and the tissue protruding into the prostatic urethra is resected. Continuous irrigation of the bladder and the prostatic urethra is required to maintain visibility, distend the operative site, and remove dissected tissue and blood.¹⁷⁸

The prostate gland contains a rich plexus of veins that can be opened during the surgical resection (see Fig. 36-7). If the pressure of the irrigating fluid during TURP procedures exceeds venous pressure, intravascular absorption of the fluid may occur via these open venous sinuses. The need for large volumes of irrigating fluid during the procedure and the potential for absorption of this fluid into the intravascular space may result in unique perioperative complications.

Irrigating Solutions for TURP

The ideal irrigating fluid for use during TURP would be isotonic and nonhemolytic if it were absorbed. In addition, it would be nonelectrolytic to disperse the electrical current, transparent to allow clear visibility for the operating surgeon, nonmetabolized, nontoxic, rapidly excreted, and inexpensive.¹⁷⁹ A variety of irrigating solutions are available for transurethral procedures (Table 36-8), but most of these solutions are hypo-osmolar (normal serum osmolality is 280–300 mOsm · l⁻¹) and acidic (pH of 4.5–6.5).¹⁸⁰

| Solution | Osmolality (mOsm · l ⁻¹) | Advantages | Disadvantages |
|-----------------|--------------------------------------|--|---|
| Distilled water | 0 | Improved visibility | Hemolysis Hemoglobinemia Hemoglobinuria Hypotension Hypovolemia |
| Glycine (0.7%) | 20 | Low likelihood of transurethral resection syndrome | Turbid postoperative visual impairment Hypernatremia Hypernatremia |
| Sorbitol (0.7%) | 16 | Safe in glycine | Hypernatremia, possible lactic acidosis Osmotic diuresis |
| Mannitol (0.7%) | 25 | Isotonic solution Not metabolized | Chemotic diuresis Possibility of acute intravascular volume expansion |

Table 36-8. PROPERTIES OF COMMONLY USED IRRIGATING SOLUTIONS FOR TRANSURETHRAL RESECTION PROCEDURES

Distilled water was the irrigating solution used by urologists in the past because it was nonconductive and interfered least with surgical visibility. However, because of its low tonicity, water absorbed into the circulation caused massive intravascular hemolysis, hemoglobinemia, and (rarely) renal failure.¹⁸¹ Absorption of large amounts of distilled water also resulted in dilutional hyponatremia. Emmett *et al*¹⁸² demonstrated a 75% decrease in the hospital mortality rate after TURP when a nonhemolytic solution was substituted for distilled water. Although distilled water is still used for transurethral procedures that do not open venous sinuses and are not associated with absorption of irrigating fluid (*i.e.*, cystoscopy), it is no longer used for TURP procedures.

Solutes such as sorbitol, mannitol, glycine, urea, and glucose have been added to water to make its osmolality closer to that of plasma^{179,183} (see Table 36-8). It is essential that the anesthesiologist be aware of the type of irrigating solution being used during an endoscopic procedure because absorption of this fluid can be associated with numerous perioperative complications. Urea is no longer used because it freely passes into both the intracellular and extracellular spaces and results in elevated blood urea concentrations.¹⁸³ Electrolyte solutions such as Ringer's lactate or normal saline would not cause electrolyte imbalance if absorbed into the circulation, but cannot be used in conjunction with an electrocautery device because they are ionized and are able to conduct electrical currents. Sorbitol is metabolized to fructose and use of this solution can produce hyperglycemia. Sorbitol is also converted to lactate, which may cause systemic acidosis, or it may induce an osmotic diuresis leading to dehydration and a hyperosmolar state. Glucose solutions have many of the same complications as sorbitol; however, glucose solutions are rarely used because they are sticky and not easily handled in the urology suite.¹⁸³

Glycine is a nonessential amino acid that is normally present in the circulation. It is metabolized in the liver by oxidative deamination into ammonia and glyoxylic acid.¹⁸⁴ Depressed mental status and coma secondary to hyperammonemia have been reported following TURP procedures in which glycine was used as the irrigating

solution.^{184,185} Blood ammonia levels as high as $834 \mu\text{M} \cdot \text{l}^{-1}$ (normal $11\text{--}35 \mu\text{M} \cdot \text{l}^{-1}$) have been documented, although the central nervous system depression was transient in these patients and they recovered within 24–48 hours.¹⁸⁵ Other investigators have observed the development of hyperoxaluria in association with glycine irrigation.¹⁸⁶ Hyperoxaluria places the patient at risk for calcium oxalate deposition in the kidneys if fluid intake is not maintained in the postoperative period. Visual disturbances, including blurred vision and transient blindness, have been reported following TURP procedures with glycine-containing irrigation fluid.^{187,188} Loss of vision after transurethral procedures was traditionally thought to be secondary to cerebral edema from the hypervolemia and hyponatremia that developed as irrigating fluid was absorbed. However, when a centrally acting mechanism, such as cerebral edema, is the cause of visual impairment, patients have normal pupillary light reflexes. A review of patients with blindness after TURP revealed that some patients had sluggish or nonreactive pupils, suggesting an anterior pathway disturbance rather than cerebral edema.¹⁸⁸ Glycine acts as an inhibitory neurotransmitter in the brain, spinal cord, and retina. Elevated serum glycine levels could exert an inhibitory action on the retina and result in transient blindness consistent with the clinical picture seen in these patients.^{188,189} It would appear that the visual disturbance after TURP may have more than one etiology.

Mannitol is an osmotic diuretic, occasionally used as an irrigating solution, which can cause dehydration and hyperosmolality if absorbed into the circulation in large quantities. In addition, marked intravascular volume expansion may occur when mannitol-containing irrigating fluid is absorbed.

Transurethral Resection Syndrome

The *transurethral resection (TUR) syndrome* (water intoxication syndrome) is a general term used to describe a wide range of neurologic and cardiopulmonary symptoms that occur when irrigating fluid is absorbed during TUR procedures, especially TURP. The principal components of this syndrome include respiratory distress secondary to volume expansion from rapid intravascular absorption of the irrigating fluid, dilution of electrolytes and proteins by the electrolyte-free irrigating fluid, and symptoms related to the type of irrigating solution used.^{179,183,190,191} and ¹⁹²

The average amount of irrigating fluid absorbed during TURP is $\sim 20 \text{ ml} \cdot \text{min}^{-1}$ of resection time.^{181,193} The volume of fluid absorbed during the procedure can be estimated with the following formula:¹⁹¹

$$\text{Volume absorbed} = \frac{\text{preoperative serum Na}^+}{\text{postoperative serum Na}^+ \times \text{ECF}} - \text{ECF}$$

where ECF = extracellular fluid volume.

The amount of irrigation fluid absorbed during the procedure is directly related to the number and size of venous sinuses opened, the duration of the resection, the hydrostatic pressure of the irrigating fluid, and the venous pressure at the irrigant-blood interface.¹⁷⁸ In an attempt to prevent excessive fluid absorption, it is recommended that resection time be limited to <1 hour and that the bag of irrigating fluid be suspended no more than 30 cm above the operating table at the beginning of the resection and 15 cm in the final stages of resection.^{178,193} Investigations have demonstrated that ethanol-labeled irrigating fluid can be used to accurately assess the degree of fluid absorption during TUR procedures.^{194,195} With this monitoring technique, a trace amount of ethanol is incorporated into the irrigating fluid so that the transfer of fluid to the patient can be detected by measuring the ethanol content of the patient's exhaled breath. The ethanol concentration in the expired breath is a reflection of the degree of uptake of irrigating fluid. When high concentrations of exhaled ethanol are detected, the surgeon is notified and the operation is terminated.¹⁹⁵

Clinical manifestations of the TUR syndrome range from mild (restlessness, nausea, shortness of breath, or dizziness) to severe (seizures, coma, hypertension, bradycardia, or cardiovascular collapse). In the awake patient with a regional block, a classic triad of symptoms has been described that consists of an increase in both systolic and diastolic pressures associated with an increase in pulse pressure, bradycardia, and mental status changes.^{179,180} During a general anesthetic, many of the more subtle signs of the TUR syndrome are obscured, making the early diagnosis of this problem more difficult. The initial hypertension and bradycardia are the result of acute volume overload, which may lead to left heart failure, pulmonary edema, and cardiovascular collapse.¹⁹⁰ With the continued absorption of electrolyte-free irrigation fluid, dilutional hyponatremia and cerebral edema develop. The acute decrease in serum sodium concentration is responsible for many of the signs and symptoms of the TUR syndrome¹⁷⁹ (Table 36-9). A serum sodium of $120 \text{ mEq} \cdot \text{l}^{-1}$ is associated with the development of central nervous system symptoms due to neuronal edema and dysfunction. Restlessness and confusion progress to loss of consciousness and seizures as sodium concentrations decline further.¹⁹⁶ Hyponatremia can also disturb the electrophysiology of cardiac cells. Electrocardiographic changes are seen when serum sodium levels fall below $115 \text{ mEq} \cdot \text{l}^{-1}$ followed by cardiac arrest at levels near $100 \text{ mEq} \cdot \text{l}^{-1}$. Rapid changes in the serum sodium concentration are more deleterious than chronic hyponatremia.¹⁹⁷

| Serum Na ⁺ | Central Nervous System Changes | Electrocardiogram Changes |
|---------------------------------------|--------------------------------|--|
| $120 \text{ mEq} \cdot \text{l}^{-1}$ | Confusion Restlessness | Possible widening of QRS complex |
| $115 \text{ mEq} \cdot \text{l}^{-1}$ | Somnolence Nausea | Widened QRS complex Elevated ST segment |
| $110 \text{ mEq} \cdot \text{l}^{-1}$ | Seizures Coma | Ventricular tachycardia or fibrillation |

Table 36-9. SIGNS AND SYMPTOMS ASSOCIATED WITH ACUTE CHANGES IN SERUM NA⁺ LEVELS

Symptoms related to absorption of a specific irrigating solution during the procedure may further complicate the TUR syndrome. For example, if excessive amounts of glycine are absorbed, the patient may become encephalopathic secondary to high blood ammonia concentrations.^{184,185} Likewise, absorption of large volumes of sorbitol may produce hyperglycemia and coma, especially in diabetic patients.

Prompt intervention is necessary when the neurologic or cardiovascular complications of TUR procedures are recognized (Table 36-10). Oxygenation, ventilation and circulatory support of the patient must be ensured and other potentially treatable conditions such as diabetic coma, hypercarbia, or drug interactions should be considered.¹⁷⁹ The surgeon should be informed of the change in the patient's status so that the procedure can be terminated as quickly as possible. Rapid measurement of serum electrolytes, creatinine, glucose, and arterial blood gases, as well as recording of an electrocardiogram are indicated. The severity of symptoms dictates the treatment of hyponatremia. If the patient's symptoms are mild and the serum sodium concentration is $>120 \text{ mEq} \cdot \text{l}^{-1}$, fluid restriction and administration of a loop diuretic, usually furosemide, are all that is necessary to return the sodium level to normal. Treatment with hypertonic saline has been associated with the development of demyelinating central nervous system lesions due to rapid increases in plasma osmolality and should be reserved for patients with severe, life-threatening symptoms.^{197,198} Three percent sodium chloride solution should be infused at a rate no greater than $100 \text{ ml} \cdot \text{h}^{-1}$ and discontinued as soon as the serum sodium is $>120 \text{ mEq} \cdot \text{l}^{-1}$. Once this goal is reached, treatment can continue with fluid restriction and diuretic therapy. The rate at which serum sodium is increased should not exceed $12 \text{ mEq} \cdot \text{l}^{-1}$ in a 24-hour period.¹⁹⁸

Ensure oxygenation and circulatory support
Notify surgeon and terminate procedure as soon as possible
Consider insertion of invasive monitors if cardiovascular instability occurs
Send blood to laboratory for electrolytes, creatinine, glucose, and arterial blood gases
Obtain 12-lead electrocardiogram
Treat mild symptoms (with serum Na⁺ concentration $>120 \text{ mEq} \cdot \text{l}^{-1}$) with fluid restriction and loop diuretic (furosemide)
Treat severe symptoms (if serum Na⁺ $<120 \text{ mEq} \cdot \text{l}^{-1}$) with 3% sodium chloride iv at a rate $<100 \text{ ml} \cdot \text{h}^{-1}$
Discontinue 3% sodium chloride when serum Na⁺ $>120 \text{ mEq} \cdot \text{l}^{-1}$

Table 36-10. TREATMENT OF THE TRANSURETHRAL RESECTION SYNDROME

Other Complications of TURP

Bleeding associated with TURP comes from either open venous sinuses or unrecognized arterial bleeding sites. Estimation of blood loss during transurethral procedures is grossly inaccurate because the shed blood is mixed with copious amounts of irrigating fluid. Typically, blood loss ranges from 2 to 4 ml · min⁻¹ during the resection and total blood loss correlates with the weight of the resected prostate tissue.¹⁷⁸ Because blood loss is difficult to assess, serial hemoglobin or hematocrit levels, as well as the patient's vital signs should be evaluated to determine the need for transfusion.¹⁸⁰ The incidence of intraoperative blood transfusion is reported to be ~2.5%; therefore, a preoperative "type and screen" for blood is all that is indicated.¹⁹⁹

Abnormal bleeding after TURP occurs in <1% of resections.¹⁷⁸ This situation occurs more commonly if a TURP procedure is performed in a patient with prostate cancer and may be caused by the release of thromboplastin, which is found in high concentrations in prostate cancer cells.¹⁸⁰ This thrombogenic stimulus produces disseminated intravascular coagulation in which an initial state of hypercoagulability is followed by a phase of secondary fibrinolysis. Continued fibrin formation and fibrinolysis cause hemorrhage from the depletion of coagulation factors and platelets. Treatment of this condition is supportive, including the administration of plasma and platelet transfusions to replace the deficient factors.²⁰⁰ Another cause of postoperative bleeding after TURP is the release of tissue plasminogen activators from the prostate. These factors activate the coagulation system and convert plasminogen to plasmin, which, in turn, causes fibrinolysis. Despite the fact that excessive bleeding after TURP has never been directly correlated with the degree of fibrinolysis, suggested treatment includes ε-aminocaproic acid, an inhibitor of fibrinolysis.²⁰¹ The recommended dosage for ε-aminocaproic acid is 4–5 g infused intravenously (iv) over the first hour followed by a continuous infusion of 1 g · hr⁻¹ for 8 hours or until the bleeding is controlled.

Perforation of the prostatic capsule occurs in ~1–2% of all patients undergoing TURP, usually resulting in extraperitoneal extravasation of fluid.^{180,199} This complication occurs more commonly during transurethral resection of the bladder (TURB) and the management of this problem is discussed in that section of this chapter.

The development of a fever in the perioperative period suggests bacteremia secondary to spread of bacteria through open prostatic venous sinuses, which is fostered by the presence of an indwelling urethral catheter.¹⁸⁰ Most patients receive prophylactic antibiotics before the surgical procedure, which are continued until 2–3 days after the catheter is removed. This risk of sepsis is increased by the use of "high-pressure" irrigation during the procedure and can be significantly decreased if the irrigation pressure is maintained at £30 cm.¹⁹³

If large volumes of room temperature irrigating fluids are used to remove blood from the operative site during TURP procedures, this may result in hypothermia in many patients, especially the elderly, who have a reduced thermoregulatory capacity. It has been shown that body temperature decreases ~1°C · h⁻¹ of surgery and shivering occurs in 16% of patients who receive room-temperature irrigation fluids, whereas hypothermia does not develop if the irrigation solution is warmed to body temperature (95–100°F).^{202,203}

Anesthetic Techniques for TURP

Regional anesthesia has long been considered the anesthetic technique of choice for TURP and is used in >70% of these procedures in the United States.^{199,204} This anesthetic technique allows the patient to remain awake, which should facilitate the early diagnosis of TUR syndrome or the extravasation of irrigation fluid. Some studies have demonstrated decreased blood loss when TURP procedures are performed using regional anesthesia, whereas others have found no difference in blood loss between regional and general anesthesia.^{205,206,207} and ²⁰⁸

The use of longer-acting regional anesthesia, compared with general anesthesia, for patients undergoing TURP is associated with improved postoperative pain control and decreased postoperative pain medication requirements. Bowman *et al*²⁰⁹ found that only 15% of patients receiving spinal anesthesia for TURP required any pain medication other than acetaminophen but that the need for analgesics was increased approximately fourfold after general anesthesia.

A prospective study comparing the effect of general versus spinal anesthesia on cognitive function after TURP found a significant decrease in mental status in both groups at 6 hours after surgery, but no differences in postoperative mental function at any time in the first 30 days after surgery.²¹⁰ Ghoneim *et al*²¹¹ also found that the type of anesthesia (regional versus general) did not affect postoperative behavior in patients undergoing prostatectomy, hysterectomy, or joint replacement.

Perioperative morbidity and mortality among patients older than 90 years of age who underwent TURP do not depend on the type of anesthesia used.²¹² A study of the occurrence of perioperative myocardial ischemia in patients undergoing transurethral surgery, assessed by Holter monitoring, determined that both the incidence and duration of myocardial ischemia increased following TUR surgery but that there was no difference between general or spinal anesthesia.²¹³ A second study confirmed these findings and concluded that the presence of short duration silent myocardial ischemia did not correlate with adverse outcome in elderly patients undergoing TURP procedures.²¹⁴ Thus, it appears that TURP can be performed safely with either type of anesthesia and the choice of anesthetic technique should be tailored to the individual patient.

If regional anesthesia is used for the procedure, a T10 dermatome anesthetic level is needed to block the pain from bladder distention by the irrigating fluid. However, an S3 level is reported to be adequate in ~25% of patients if the bladder is not allowed to overfill.²⁰⁴ Spinal anesthesia is usually preferred over lumbar epidural anesthesia because sacral segments are sometimes inadequately blocked with lumbar epidural techniques.

Local anesthesia has also been used for TURP procedures in patients with small to moderately sized prostate glands.²¹⁵ This anesthetic technique involves infiltration of 1–3 ml of local anesthetic solution (0.25% bupivacaine, 1% lidocaine) into the bladder neck and lateral lobes of the prostate to block the inferior hypogastric plexus of nerves, along with transurethral injection of local anesthesia into the gland surrounding the prostatic urethra. With this type of anesthetic, the surgeon can remove small amounts of prostatic tissue with minimal patient discomfort. Although the authors reported that this technique was difficult to implement on a large scale, they speculated that it might prove useful in high-risk patients who cannot tolerate spinal or general anesthesia.²¹⁵

Morbidity and Mortality After TURP

An American Urological Association (AUA) cooperative study evaluated postoperative complications in 3885 patients after TURP;¹⁹⁹ the average patient age was 69 years and most (>75%) patients had coexisting medical problems that involved many of the major organ systems. The complication rate for the intraoperative period was 6.9%, and the most common intraoperative problems were bleeding requiring transfusion in 2.5% of patients, the TUR syndrome in 2% of patients, cardiac dysrhythmias in 1% of patients, and extravasation of irrigating fluid in 0.9% of patients. No intraoperative deaths occurred. Immediate postoperative problems following TURP occurred in 18% of patients, with the most common problem during this period being failure to void. Other common postoperative problems were bleeding, clot retention, and infection. Patients at an increased risk for perioperative morbidity after TURP were identified as those patients with large prostate glands (>45 g), resection times longer than 90 minutes, acute urinary retention, or age >80 years.

Despite the high incidence of coexisting medical problems in patients undergoing TURP, the mortality rate in the first month after this procedure has declined over the years. In 1962, the mortality rate after TURP was 2.5%, whereas the AUA cooperative study evaluating these procedures during the years 1978–1987 found a mortality rate of 0.2%, even though patient age and the amount of prostate tissue resected had not changed from earlier surveys.¹⁹⁹

The Future of TURP

Since 1980, TURP has been the most common operative procedure performed in urologic surgery.^{216,217} In 1986, TURP accounted for >90% of prostatectomy procedures in the United States. However, since that time, the number of operations has fallen by nearly 20%.²¹⁷ Potential factors in the decline of TURP include the development of less invasive surgical alternative treatments, including balloon dilation, transurethral incision of the prostate (TUIP), laser prostatectomy, and prostate stents. In addition, drug therapy with α-blocking agents or 5α-reductase inhibitors is now available.²¹⁶

Balloon dilation of the prostate has been used as an alternative to TURP since the 1980s.¹⁹³ With this technique, a balloon is inflated in the prostatic urethra and left in place for 10 minutes.²¹⁸ The advantages of this technique include lower cost and shorter hospital stay, as well as the fact that it can usually be performed under local anesthesia with supplemental iv sedation. However, the future of balloon dilation is in question because it has been shown to be no more effective than dilation with

cystoscopy alone.²¹⁷

Transurethral incision of the prostate is the alternative to TURP that comes closest to matching its effectiveness in relieving urinary symptoms.^{219,220} The incision can be performed at a variety of locations around the bladder neck using laser or a cutting balloon.²²⁰ This procedure can be performed on an outpatient basis and is associated with shorter surgical times and significantly less blood loss.¹⁷⁷ Although some patients need only local anesthesia with iv sedation for TUIP, most require a spinal or “light” general anesthetic.

The technique of laser prostatectomy has recently been approved by the U.S. Food and Drug Administration. A neodymium–yttrium-aluminum-garnet (Nd-YAG) laser can be used to coagulate the prostate tissue, and the coagulated tissue is sloughed for the next several months. This procedure is associated with minimal bleeding and a decreased risk of absorption of the irrigating fluid, thereby minimizing the risk of TUR syndrome.²²¹ Because of these advantages, laser prostatectomy is preferred over TURP in elderly patients with significant co-morbidity.

Transurethral Resection of Bladder Tumors

Bladder cancer is the second most common urologic malignancy, with nearly 50,000 new cases diagnosed in the United States each year.^{222,223} Bladder tumors occur with a male-to-female ratio of ~3:1. Although the etiology of this tumor is not known, numerous lifestyle and environmental factors have been associated with the development of bladder cancer, including cigarette smoking, coffee drinking, use of artificial sweeteners, pelvic irradiation, and exposure to industrial carcinogens.

Superficial transitional cell carcinoma accounts for ~90% of bladder cancers, and most patients undergo endoscopic procedures transurethral resection of the bladder for both the diagnosis and treatment of this disease.^{222,223} This procedure can be performed with either regional or general anesthesia. If a regional anesthetic is employed, an anesthetic level to T10 is required to block the pain associated with bladder distention during the procedure. However, if the bladder tumor lies near the obturator nerve, general anesthesia with muscle relaxation is the preferred technique.

Complications During Transurethral Resection of the Bladder

Perforation of the bladder has been reported during transurethral surgery.^{224,225} This complication can occur if the bladder is over distended in the later stages of the procedure, causing tears in bladder areas thinned by the resection. Perforation of the bladder results in intraperitoneal extravasation of the fluid that is being used to irrigate the bladder, causing an abnormal irrigating pattern in which fluid is instilled into the bladder but not recovered. The clinical diagnosis of bladder perforation is simplified if the procedure is performed under regional anesthesia. The conscious patient describes sudden, severe abdominal pain, often associated with referred pain to the shoulder.^{181,224} Associated symptoms include pallor, sweating, abdominal rigidity, nausea, and vomiting. If extravasation is suspected, the operation should be terminated as quickly as possible. Small perforations with minimal intraperitoneal leakage rarely cause hemodynamic changes and can usually be managed with catheter drainage and diuretics. Open exploration with closure of the perforation is recommended for patients with respiratory embarrassment.^{181,224}

The obturator nerve passes near the lateral bladder wall, bladder neck, and lateral prostatic urethra as it courses through the pelvis. Stimulation of the obturator nerve by an electro-cautery device during transurethral surgery may cause the thigh muscles to contract violently, leading to inadvertent bladder perforation.^{226,227} Spinal anesthesia, “deep” general anesthesia, nerve cooling, and changing either the electrocautery current frequency or site of the inactive electrode have all been ineffective in blocking the muscle contraction.²²⁶ However, this reflex may be eliminated either by use of a muscle relaxant during general anesthesia or local anesthetic infiltration of the obturator nerve as it passes through the obturator canal.^{226,227,228,229} and ²³⁰

Extracorporeal Shock Wave Lithotripsy

In the United States, the annual incidence of urolithiasis is 16.4 per 10,000 people, and it is estimated that 12% of all people will experience calculus disease in their lifetime.²³¹ This disease is three times more common in men than in women, with a peak age incidence in the third to fourth decade of life.²³² Small calculi of <4.0 mm usually pass spontaneously; however, 10–20% of stones cause enough symptoms to justify surgical treatment.²³³ Several therapeutic modalities exist for the surgical treatment of urinary calculi. The final treatment decision is based on the size of the stone being treated, its location in the urinary tract, and its composition.^{232,233}

The introduction of extracorporeal shock wave lithotripsy (SWL) in 1980 dramatically changed the management of urolithiasis. Before the development of this modality, open surgical removal was the most common technique for treatment of urethral and renal calculi.²³⁴ Now only 5% of all urinary calculi require treatment with open surgical procedures. SWL has the advantages of being a minimally invasive technique that can be performed on an outpatient basis and is associated with minimal perioperative morbidity, which translates into a significant reduction in treatment costs.²³⁵

Technical Aspects of Shock Wave Lithotripsy

All lithotriptors have four main components: an energy source, a focusing device, a coupling medium, and a stone localization system.²³³ The original lithotripter was the Dornier HM-3, in which the patient is placed in a hydraulically supported gantry chair and immersed in a water bath (Fig. 36-8). The Dornier HM-3 energy source is a spark-plug generator that creates an explosive impact and transmits very high pressures (shock waves) to the water when it discharges. An ellipsoidal reflector aims the shock waves at a focal point. Two fluoroscopes are oriented so that their beam paths intersect at the focal point above the ellipsoidal reflector, and the patient's position in the tub is adjusted so that the calculus is centered in these beam paths.²³⁶ The water bath transmits the shock wave to the patient. It also serves as the coupling medium, allowing the shock wave to pass into the body without dissipation because the acoustic impedance of body tissue is close to that of water.²³⁵

Figure 36-8. Schematic of patient positioned in the Dornier HM-3 lithotripter. (Reprinted from Hunter PT II: The physics and geometry pertinent to ESWL. In Riehle RA Jr., Newman RC [eds]: Principles of Extracorporeal Shock Wave Lithotripsy, p 14. New York, Churchill Livingstone, 1987.)

During lithotripsy on the Dornier HM-3, the shock waves are delivered at an energy level of 18–20 kV, which corresponds to a pressure of ~900–1100 bar (1 bar = 14.7 psi) at the focal point on the calculus.²³⁷ Initial SWL treatments were associated with ventricular ectopic beats and even ventricular tachycardia.²³⁸ It was postulated that these dysrhythmias were caused by stimulation of the myocardium when shock waves were delivered during the repolarization phase of the heart. To avoid this problem, shock waves are now triggered off the electrocardiogram to occur 20 milliseconds after the R wave during the refractory period of the heart.²³⁸ The average treatment on the Dornier HM-3 lithotripter uses 1500–2000 shocks.²³⁵

Physiologic Effects of Immersion Lithotripsy

Placement of a patient into the water bath during lithotripsy produces a number of physiologic alterations in the cardiovascular system (Fig. 36-9). Immersion causes peripheral venous compression, resulting in an increase in central blood volume as well as central venous pressure (CVP) and PCWP.^{239,240} The increases in CVP and PCWP are linearly related to the depth of immersion, with immersion to the clavicles increasing CVP by 10–14 cm H₂O.²⁴¹ Despite the increase in venous return during immersion, some patients experience hypotension as a result of vasodilatation from the warm water.^{242,243} Other investigators have reported an increase in blood pressure and a decrease in cardiac output secondary to increased systemic vascular resistance during these procedures.^{244,245} The wide variety of cardiovascular changes that are possible during SWL procedures dictates the use of extreme caution when caring for patients with significant cardiac disease undergoing this

procedure. For example, patients with congestive heart failure may decompensate as their central blood volume increases during immersion. Likewise, patients with coronary artery disease may experience myocardial ischemia if hypotension or large increases in cardiac work occur during the procedure. In patients at risk for cardiovascular problems, immersion should be achieved in a gradual fashion so that alterations in the cardiovascular system can be closely monitored and the process terminated, if necessary. The procedure can also be performed with minimal immersion so that only the entry site is covered with water, or a nonimmersion (second- or third-generation) lithotripter may be used.

Figure 36-9. Effects of positioning, immersion, and immersion on heart rate (HR; beats · min⁻¹); systolic (syst.), mean and diastolic (diast.) arterial pressure (AP); and central venous (CVP) and esophageal (EP) pressures and transmural CVP (CVP_{TM}) in 25 patients during treatment with extracorporeal shock wave lithotripsy (ESWL). The numbers along the bottom refer to the number of measurements. Mean and standard deviations are shown. (Reprinted with permission from Weber W, Madler C, Keil B *et al*: Cardiovascular effects of ESWL. In Gravenstein JS, Peter K [eds]: Extracorporeal Shock-Wave Lithotripsy for Renal Stone Disease, p 105. Boston, Butterworths, 1986.)

Immersion lithotripsy also affects the respiratory system. Placement of a patient in water to the level of the clavicles increases the work of breathing, and respirations often become shallow and rapid.^{246,247} Other respiratory effects include a decrease in vital capacity and functional residual capacity secondary to extrinsic pressure on the upper abdomen and thorax. Bromage *et al*²⁴⁷ demonstrated that the addition of iv sedation during SWL procedures resulted in a potentiation of the respiratory depressant effects of immersion. Continuous monitoring of respiratory gas exchange and oxygenation should be used in all patients undergoing SWL but are of paramount importance in patients with pre-existing respiratory disease.

Problems involving temperature regulation may occur during SWL, especially in elderly patients with impaired thermoregulatory systems. Water in the lithotripter tub should be maintained in the temperature range of 35.8–37.5 °C.^{237,248,249} Water temperature should be checked before immersion, temperature monitoring used in every patient, and temperature alarms installed in the tub to signal excessively high or low temperatures.²⁴⁹

Patient Selection for Lithotripsy Procedures

Lithotripsy was initially limited to the treatment of renal calculi, but the indications for SWL have been expanded to include most ureteral stones. The only absolute contraindications to this procedure are pregnancy, abnormal coagulation parameters, and the presence of an active urinary tract infection. Consequently, women of child-bearing potential should be carefully evaluated for pregnancy before lithotripsy to avoid possible fetal damage from exposure to shock waves or radiation. Other pretreatment testing should include coagulation tests (*i.e.*, prothrombin time, partial thromboplastin time, and platelet count), and a urine culture. The risk of subcapsular renal bleeding or perinephric hematoma mandates that all coagulation parameters be normalized before lithotripsy. Aspirin-containing medications and NSAIDs should be discontinued for a minimum of 10 days before surgery.²⁵⁰ To minimize septic complications, all patients with active urinary tract infections should be treated with antibiotics before SWL.

Lithotripsy may be problematic in children or patients of small stature (height <48 inches) because positioning in the lithotripter chair is more difficult and there is a higher risk of pulmonary contusion by shock waves.²⁵⁰ The lungs of small patients can be shielded by foam padding during the treatment in an effort to prevent this complication.

It was initially thought that the presence of a cardiac pacemaker was a contraindication to SWL because of the possibility that electrical interference from the spark gap generating the shock wave might inhibit, reprogram, or damage the pacemaker.²³⁵ However, a review of 142 SWL treatments in pacemaker-dependent patients found a low (<1%) incidence of major pacemaker complications in these patients with only one pacemaker deprogrammed during the treatment period.²⁵¹ Based on these findings, patients with pacemakers are considered acceptable candidates for lithotripsy provided that certain precautions are taken, including (1) preoperative determination of the type of pacemaker and its functional status, (2) availability of a magnet or programming device in the operating room along with a person skilled in its use, (3) availability of an alternative pacing device, and (4) positioning of the patient so that the pacemaker is not in the shock wave path.

Other relative contraindications to SWL include complete urinary tract obstruction distal to the stone, calcification or aneurysm of the renal artery or aorta, the presence of an orthopedic prosthesis, or renal insufficiency as indicated by serum creatinine level of ≥ 3 mg · dl⁻¹. Patients with small abdominal aortic aneurysms have been safely treated if they are carefully positioned; however, patients with aneurysms measuring >6 cm in diameter should not be treated because the risk of accidental rupture increases exponentially with size.²⁵⁰

Complications of Shock Wave Lithotripsy

Renal parenchymal damage is thought to be responsible for the hematuria that occurs in nearly all patients, while subcapsular hematoma is seen in only 0.5% of patients after lithotripsy.²³⁴ These problems usually resolve spontaneously and bleeding that requires transfusion is rare.²⁵² Transient renal failure after SWL has been reported; however, there is no evidence that lithotripsy is associated with permanent renal dysfunction. Nevertheless, it seems prudent to avoid bilateral lithotripsy in a single procedure.²⁵²

After treatment, many patients complain of flank pain, which may be severe for several days.^{252,253} Petechiae and soft tissue swelling are often seen at the entry site of the shock wave, especially in thin patients. These skin changes resolve quickly and appear to be of little clinical significance. Up to 10% of patients have significant urinary tract colic, occasionally requiring hospitalization and opioid analgesics. Broken stone fragments can also collect in the ureter and form a column of stone, which is commonly referred to as *steinstrasse* or “stone street.” Although some patients have little pain associated with this condition, others may experience severe postoperative pain. If *steinstrasse* results in total ureteral obstruction, rising creatinine levels, or severe pain, the patient may require an endoscopic procedure with ureteral stent placement to relieve the obstruction.²⁵²

Other potential complications following lithotripsy include damage to adjacent organs by the shock waves.²³⁴ As previously mentioned, pulmonary contusions may occur if shock waves strike the lungs. Several cases of pancreatitis and transient gastrointestinal erosions have also been reported. Approximately 1% of patients have septic complications after SWL. Brachial plexus injuries have also occurred from improper positioning of patients in the lithotripter chair. Despite the wide array of potential complications, the mortality rate after SWL was only 0.02% in a review of >62,000 patients.²³⁴ It appears that with proper patient selection and cautious intraoperative management, most patients can safely undergo lithotripsy procedures.

Recent Advances in Lithotripsy

Modifications of the original Dornier HM-3 lithotripter have produced second- and third-generation lithotriptors with several advantages.^{233,234} First, newer lithotriptors generate shock waves within a “shock tube” that is coupled to the body surface with a water cushion, thus eliminating the water bath and all the problems associated with immersion of the patient. Second, recent modifications have focused on the development of pain-free lithotripsy by decreasing the power of the lithotripter. Although newer lithotriptors cause less pain, they are not pain-free and most patients still require iv sedation during treatments. In addition, decreasing the power in these machines has reduced the efficiency of stone fragmentation and resulted in a higher retreatment rate compared with treatment on the HM-3 lithotripter.²³⁴ For this reason, many urologists prefer to use the HM-3, ensuring that anesthesiologists will continue to care for patients treated with immersion lithotripsy for some time to come.

Anesthetic Techniques for Shock Wave Lithotripsy

During lithotripsy shock waves release energy as they pass through the interface between substances of different acoustic density. It is the impact of the shock waves on the skin and viscera that is responsible for the pain experienced during the procedure.²⁵⁴ The initial approach to anesthesia for lithotripsy on the Dornier HM-3 used either a regional or general technique. General anesthesia offers the advantages of control of patient ventilation and movement, as well as a rapid induction of anesthesia and a quicker recovery from anesthesia compared with epidural anesthesia.²⁵⁵ However, patients have to be positioned in the lithotripter chair while unconscious, increasing the risk of peripheral nerve injuries. With regional anesthesia, the patient is awake and cooperative during transport, simplifying patient positioning. In addition, the anesthetic can be used for additional operative procedures should they become necessary. Regional anesthetic techniques for this procedure require a sensory level of T6. Spinal anesthesia has a quicker onset and shorter preparation time compared with epidural anesthesia, but produces a more profound sympathetic blockade and is associated with a higher incidence of intraoperative hypotension.²⁵⁶

Conscious sedation techniques have been developed for use during lithotripsy.^{253,257} A wide variety of sedative-hypnotic, anxiolytic, and analgesic drugs have been used, but the most successful regimens use agents with small volumes of distribution, rapid clearance rates, and short elimination half-lives. Monk *et al*²⁵³ examined the use of propofol and fentanyl or midazolam and alfentanil for iv sedation during treatments on the Dornier HM-3 immersion lithotripter. Both sedative-analgesic combinations provided good treatment conditions and were associated with a high degree of patient satisfaction. Compared with epidural anesthesia for the same procedures, anesthesia and recovery times were significantly shortened and hospital costs decreased by the use of iv sedation.²⁵³ Local anesthetic infiltration of the flank alone or in combination with intercostal blocks and topical application of local anesthetic cream have also been used during lithotripsy on the Dornier HM-3 to decrease iv analgesic requirements for SWL.^{254,258} Although both local anesthetic techniques produced cutaneous analgesia, iv analgesics were still required for intraoperative patient comfort. It is unclear whether the addition of local anesthesia decreases the overall need for iv medication. Currently, conscious sedation is the preferred anesthetic technique for most routine SWL procedures, particularly those performed using the newer-generation lithotriptors.^{259,260}

Percutaneous Renal Procedures

Percutaneous nephrostomy (PCN) is commonly performed for the diagnosis and treatment of a wide variety of urologic problems, including relief of renal obstruction, stone removal, biopsy of tumors, and ureteral stent placement.¹⁶⁷ During a PCN procedure, a needle is passed into the renal collecting system under fluoroscopic guidance. After the needle is properly positioned, a guidewire is inserted through the needle and the needle is removed. A catheter is then placed over the guidewire, establishing access and drainage of the kidney. This procedure is performed with the patient prone, and local anesthesia with iv sedation is utilized for analgesia.¹⁶⁷ However, if the patient requires more than drainage catheter placement, the nephrostomy tract is dilated by the passage of graduated plastic dilators over the guidewire. Dilatation of the nephrostomy tract is associated with considerable discomfort and requires either general or regional (spinal or epidural) anesthesia. PCN involves the passage of an endoscope through the nephrostomy tract. Percutaneous nephrolithotomy, a procedure to remove renal calculi too large to be treated with lithotripsy, is one of the most common endosurgical procedures requiring dilation of a nephrostomy tract.

Although percutaneous surgical techniques are considerably less invasive than open surgical procedures, a variety of complications may occur during these procedures.²⁶¹ During insertion of the nephrostomy tube, trauma to the spleen, liver, or kidney can result in acute blood loss necessitating an emergency open surgical procedure. Colon injury has been reported if a retrorenal colon overlies the lower pole of the kidney.¹⁶⁷ This problem is usually managed by the placement of a colostomy tube, but a colostomy may be indicated if the patient exhibits signs of peritonitis. Pleural injury may occur during nephrostomy tube placement when access is created above the 12th rib or the kidney lies in a more cephalad position than normal. Nephrostomy tract dilation causes bleeding in most patients, with the hemoglobin declining by an average of $1.2 \text{ g} \cdot \text{dl}^{-1}$. If excessive intraoperative bleeding occurs, it is wise to stop the procedure and insert a large-caliber nephrostomy tube or high-pressure balloon nephrostomy catheter to tamponade the bleeding.²⁶¹ In a study of 50 patients undergoing PCN for stone removal, the complication rate was 12%, with pleural effusion and hydropneumothorax the most common problems encountered.²⁶²

During nephroscopy procedures, continuous irrigation of fluid through the endoscope is necessary to prevent blood and debris from obscuring the surgeon's vision. Because extravasation of irrigation fluid into the retroperitoneal, intraperitoneal, intravascular, or pleural spaces is possible, it should be standard practice to compare the quantity of irrigating fluid used with the output of fluid into the suction and urinary catheters. If there is a discrepancy between the amount of fluid infused and the output from the patient, extravasation must be assumed to have occurred. If the discrepancy between intake and output exceeds 500 ml and the difference cannot be accounted for by spillage or other losses, consideration should be given to stopping the procedure.²⁶¹ Intravenous absorption of irrigation fluid during percutaneous renal procedures can create a situation similar to that seen with the TUR syndrome, in which electrolyte abnormalities and fluid overload can occur. Because electrocautery is rarely used during percutaneous renal procedures, the preferred irrigating solution is 0.9% sodium chloride.²⁶³ If an electrocautery device is needed, the irrigation fluid is temporarily changed to sorbitol solution.

LASER SURGERY IN UROLOGY

Laser therapy has been shown to be effective in the treatment of a multitude of urologic problems, including condyloma acuminatum of the external genitalia and urethra, ureteral stricture or bladder neck contracture, interstitial cystitis, BPH, ureteral calculi, and superficial carcinoma of the penis, bladder, ureter, and renal pelvis.²⁶⁴ The major advantages of laser surgery over traditional surgical approaches are minimal blood loss, decreased postoperative pain, and tissue denaturation, which reduces the risk of tumor implantation.

Because lasers are an integral part of urologic surgery, an understanding of the indications and limitations of each type of laser is essential.²⁶⁵ The *carbon dioxide* (CO_2) *laser* produces intense heat with vaporization but has minimal tissue penetration and is unable to penetrate water. Thus, its use is limited to the treatment of cutaneous lesions of the external genitalia. The *argon laser* is poorly absorbed by water but is selectively absorbed by hemoglobin and melanin, making this laser useful for procedures in the bladder requiring coagulation of bleeding sites. The *pulsed dye laser* generates a pulsed output and is useful for destroying ureteral calculi. One of the most versatile and widely used lasers in urologic surgery is the *Nd-YAG laser*.²⁶⁴ This laser produces deep tissue penetration *via* protein denaturation with minimal vaporization. It can be used in water or urine without loss of effectiveness and delivered with a fiberoptic laser delivery system for endourologic surgery. Excellent results have been reported after the treatment of lesions of the penis, urethra, bladder, ureters, and kidneys with the Nd-YAG laser. The *KTP-532 laser* is a frequency-doubled Nd-YAG laser that does not penetrate tissue as deeply as the Nd-YAG but has a better cutting effect.²⁶⁵ It is extremely effective in the treatment of urethral strictures and bladder neck contractures.

Safety issues assume paramount importance during laser surgery. Damage to the eye is the potential injury that requires the greatest attention because both direct and reflected laser beams can cause eye injury.²⁶⁶ The part of the eye that is damaged by the laser depends on the wavelength. CO_2 laser beams cause a corneal ulceration, but no energy is transmitted to the fundus. Argon, Nd-YAG, and *KTP-532* lasers pass through the anterior chamber of the eye with minimal absorption and can therefore damage the retina. Protective goggles with appropriate filtering lenses are available for each type of laser, and laser equipment should not be activated until all operating room personnel and the patient are wearing glasses. It is also desirable to limit access to the operating room during laser surgery. Although less critical than eye damage, inadvertent thermal injury to the skin may also occur during laser treatments. Thermal injuries are avoidable if the laser is placed in the "standby" mode when not in operation and the laser is activated only by the surgeon performing the procedure. During CO_2 laser therapy for condyloma acuminatum, the plume (smoke) from the vaporization of tissue contains active human papilloma virus particles.²⁶⁷ To avoid inhalation of infectious agents, all operating room personnel involved in CO_2 laser procedures for genital lesions should wear protective laser masks that prevent small particles from being inhaled. In addition, the laser plume should be removed from the operating room with a smoke-evacuation system.

UROLOGIC LAPAROSCOPY

Urologic laparoscopy techniques are minimally invasive and have rapidly gained acceptance because they are associated with decreased postoperative pain, shorter hospital stays, and more rapid convalescence than open surgical procedures.¹⁶⁷ Laparoscopic procedures performed in urology include diagnostic procedures for the evaluation of undescended testis, orchiopexy, varicocelectomy, bladder suspension, pelvic lymphadenectomy, nephrectomy, nephroureterectomy, adrenalectomy, and cystectomy.

Unique cardiopulmonary changes may occur during laparoscopic surgery (see [Chapter 38](#)). Physiologic alterations during laparoscopy are often related to the surgical technique itself, in particular, the creation of the pneumoperitoneum and absorption of the insufflating gas.²⁶⁸ A wide variety of intraoperative complications are also possible during laparoscopy ([Table 36-11](#)). Complication rates for large laparoscopy series are reported to range from 0.6% to 2.4%, with approximately one third of the complications being cardiopulmonary in nature.²⁶⁹ These factors often make the intraoperative management of laparoscopic procedures more challenging for the anesthesiologist than open surgical procedures for the same indication.

Table 36-11. POTENTIAL INTRAOPERATIVE COMPLICATIONS DURING LAPAROSCOPIC SURGERY

Laparoscopic urologic procedures differ from conventional laparoscopy in several respects. Many structures in the genitourinary system are extraperitoneal (*i.e.*, the pelvic lymph nodes, bladder, ureters, adrenal glands, and kidneys), and urologists often prefer extraperitoneal insufflation during laparoscopic surgery on these organs. Several studies have suggested that CO₂ absorption is greater with extraperitoneal compared with intraperitoneal insufflation. Mullet *et al*²⁷⁰ reported that extraperitoneal laparoscopic pelvic lymphadenectomy caused a 76% increase in CO₂ elimination, whereas intraperitoneal diagnostic pelvic laparoscopy and laparoscopic cholecystectomy were associated with increases in CO₂ elimination of only 15% and 25%, respectively. A retrospective analysis of patients undergoing laparoscopic renal and pelvic surgery revealed that CO₂ elimination increased as much as 135% when the operation was approached with an extraperitoneal approach versus 61% when intraperitoneal insufflation was used.^{271,272} The increased absorption of CO₂ during extraperitoneal laparoscopic techniques mandates that the anesthesiologist carefully monitor and adjust ventilation as needed to maintain normocarbica.

Some laparoscopic procedures in urology, namely, cystectomy and nephrectomy, tend to be lengthy. Prolonged insufflation times during these procedures increase the amount of CO₂ absorbed and also necessitate the use of general anesthesia to guarantee patient comfort. Oliguria has been associated with prolonged durations of pneumoperitoneum during laparoscopic nephrectomy surgery.²⁷³ In a porcine laparoscopic model, McDougall *et al*²⁷⁴ demonstrated that prolonged increases in intra-abdominal pressure of 315 mm Hg resulted in a significant decrease in urine output despite adequate circulating blood volume and cardiac output. The mechanism for the intraoperative renal dysfunction was considered to be decreased renal cortical blood flow and renal vein obstruction during insufflation. In this study, the intraoperative oliguria was transient and not associated with any permanent renal derangement in the postoperative period. A review of the first 10 patients undergoing laparoscopic nephrectomy found that transient congestive heart failure developed in two of the patients in the postoperative period.²⁷⁵ The authors postulated that this problem occurred secondary to excessive fluid and blood administration to treat oliguria. Another possible mechanism for intraoperative oliguria during laparoscopic surgery is an increase in stress hormone levels, such as ADH.²⁷⁶ Because intraoperative oliguria is often treated with fluid administration, it is important that the anesthesiologist be aware that oliguria during prolonged laparoscopic procedures may not reflect intravascular volume depletion.

RADICAL CANCER SURGERY

Most major, open surgical procedures in urology are performed to treat cancer of the prostate, bladder, or kidney. These procedures are often lengthy and require intraoperative patient positions that are associated with significant impact on cardiorespiratory function. Radical urologic surgery also carries a potential for hemorrhage and large intraoperative blood and fluid requirements. In addition, patients undergoing these procedures are often elderly with pre-existing medical conditions.

Radical Prostatectomy

Cancer of the prostate is the most commonly diagnosed cancer in men, as well as the second most common cause of prostate-related mortality in American men.²⁷⁷ Localized prostate cancer (Stage A or B) is treated with either radical prostatectomy or radiation therapy. Considerable controversy exists over the best therapy for this disease because only one prospective, randomized trial to date has compared radical prostatectomy with radiation therapy in patients with organ-confined disease.²⁷⁸ These investigators found that radical prostatectomy offered a “distinct survival advantage” for localized prostate cancer. In the United States, men with clinically localized prostate cancer whose life expectancy is 10 years or longer tend to undergo radical prostatectomy, whereas patients older than 70 years of age or with a life expectancy of less than 10 years usually opt for radiation therapy or observation.²⁷⁹

Radical prostatectomy has been the most commonly used curative procedure for the treatment of prostate cancer since its introduction into the United States in 1905. This procedure involves the *en bloc* surgical removal of the entire prostate gland, the seminal vesicles, the ejaculatory ducts, and a portion of the bladder neck. After these structures are removed, the remaining bladder neck is anastomosed to the membranous urethra over an indwelling urethral catheter. A limited pelvic lymphadenectomy is usually performed during the procedure to aid in cancer staging.²⁸⁰ Radical prostatectomy can be performed with either a retropubic or perineal approach.

Radical retropubic prostatectomy is performed through a midline lower abdominal incision with the patient in the supine position. The operating room table is broken in the midline or the kidney rest is elevated to provide a slight hyperextension, which increases the distance from the symphysis pubis to the umbilicus. The table is then placed in the Trendelenburg position until the patient’s legs are parallel to the floor.²⁸⁰ Either general anesthesia or regional (epidural or spinal) anesthesia with sedation may be used for this procedure. If a regional anesthetic technique is utilized, a sensory block of T6–T8 is adequate.²⁰⁴ Advocates of general anesthesia believe that it provides greater intraoperative patient comfort and improved airway control as well as a faster onset and more controllable duration of action. Other anesthesiologists suggest that regional anesthesia is preferable for this procedure because it is associated with decreased intraoperative blood loss, a lower incidence of thromboembolic complication, and less postoperative mortality. A prospective study evaluating the influence of anesthetic technique on postoperative morbidity after radical retropubic prostatectomy randomized patients to receive epidural, general, or combined epidural-general anesthesia for their prostatectomy procedure.²⁸¹ Epidural patient-controlled analgesia was maintained in all groups for 3–5 days after the procedure. There were no differences in postoperative morbidity among the three groups. None of the patients died or experienced a major pulmonary, cardiovascular, or neurologic complication in the initial 3 months after surgery. These authors concluded that the intraoperative anesthetic technique did not influence postoperative outcome in patients undergoing radical prostatectomy. A review of the surgical literature supports this finding.²⁸²

Proponents of radical perineal prostatectomy claim that the perineal approach is superior to the retropubic approach to the prostate because it is associated with less intraoperative blood loss, better exposure for the vesicourethral anastomosis, and shorter convalescence times.²⁸³ During a radical perineal prostatectomy, the patient is placed in the exaggerated lithotomy position combined with slight flexion of the trunk and a Trendelenburg tilt. This position flexes the spine and results in the sacrum and the pelvis being tilted upward so that the perineum is horizontal and parallel to the floor.²⁰⁴ The exaggerated lithotomy position places the abdominal contents upon the diaphragm, which may cause respiratory embarrassment (see Chapter 24). Rhabdomyolysis with secondary ARF has also been reported after perineal prostatectomy in the exaggerated lithotomy position.^{120,121 and 122,284} These reports suggest that the muscle damage is probably secondary to ischemia of the muscles in the elevated legs or the lumbar and pelvic muscles that were compressed by the exaggerated position. Because of the positioning used for radical perineal prostatectomy, most anesthesiologists prefer either general or a combined epidural-general anesthetic for the procedure.²⁰⁴

The Trendelenburg position is used during both perineal and retropubic prostatectomy procedures. This position produces physiologic changes in the respiratory, circulatory, and cerebrovascular systems in proportion to the degree of head-down tilt.²⁸⁵ The head-down position induces venous distention of the upper body and jugular venous distention, which can lead to edema of the airway, tongue, and face. Airway management can be difficult if intubation becomes necessary during a prostatectomy procedure using regional anesthesia. The increase in venous pressure during Trendelenburg positioning can also increase intracranial pressure and has the potential to decrease cerebral perfusion. Therefore, this position should be avoided in patients with pre-existing elevation of intracranial pressure or glaucoma.²⁸⁶ Trendelenburg positioning during prostatectomy procedures places the operative site in the pelvis above the heart, creating a gravitational gradient between the prostatic fossa and the heart. An air embolism may occur if the prostatic venous network is opened while the patient is in this position.^{287,288} Some authors recommend that patients be monitored with a precordial Doppler and have a multiorificed CVP line in place for air aspiration during radical prostatectomy.

The most common intraoperative problem during radical prostatectomy is hemorrhage.²⁸⁰ Massive blood loss may occur if one of the branches of the hypogastric vein is inadvertently torn during pelvic lymphadenectomy or during transection of the dorsal venous complex. The potential for rapid blood loss is high and direct arterial blood pressure monitoring is recommended, especially in elderly or high-risk patients. Hemodynamic monitoring of volume status with a CVP catheter may be necessary because the bladder is opened during the procedure, making it impossible for the anesthesiologist to evaluate fluid status with urinary output. The potential for a venous air embolism during these procedures may also necessitate the use of a CVP catheter. In patients with severe pre-existing pulmonary or cardiovascular

problems, a pulmonary artery catheter may be needed accurately to assess cardiac filling pressures and hemodynamic status.

Radical Cystectomy

The standard of care for the treatment of muscle-invasive bladder cancer is a radical cystectomy.²⁸⁹ In men, this surgery involves the *en bloc* removal of the bladder, prostate, seminal vesicles, and proximal urethra. In women, it is necessary to remove the bladder, urethra, and anterior vaginal wall as well as to perform a total hysterectomy and bilateral salpingo-oophorectomy. At the completion of the procedure, a urinary diversion is performed, most commonly as an ileal conduit or a colon conduit.

Patient positioning and monitoring are similar to those used during radical retropubic prostatectomy procedures. Likewise, the same intraoperative problems may occur. However, this is an intraperitoneal procedure and fluid requirements are increased, similar to a major bowel procedure. The urinary diversion also prolongs the procedure, and most anesthesiologists find that the additional length and extent of surgery mandate a general or combined general-epidural anesthetic.²⁰⁴ Patients with bladder cancer may have been treated with chemotherapy before their procedure. The most commonly chemotherapeutic agents used include methotrexate, vinblastine, cisplatin, and doxorubicin. The anesthesiologist should be aware of the previous use of any chemotherapeutic agent so that any possible drug toxicity can be elucidated. In particular, doxorubicin has cardiotoxic effects, methotrexate may cause hepatic toxicity, and both cisplatin and methotrexate are associated with neurotoxicity and renal injury.

Radical Nephrectomy

Renal cell carcinoma accounts for ~3% of all adult malignancies.²⁹⁰ Surgery is the only effective method for treating renal cell carcinoma, with radical nephrectomy the treatment of choice. This surgical procedure involves the *en bloc* removal of the kidney and surrounding fascia, the ipsilateral adrenal gland, and the upper ureter. The tumor extends into the vena cava in ~5% of patients, and aggressive surgical therapy is warranted if there is no evidence of metastasis. On occasion, CPB and circulatory arrest have been used to treat extensive caval tumor invasion.

The kidney can be approached through a lumbar, transabdominal, or thoracoabdominal incision.²⁰⁴ If a lumbar approach is used, the patient is placed in the flexed lateral decubitus position with the operative side up and the kidney rest elevated beneath the 12th rib. General anesthesia or combined epidural-general anesthesia is used for patients placed in the "kidney position" because the position is extremely uncomfortable. This position may predispose patients to nerve damage or cardiopulmonary alterations (see Chapter 24). During radical nephrectomy procedures, the anesthesiologist needs to be prepared for acute blood loss because of the proximity of the kidney to large blood vessels. The patient also needs to be adequately hydrated to optimize blood flow to the remaining kidney and to prevent hypotension from inferior vena caval compression during positioning. Pneumothorax may also occur during surgery if the chest is inadvertently entered. A chest radiograph should be obtained in the postanesthesia care unit if a pneumothorax is suspected. Venous air embolisms are also possible during nephrectomy procedures if the positioning places the operative site above the heart.

Radical Surgery for Testicular Cancer

Although testicular cancer accounts for only 1% of all cancers in men, it is the most common malignancy in men between 15 and 34 years of age.²⁹¹ All intratesticular masses are considered cancer until proven otherwise, and radical orchiectomy is performed for both definitive diagnosis and as the initial step of most treatment regimens. Either regional or general anesthesia can be used for this surgical procedure.

Subsequent treatment depends on the stage and histology of the testicular tumor. Potential treatment options include observation, radiation to the inguinal and retroperitoneal areas, chemotherapy, or retroperitoneal lymph node dissection. Because chemotherapy regimens change frequently, the National Cancer Institute's CancerNet Internet site (<http://cancer.net.nci.nih.gov>) carries the current treatment protocols for each type and stage of testicular cancer. Prior to surgery, the anesthesiologist should identify the chemotherapeutic agents used and be aware of the side effects of these drugs. One commonly used chemotherapeutic agent, bleomycin, is an antitumor antibiotic used against germ cell tumors of the testis. Its use is associated with pulmonary toxicity and there are numerous reports of postoperative respiratory failure after retroperitoneal lymph node dissection in patients treated with bleomycin.^{292,293} and ²⁹⁴ The onset of respiratory failure usually occurs 3–10 days after surgery. Risk factors for postoperative respiratory distress include preoperative evidence of pulmonary injury, recent exposure to bleomycin (within 1 to 2 months), a total dose of bleomycin >450 mg, or a Ccr of <35 ml · min⁻¹.²⁹³ Although intraoperative exposure to hyperoxia (inspired oxygen concentrations >30%) has been linked to postoperative pulmonary toxicity, this relationship is controversial.^{292,293} A retrospective study found that iv fluid management, including blood transfusion, was the most significant factor affecting postoperative pulmonary morbidity and clinical outcome.²⁹² These authors recommended that iv fluid administration should primarily consist of colloid administration and be limited to the minimum volume necessary to maintain hemodynamic stability and adequate renal output.

OBESITY

Obesity is usually defined relative to actuarially derived *ideal body weight* (IBW), or relative to height using indices such as the *body mass index* (BMI), defined as weight (kg) divided by height (m) squared (wt/ht^2). For example, a 70-kg, 1.7-m patient has a BMI of 24. Patients who weigh 20% above IBW or have a BMI greater than 28 are regarded as obese. Approximately one third of the U.S. population meets these definitions of obesity,^{1,2 and 3} and the prevalence of BMI greater than 28 has risen 8% since the early 1980s. The very obese, usually termed the *morbidly obese*, weigh more than 45 kg above IBW or have a BMI of greater than 35, and constitute some 3–5% of the U.S. population.⁴

Obesity is associated with a number of anatomic, physiologic, and biochemical deviations from normality that may affect all bodily systems. Even modest obesity (BMI = 28) is associated with increased risks for poor health and premature death⁵ and, in the narrower anesthesiologic perspective, high risk for complications in the perioperative period.^{3,6,7} Much of the information on the perioperative management of obese patients has come from studies of morbidly obese patients with no systemic clinical disease. Caution should be used when applying such information to the less obese, or to the morbidly obese population as a whole, which has a high prevalence of systemic clinical disease.

The physiologic and pathophysiologic consequences of obesity vary with the anatomic distribution of fat. Fat of primarily truncal distribution—android obesity—with a waist–hip circumference ratio of 0.9 in men and 0.8 in women, is associated with increased oxygen consumption ($\dot{V}O_2$) and an increased incidence of cardiovascular disease. Fat primarily of the buttocks and thighs—gynecoid obesity—is metabolically less active and less closely associated with cardiovascular disease.⁸ Fat distributed intra-abdominally appears to be particularly associated with cardiovascular risk^{9,10} and left ventricular (LV) dysfunction.¹¹

Pathophysiology of Obesity

Respiratory System

Obese people have increased $\dot{V}O_2$ and carbon dioxide production ($\dot{V}CO_2$), but the basal metabolic rate, because it is related to body surface area, is usually normal.^{12,13 and 14} Contributing to the increased $\dot{V}O_2$ are the metabolic activity of fat and an increase in energy expenditure for locomotion and breathing (to move the mass-loaded chest and abdomen, and to maintain a high minute volume in order to remain normocarbic with an increased $\dot{V}CO_2$). With exercise, $\dot{V}O_2$ and $\dot{V}CO_2$ rise more sharply than in people of normal body weight, as does the oxygen cost of respiration, implying respiratory muscle inefficiency.

Mass loading of the chest wall and abdomen by fat results in alterations in both the static and dynamic performance of the respiratory system. In the upright position, expiratory reserve volume and functional residual capacity (FRC) are reduced so that tidal ventilation may fall within the range of closing capacity, with ensuing ventilation–perfusion (\dot{V}/\dot{Q}) abnormalities, or frank right-to-left shunt, with ensuing hypoxemia (Fig. 37-1). In the supine position, FRC often falls further within the range of closing capacity, with worsening hypoxemia (see Fig. 37-1). Fat mass loading of the chest and abdomen reduces chest wall compliance, with lung compliance remaining unaffected, and respiratory resistance increases.¹⁵ Despite these changes in respiratory variables, the usual clinical tests of respiratory function (e.g., forced vital capacity, forced expiratory volume in 1 second [FEV₁], and peak expiratory flow rate) are usually normal in the healthy obese patient.

Figure 37-1. The effect of change in position on various lung volumes in nonobese and morbidly obese patients. FRC = functional residual capacity; RV = residual volume; CC = closing capacity. (Reprinted with permission from Vaughan RW: Pulmonary and cardiovascular derangements. In Brown BR [ed]: Anesthesia and the Obese Patient. Contemporary Anesthesia Practice Series, p 19. Philadelphia, FA Davis, 1982.)

Most obese patients maintain a sufficient minute volume of ventilation ($\dot{V}E$) to remain normocarbic and preserve a normal response to carbon dioxide challenge. However, with increasing obesity, intercurrent lung disease, and the changes wrought by pulmonary hypertension, their condition may deteriorate to the *obesity hypoventilation syndrome* (loss of hypercarbic drive, sleep apnea, hypersomnolence, and potential or overt airway difficulties) or to the worst end of the spectrum, the *pickwickian syndrome* (hypercarbia, hypoxemia, polycythemia, hypersomnolence, pulmonary hypertension, and biventricular failure).¹⁶ The interactions of the respiratory and cardiovascular effects of obesity that lead to these conditions are shown schematically in [Figure 37-2](#).

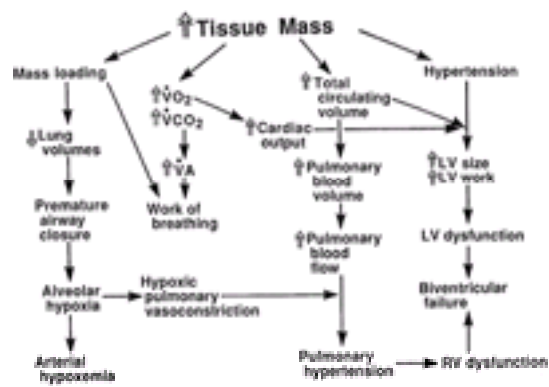

Figure 37-2. A schema interrelating the cardiovascular and respiratory abnormalities in morbidly obese patients to the pathophysiologic changes found in such patients. LV = left ventricular; RV = right ventricular.

Cardiovascular System

In obese people, circulating blood volume, plasma volume, and cardiac output increase proportionately with rising weight and $\dot{V}O_2$. Cerebral and renal blood flows are similar to those in normal people, but splanchnic blood flow is 20% higher than in normal-weight people.^{14,17,18} and ¹⁹ At rest, blood flow to fat is 2–3 ml · 100 g⁻¹ tissue; for a patient with a fat mass of 50 kg, blood flow to this fat mass accounts for an extra cardiac output of 1.5–2.0 l · min⁻¹. The increase in cardiac output parallels the rise in $\dot{V}O_2$; thus, systemic arteriovenous oxygen difference remains normal or slightly above normal. The pulse rate in the obese person is usually within normal limits; thus, with an increased cardiac output, stroke volume is increased.

Arterial hypertension occurs frequently in the morbidly obese. It is severe in 5–10% of the obese population and moderate in 50%. The increase in cardiac output in response to exercise is more abrupt than in normal-weight people and may be accompanied by increases in LV end-diastolic pressure and pulmonary capillary wedge pressure.¹⁸ Changes similar to those seen during exercise have been observed in the perioperative period.¹⁹ Thus, patients with any degree of cardiovascular compromise are particularly at risk in the perioperative period.

The pathophysiologic effects of obesity on cardiac function are complex. In the setting of elevated circulating blood volume and cardiac output cardiomegaly is common, particularly in association with hypertension. Catheterization studies in the obese (IBW > 50%) without hypertension show increased filling pressures and increased chamber size but normal LV performance.²⁰ More severe obesity (BMI = 30) is associated with impairment of both diastolic and systolic function,^{21,22} and ²³ which are most severely affected in patients with congestive heart failure and may be improved by weight loss. Patients with sleep apnea appear to be particularly at risk for ventricular dysfunction.²⁴ Most morbidly obese patients can maintain a normal ejection fraction at rest but cannot produce a rise in ejection fraction in response to exercise.²⁵ Thus, in the more obese and older patients, and in those with demonstrable cardiac disease, a low threshold for performing detailed cardiac investigations is appropriate.

The pulmonary circulation is also vulnerable to the pathophysiologic changes produced by obesity. An increase in pulmonary blood volumes and flows predisposes obese patients to pulmonary hypertension, which may be accentuated or precipitated by hypoxic pulmonary vasoconstriction, which in turn occurs as a result of the static lung volume changes found in the morbidly obese (see [Fig. 37-2](#)).

Endocrine and Metabolic Systems

To maintain a stable weight, morbidly obese patients have to maintain a greater-than-normal caloric intake.²⁶ But, as with $\dot{V}O_2$, when this intake is related to body surface area, the values are similar to those of normal-weight people. Glucose tolerance is frequently impaired, with pancreatic islet cell hypertrophy and hyperinsulinemia, regardless of the state of carbohydrate tolerance, and is reflected in a high prevalence of diabetes mellitus in the morbidly obese. Abnormal serum lipid profiles are often found and may be associated with an increased prevalence of ischemic heart disease.

Gastrointestinal System

Morbidly obese patients have an increased prevalence of hiatal hernia and a linear increase in intra-abdominal pressure with increasing weight. At induction of anesthesia, 90% of fasted (>8 hours) morbidly obese patients presenting for elective surgery have a gastric fluid volume in excess of 25 ml and a gastric fluid pH of less than 2.5.²⁷ Such volume and pH figures are generally accepted as being indicative of a high risk for acid aspiration pneumonitis if the gastric fluid reaches the airway. The effects of more modern preoperative fasting regimens, which permit clear fluid intake up to a few hours before surgery, are unclear. Because both intra-abdominal pressure and the volume of gastric content increase during pregnancy, the pregnant morbidly obese woman is at particular risk for aspiration pneumonitis.

There is an increase in liver fat content in 90% of morbidly obese patients^{26,28} that may not be evident with the usual clinical tests of hepatic function.²⁸ The increase appears to reflect the duration rather than the degree of obesity. The prevalence of hepatic dysfunction is particularly high in patients who have undergone intestinal bypass operations.²⁹ The effect of gastric partitioning operations on hepatic function is uncertain.

Airway

Obesity produces a number of anatomic changes that can affect the airway. Flexion of the cervical spine and the atlantoaxial joint may be limited by numerous “chins” and by thoracic wall or breast fat. Extension of these joints may be limited by low cervical or upper thoracic fat pads. Mouth opening may be restricted by submental fat. Fleshy cheeks, a large tongue, and copious flaps of palatal, pharyngeal, and supralaryngeal soft tissue may narrow the airway. Moreover, the laryngeal aperture may occupy a “high and anterior” infantile position. The morbidly obese have a high prevalence of obstructive apnea syndrome (see [Chapter 35](#)).³⁰ Such patients often present particular airway difficulties when anesthetized.

Psychology of the Obese

In addition to its negative health consequences, obesity is associated with significant negative consequences in the educational, social, and economic spheres.³¹ The attitudes of the public toward the obese and the purported stereotypic features of the obese are quite negative.³² Neither medical students³³ nor physicians, who may characterize the obese as lazy, lacking in self-control, noncompliant with therapies, and difficult to manage,³⁴ are exempt from these negative attitudes. It is unclear whether the character traits attributed to the obese are attributed incorrectly or correctly. If correct, it is also unclear whether these features are inherent in their condition (the prevalence of psychopathology in the obese population as a whole is similar to that in the normal-weight population, but it may be somewhat higher in the morbidly obese³⁵), or whether they result from the interactions of the obese with a population that holds them in negative regard, or is prejudiced against them. Whichever is the case, negative attitudes and behaviors from health care workers toward the obese will not change the characteristics or behavior of the obese, and should be avoided (see section on [preoperative evaluation](#)). In our experience with morbidly obese patients about to undergo gastric stapling operations, the patients were compliant with management regimens and conducted themselves normally throughout the perioperative period.³⁶ However, much time and effort were expended with this group, and the patients were obviously highly selected and motivated, having decided on a very dramatic course of action in an attempt to reduce their obesity.

Pharmacokinetics and Pharmacodynamics in the Obese

The many pathophysiologic deviations from normal that occur in the obese result in changes in drug pharmacokinetics and pharmacodynamics.^{37,38} A summary of the deviations from normal and their consequences is given in [Table 37-1](#).³⁸

| Variable | Altered Physiology | Clinical Observations |
|----------------------|---|--|
| Absorption | None | None |
| Distribution | Lean body mass Organ size Blood volume | Lipid-soluble drugs tend to have ↑ volume of distribution |
| Protein binding | Albumin α ₁ -acid glycoprotein Triglycerides | Free fraction of lipid drugs ↑ Free fraction of basic drugs ↑ |
| Metabolism (hepatic) | Hepatic blood flow Hepatic enzyme activity Phase I metabolism Phase II metabolism Renal excretion | Metabolism is decreased ↓ (change of high-intrinsic clearance) |
| Excretion (renal) | Glomerular filtration rate Tubular secretion | Renally excreted drugs (e.g., aminoglycoside antibiotics, cimetidine) may need increased dosages |

Table 37-1. FACTORS AFFECTING DRUG DISPOSITION AND RESPONSE IN OBESITY

Physiologic changes in obesity that affect drug distribution include increased cardiac output, blood volume, lean body mass, organ size, and fat mass. In general, water-soluble compounds have smaller distribution volumes than lipophilic compounds and their distribution is less affected by obesity. Drugs with high affinity for fat show an increase in volume of distribution. Albumin binding of drugs is unchanged in the obese, although changes in levels of fatty acids, triglycerides, and α_1 -acid glycoprotein may influence plasma protein binding.

Pathophysiologic changes in hepatic function in obesity may affect hepatically mediated drug clearance. Obesity is not associated with changes in Phase I metabolism (oxidation, reduction, hydrolysis), which affects drugs with low intrinsic clearance. Drugs eliminated through Phase II conjugation pathways (glucuronidation and sulfation) appear to be cleared faster in the obese.

Both renal glomerular filtration and tubular secretion are increased in the obese, and renally excreted drugs (e.g., aminoglycoside antibiotics, cimetidine) may need increased dosages.

Of specific drugs of interest to the anesthesiologist, lipophilic drugs such as the benzodiazepines³⁹ and thiopental⁴⁰ have an increased volume of distribution, more selective distribution to fat stores, and a longer elimination half-life in obese subjects than in normal-weight people, but clearance values are similar in both groups. For thiopental, the dosage suggestions are a larger absolute dose, but smaller dose per unit weight. An implication of the longer elimination half-life has been that fat-soluble volatile anesthetics may have a prolonged elimination time, with a consequent slow recovery. However, theoretical studies have shown that for prolonged recovery to occur, such agents would have to be administered for periods in excess of 24 hours.⁴¹ Clinical studies of volatile agents administered to morbidly obese patients for commonly encountered operative times (2-4 hours) have shown normal recovery times.⁴²

There are minimal data on the pharmacokinetics of propofol administered as a bolus. A dose based on IBW is advised. When used by infusion for maintenance of anesthesia, propofol volume of distribution and clearance rise in correlation with weight in the obese, but on average are similar to those in nonobese patients.⁴³ Moreover, speed of recovery, as judged by relatively crude methods, is similar in the obese and nonobese.⁴³

Fentanyl, when administered to the obese patient on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, has pharmacokinetic parameters similar to those in normal-weight subjects.⁴⁴ When administered on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, sufentanil shows a large volume of distribution and a similar mean elimination half-life that is variable.⁴⁵ When administered on a $\text{mg} \cdot \text{kg}^{-1}$ lean body weight basis, alfentanil has a volume of distribution in obese patients similar to that in normal-weight patients, but a longer elimination half-life secondary to reduced clearance.⁴⁶ Remifentanyl, when administered to obese patients on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, produces higher peak blood levels of drug but shows pharmacokinetic parameters similar to those in the nonobese patient, but are most closely related to lean body mass of ideal weight, which should form the basis of dosage regimens.⁴⁷

Hydrophilic drugs have similar volumes of distribution, elimination half-lives, and clearance times in obese and nonobese patients. Morbidly obese patients have a higher pseudocholinesterase activity than nonobese subjects,⁴⁸ and dosages of 1.2–1.5 $\text{mg} \cdot \text{kg}^{-1}$ of succinylcholine are advised. When administered on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, mivacurium has similar pharmacodynamics in normal-weight and morbidly obese patients.⁴⁹ To produce a given degree of neuromuscular blockade, a larger dose of pancuronium must be given to morbidly obese patients than to normal-weight patients. However, when this dose is related to body surface area, it is similar to the dose in normal-weight patients.⁵⁰ When vecuronium,⁵¹ metocurine,⁵² and rocuronium⁵³ are administered on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, recovery in the morbidly obese is slower than in normal-weight subjects, probably as a consequence of relative overdose (higher blood levels).⁵¹ In contrast, when atracurium is administered on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, the speed of recovery is similar in both populations,^{51,54} even though blood levels of atracurium at the time of recovery are higher in the morbidly obese patients.⁵⁴ Specific data on cisatracurium are lacking, but as its properties seem to be very similar to atracurium, and it is probably an acceptable drug to use in the obese. Specific data on rapacurium use in the obese are lacking.

Preoperative Evaluation

Although obese people have a reputation for being difficult to manage, this difficulty can be minimized by a suitable preoperative evaluation and visit. The anesthesiologist should be aware of his or her feelings, attitudes, and prejudices toward obesity and avoid condescension. Obese patients should be evaluated in a thorough, nonjudgmental fashion, with particular emphasis on the difficulties obesity presents to the anesthesiologist. Time should be allowed for the patient to detail previous adverse experiences with anesthetics and operations, as well as any fears and anxieties about the upcoming experience. The various potential difficulties that the patient presents, and the specific anesthesia plan that is to be used to minimize or avoid such difficulties, should be discussed with the patient. The likely postoperative course should be discussed, and the patient should be allowed some degree of input and choice in the management plan.

Cardiovascular System

The evaluation should be directed toward the abnormalities detailed in the section on pathophysiology. Hypertension, signs of LV or right ventricular failure, and signs of pulmonary hypertension should be sought. Sites for venous access and, if needed, arterial cannulation should be identified. The electrocardiogram and chest radiograph should be scrutinized for evidence of ischemic heart disease, LV or right ventricular hypertrophy, and pulmonary congestion. The finding of any of these abnormalities should lead to appropriate investigations. For patients with the obesity hypoventilation syndrome or the pickwickian syndrome, a cardiologist's opinion should be sought, both to define the magnitude of the problem and for advice on how best to optimize the patient's condition before surgery.

Respiratory System

The clinical history should seek to identify symptoms indicative of severe degrees of respiratory disease (e.g., orthopnea), obesity hypoventilation syndrome, or sleep apnea syndrome, and should elicit any history of upper airway obstruction, especially if associated with previous anesthesia and surgery. In young morbidly obese patients, the results of routine pulmonary function tests such as forced vital capacity, FEV₁, and peak expiratory flow rate are usually normal, but in older patients and those who smoke, the results may reveal unsuspected bronchospastic disease. Chest radiographs should be obtained, and blood gases should be measured with the patient seated and supine to rule out carbon dioxide retention and provide guidelines for perioperative oxygen administration.⁵⁵ More detailed pulmonary investigations should be reserved for those with severe disease. Because the degree of respiratory compromise in the postoperative period is often pronounced, it is imperative to optimize the patient's pulmonary status before embarking on anesthesia or surgery.

Endocrine, Metabolic, and Gastrointestinal Systems

Fasting blood glucose levels should be determined and the urine should be tested for ketones. If gross carbohydrate intolerance, diabetes, or ketosis is found, it should be corrected before either elective or emergency operations are begun. The patient should be closely questioned for symptoms of esophageal reflux and for a previous history of investigations or therapies that might be aimed at such a problem. Routine liver function tests should be performed.

Airway

A history of airway difficulties during previous anesthetics and operations should be obtained from the patient or previous anesthetic records. The patient should be questioned about symptoms suggestive of obstructive sleep apnea (excessive nocturnal snoring, with or without apneic episodes), which may suggest a potential for

mechanical airway obstruction when the level of consciousness is decreased. Patients with such histories, and those presenting for operations designed to alleviate such conditions (tracheostomy, palatoplasty), should be scrutinized especially closely, because they may present formidable airway difficulties. Physical examination of the patient should include range-of-motion testing of the atlantoaxial joint and cervical spine, the degree to which the mouth can open, and the distance between the tip of the chin and the hyoid cartilage. The interior of the mouth and pharynx should be scrutinized for excessive folds of tissue. The Mallampati classification, based on an ability to visualize the uvula, may help identify those with potentially difficult laryngeal visualization. Lateral soft tissue radiographs of the neck in neutral and extended positions, computed tomographs of the pharynx, hypopharynx, and the larynx, or consultation with an otolaryngologist for a specialized work-up⁵⁶ may help delineate airway difficulties before surgery (see [Chapter 23](#)).

Pharmacologic Treatment of Obesity

A number of medications have been developed and used in attempts to assist the obese with weight loss. Perhaps the most notorious of these medications is the fenfluramine–phentermine combination that was withdrawn from the market because of concerns that the combination produced cardiac valve defects. More recently, sibutramide, a serotonin and norepinephrine uptake inhibitor, has been introduced. This drug appears to facilitate weight loss and is associated with modest hypertension and with the rare “serotonin syndrome.”⁵⁷ There are no available data on interactions between sibutramide and anesthetic agents or techniques.

Perioperative Management

Premedication

Premedication, if any, should be given intravenously (iv) or orally. Attempts to give an intramuscular injection usually result in an intrafat injection, which leads to unpredictable absorption. In the morbidly obese patient, the effects of central nervous system–active drugs are not predictable and, because of the high prevalence of respiratory disease in this population, premedication should not be administered until the patient is in a safely monitored environment (e.g., the holding area or the operating room). This is particularly true for any patient with a history of airway obstruction or cardiovascular or respiratory disease. Even when such drugs are administered in the operating room, the patient should be monitored diligently. If an awake intubation of the trachea is anticipated, anticholinergic drugs should be given in an attempt to reduce secretions.

Because the risk of gastric regurgitation is high in obese patients, specific measures should be taken to guard against it. If a large volume of gastric contents is suspected (e.g., in an emergency situation), an attempt should be made to empty the stomach with a nasogastric tube. The tube should be removed before induction of anesthesia because of its potential for making a likely difficult tracheal intubation even more difficult. For elective cases, the preoperative administration of a clear antacid, metoclopramide, and histamine (H₂) blockers is advisable both to lower the volume and to increase the pH of gastric contents.^{58,59,60} and ⁶¹ Suggested doses are metoclopramide, 10 mg iv; cimetidine, 300 mg; or ranitidine, 50 mg iv, given 1 hour before operation.

Operating Room Preparation

It is important to ensure that equipment such as gurneys, operating tables, and lithotomy stirrups are capable of bearing the load imposed by the obese patient. The heels, buttocks, and shoulders of obese people are at risk for development of decubitus ulcers. All vulnerable areas should be padded. The distribution of body fat may make the usual operating table positions hazardous to the obese. For example, excessive posterior extension of the shoulder with the potential for brachial plexus injury may occur when a patient with a large posterior thoracic fat pad is placed supine with arms abducted at 90 degrees to the body. Because the obese patient may have reduced respiratory compliance, increased respiratory resistance, and a need for a higher-than-normal minute volume, the use of ventilators more powerful than the usual operating room ventilators should be considered.

Monitoring

If cuff blood pressure monitoring is to be used, the cuff should be of an appropriate size (the bladder should enclose 70% of the arm). Cuff blood pressure monitoring may be both difficult and inaccurate in obese patients, and intra-arterial monitoring is advised for all but the shortest and simplest cases. Paradoxically, although it is often difficult to secure venous access in the obese, intra-arterial cannulation is usually no more difficult than in nonobese people. A V₅ or equivalent electrocardiogram lead should be used on all patients. Monitoring of patients with cardiovascular disease is dictated by their specific problem. Pulmonary artery catheterization and transesophageal echocardiography may be indicated in patients with LV compromise or pulmonary hypertension.²⁵

Perioperative hypoxia is a constant threat in obese patients, and oxygenation should be monitored by pulse oximetry and by frequent arterial blood gas measurements. Capnography should be used to ensure adequacy of mechanical ventilation and to confirm correct endotracheal tube placement.

To ensure that any nondepolarizing neuromuscular blockade is adequate during surgery and fully reversed at the conclusion of the operation, such blockade must be monitored with a peripheral nerve stimulator. It may be difficult to achieve adequate peripheral nerve stimulation with skin electrodes because considerable amounts of tissue may separate skin electrodes from the relevant nerve. This problem may be circumvented by the use of percutaneous needle electrodes.

Because obese patients are no less likely than normal-weight patients to lose heat during surgery, body temperature should be monitored and maintained with forced air warming, which is effective in the obese.⁵² It is best to avoid postoperative shivering in obese patients because this may result in further mixed venous hypoxia and subsequent arterial hypoxia in patients who may be borderline normal in this regard.

Intraoperative Management

Airway Maintenance

Other than for the shortest general anesthetics in highly selected patients, general anesthesia should be delivered by an endotracheal tube. This is advocated because:

1. It may be difficult or impossible to maintain a gastight fit with a mask while maintaining an adequate airway and attending to the manual tasks necessary during anesthesia.
2. Obese patients are at high risk for aspiration of gastric contents.
3. Obese patients, if allowed to breathe spontaneously under general anesthesia, hypoventilate and become undesirably hypoxic or hypercarbic. Mechanical ventilation through an endotracheal tube is almost mandatory.

Difficulties with endotracheal intubation should be anticipated in all obese patients, and the person doing the intubation should thoroughly evaluate the patient and define all risks at the preoperative visit. All appropriate airway management equipment should be available, including a selection of oropharyngeal and nasopharyngeal airways, endotracheal tubes with introducers, a selection of laryngeal mask airways, intubation stylets, and laryngoscope blades of different patterns and sizes. If chest wall or breast fat is likely to obstruct the usual laryngoscope handles, a short-handled laryngoscope or a “polio blade” laryngoscope, which has a handle in the reverse of the usual direction, may be helpful. Fiberoptic intubation devices should also be available (see [Chapter 23](#)).

A carefully considered choice between awake and asleep tracheal intubation should be made in each case, bearing in mind the anticipated difficulties and the expertise of the anesthesiologist. An estimated 13% of morbidly obese patients pose difficulties for tracheal intubation using direct laryngoscopy.³⁶ Awake tracheal intubation has been recommended for all patients more than 75% above IBW,⁶³ but difficulties may also be encountered at weights below that cutoff point. Inability to visualize the patient’s uvula with the mouth open may be helpful in identifying those patients in whom intubation is likely to be difficult.^{55,64}

The “awake look” is a useful practice. The practitioner typically anesthetizes the mouth, pharynx, and supralaryngeal area with a local anesthetic and then gently introduces a standard laryngoscope and attempts to visualize the epiglottis and the larynx. If it is possible to see these structures, it is likely that intubation of the trachea after induction of anesthesia can be performed; if not, intubation of the trachea with the patient awake should be performed. If in doubt, the anesthesiologist should err on the side of caution and perform an awake intubation. Awake intubations should be accomplished with a fiberoptic instrument after suitable topical anesthesia. Any central nervous system depressant drug used to provide patient comfort should be kept to a minimum dosage and its effects monitored closely. Supplemental oxygen should be given during awake tracheal intubations.

Patients with a history suggestive of obstructive sleep apnea and those who are to undergo operations designed to alleviate such conditions almost invariably pose formidable endotracheal intubation difficulties. Endotracheal intubation attempted under general anesthesia in such patients frequently fails. Difficulty with bag-and-mask ventilation subsequent to a failed tracheal intubation, and the ensuing hypoxia, dictate that the trachea of many of these patients should be intubated

while the patients are awake.

If tracheal intubation under general anesthesia is to be performed, it is a useful policy to have two people and two pairs of experienced hands available. If the initial attempt at intubation is not successful and it is necessary to resort to bag-and-mask ventilation, one person maintains a gastight mask fit and the airway, and the second person ventilates manually. A second pair of educated hands is also useful to cope with other difficulties.

Intubation under general anesthesia should be performed in a manner designed to avoid hypoxia and the aspiration of vomited or regurgitated gastric contents. Cricothyroid pressure (Sellick maneuver) is indicated in most cases. Thorough preoxygenation/denitrogenation by a conventional 3-minute period or a four-breath technique⁶⁵ is essential because intubation may take longer than usual, and obese patients have smaller-than-normal oxygen stores in their lungs (low FRC) and a high \dot{V}_{O_2} and therefore become hypoxic much faster than normal-weight patients.^{65,66}

Regardless of the method used to place the endotracheal tube, correct tracheal placement should be confirmed with capnography because auscultation through chest wall fat may be difficult and inaccurate. Similarly, confirmation that the tip of the endotracheal tube is above the carina may necessitate fiberoptic bronchoscopy.

Choice of Anesthetic Technique

General Anesthesia. The doses of induction drugs used for the obese patient should be larger than for normal-weight patients (e.g., thiopental, $7.5 \text{ mg} \cdot \text{kg}^{-1}$ IBW), but allowance should be made for any cardiovascular dysfunction. Nitrous oxide is a logical choice for maintenance of anesthesia because it is fat insoluble, has a rapid onset and decrement of action, and is subject to little metabolism. However, even in fit morbidly obese patients, it may be necessary to use an inspired oxygen concentration (FIO_2) in excess of 0.5 to maintain an adequate PaO_2 ;⁶⁷ thus, the usefulness of nitrous oxide is limited.

Obese patients metabolize volatile anesthetics to a greater extent than normal patients. The blood levels of fluoride after administration of methoxyflurane, halothane, and enflurane, and the blood levels of bromide after halothane are higher in the morbidly obese than in normal-weight patients.⁶⁸ Moreover, because the incidence of "halothane hepatitis" is allegedly higher in the obese, and because obese subjects metabolize some halothane by a potentially hepatotoxic reductive pathway,⁶⁸ this drug should be used with caution, if at all. However, simple tests of hepatic function are similarly marginally impaired after either halothane or enflurane anesthesia. Because morbidly obese patients metabolize isoflurane⁶⁹ and sevoflurane⁷⁰ to a minimal extent, and because desflurane appears strongly to resist biodegradation,⁷¹ these are the volatile agents of choice in the obese patient.

The supposition that recovery from fat-soluble volatile anesthetics may be prolonged in the obese patient because such drugs may take a long time to leach out of fat stores has been elegantly disproved in theory⁴¹ and in clinical studies of speed of awakening⁴² (see [Pharmacokinetics and Pharmacodynamics in the Obese](#)).

When used in association with inhaled anesthetics at low dose, a propofol infusion at a rate of $6 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ (where weight used for the calculation is IBW + [0.4 × excess weight]) appears to produce satisfactory anesthesia and rapid emergence (see [Pharmacokinetics and Pharmacodynamics in the Obese](#)).⁴³

Great care should be exercised when giving opioids to obese patients. Unless the patient's trachea is to be left intubated and the patient provided with ventilator support in the immediate postoperative period, it is wise to keep the dose of opioid to a minimum. Maintenance of normal ventilation is already difficult for obese patients, and further respiratory depression with opioids could predispose to hypoxia or hypercarbia in the recovery room.

When administered on a $\text{mg} \cdot \text{kg}^{-1}$ body weight basis, the magnitude and duration of effect of succinylcholine are similar in morbidly obese and normal-weight subjects.⁴⁸ Of the nondepolarizing neuromuscular blocking drugs, atracurium,^{51,54} cisatracurium, vecuronium,⁵¹ and rocuronium⁵³ are all reasonable choices.

Paramount among the changes in the physiology of obese patients produced by general anesthesia are respiratory abnormalities. With the induction of anesthesia, there is further disruption of the already altered FRC-closing capacity relationship, with a further deterioration in \dot{V}/\dot{Q} relations or the development of a frank right-to-left shunt. The impairment of pulmonary hypoxic vasoconstriction by volatile agents contributes further to such changes. All obese patients should be considered at risk for hypoxia under general anesthesia. Obese patients should initially receive an FIO_2 of 1.0. Then, based on SpO_2 or PaO_2 , the FIO_2 may be titrated downward, slowly. The application of positive end-expiratory pressure may improve PaO_2 .^{72,73}

Even in fit obese patients, intraoperative events that influence lung volumes may produce changes in oxygenation. The Trendelenburg or lithotomy position and the placement of subdiaphragmatic packs or retractors may lead to further decreases in SpO_2 and PaO_2 .¹⁴ Given these findings, it is important that particular attention be paid to oxygenation at the time of positional changes and various surgical maneuvers. The assumption of the prone position may improve some aspects of pulmonary function,⁷⁴ although this improvement may depend on the frame on which the patient is placed.⁷⁵ Morbidly obese patients may, however, be safely maintained by one-lung anesthesia performed through a double-lumen endobronchial tube during transthoracic operations.⁷⁶

Because of the hypoventilation produced by general anesthesia, spontaneous respiration during general anesthesia is relatively contraindicated. Intermittent positive-pressure ventilation is best accomplished with large tidal volumes* at a rate of 8–10 breaths $\cdot \text{min}^{-1}$. Hypocarbia with a PaCO_2 of less than 30 mm Hg is best avoided because this may result in a rise in shunt fraction.⁷⁷

At the conclusion of the operation, any neuromuscular blockade must be totally reversed, as judged by the response to peripheral nerve stimulation, and the parameters for extubation must be fulfilled. The trachea should not be extubated until the patient is fully awake and in control of the airway to avoid hazards of pulmonary aspiration or airway obstruction. Before extubating the patient, the anesthesiologist should ensure, either by pulse oximetry or arterial blood gas measurements, that hypoxia is not present.

Regional Anesthesia. Regional anesthesia would appear to be a useful alternative to general anesthesia but is accompanied by its own constellation of difficulties. The considerable body fat and the indistinct nature of bony landmarks make regional anesthesia technically difficult in the obese patient. For peripheral nerve blocks, these difficulties may be circumvented by the use of insulated needles and a peripheral nerve stimulator to ensure correct needle and drug placement.

Subarachnoid blockade may be more difficult to perform in obese patients than in normal-weight patients, but the difficulties are not insurmountable. The midline of the back in the lumbar region usually does not have as thick a layer of fat as do the more lateral portions, and subarachnoid puncture may be facilitated by having the patient sit up. Needles longer than usual often are needed. For a given age and height of a patient, the dose requirement for subarachnoid anesthesia in obese patients is approximately 75–80% that of normal,^{79,80} and with more variability than in normal subjects.⁸¹ However, the influence of body weight on dose requirements for spinal anesthesia is debatable (see [Chapter 26](#)). Evidence from case reports implies that the level of blockade produced by subarachnoid local anesthetics is not predictable and that the blockade is of slow onset and creeps insidiously higher over the first 30 minutes.⁸² Anecdotal reports have implied that a high subarachnoid blockade tends to produce respiratory compromise, especially if patients are sedated.⁸² However, in obese patients with a blockade at T5, both respiratory volume⁸³ and blood gases⁸⁴ show minimal change from baseline. If the blockade does extend higher in the thoracic area than T5, there is a distinct possibility of respiratory compromise, particularly in obese patients with respiratory disease. Moreover, the high extension of the blockade, with the variable extent of the autonomic blockade above the somatic blockade,⁸⁵ may lead to cardiovascular compromise, which can also be precipitated by panniculus retraction.⁸⁶ A strong case can be made for the use of a continuous subarachnoid block. This could provide all the benefits of regional anesthesia, allowing careful titration of the drug to the desired effect, thus circumventing the potential unpredictability of "single-shot" subarachnoid blocks. Moreover, the incidence of postdural puncture headache after large-bore needle dural puncture appears to be lower in the morbidly obese parturient than the nonobese parturient.⁸⁷

Although technically more exacting than subarachnoid anesthesia, epidural anesthesia has been widely used and described in obese patients,^{36,88,89} particularly for abdominal operations. The technique usually consists of a high lumbar or thoracic puncture, followed by the introduction of a catheter and induction of a segmental block. Catheter placement may be easier with fluoroscopic guidance.⁸⁹ The technique is usually used in combination with a light general anesthetic delivered by an endotracheal tube, with intermittent positive-pressure ventilation. Such a technique bypasses many of the problems of general anesthesia, reduces the volatile drug requirement, eliminates the need for neuromuscular blocking drugs, and permits rapid postoperative mobilization. As is true for subarachnoid anesthesia, the dose requirement for epidural anesthesia for operative procedures is approximately 75–80% that for normal-weight patients.^{36,90} The use of epidural analgesia may confer some intraoperative and postoperative benefits on morbidly obese patients (decreased shunt fraction, LV work, A-VdO_2 , and \dot{V}_{O_2}).⁹¹ The catheter used to provide epidural anesthesia may be used again to provide postoperative analgesia either with local anesthesia^{36,88} or with opioids,⁹² which may be particularly beneficial in morbidly obese patients.^{26,88} The epidural dose requirement for analgesia in obese patients appears to be similar to that in normal-weight patients for both local anesthetics^{36,93} and opioids.⁹²

Because it may be difficult to deal with respiratory or cardiovascular emergencies in the obese, any such potential hazards must be detected as early as possible and dealt with vigorously. The obese patient receiving a regional anesthetic should receive supplemental oxygen and minimal sedation or analgesia, and must be monitored in the same fashion as if he or she were receiving a general anesthetic. The anesthesiologist should not choose regional anesthesia for a patient unless prepared to convert to general anesthesia if the regional anesthesia is unsatisfactory for the surgical procedure or if respiratory difficulties develop in the patient.

Postoperative Care

Obese patients with a previous history of respiratory disease, those with obesity hypoventilation syndrome or pickwickian syndrome, and those who have undergone major abdominal and thoracic operations are likely to have a high incidence of postoperative respiratory complications. Thus, it may be wise to admit these patients electively to an intensive care unit. Their management in the intensive care unit depends on the individual patient but should include mechanical ventilation, if necessary, and aggressive prophylaxis against the development of respiratory complications. Obese patients are highly immobile after surgery; measures should be taken to assist them in moving by the provision of an adjustable bed, overhead trapeze, and sufficient nursing staff.

Respiratory Function

Even in healthy obese patients, postoperative hypoxemia is a universal hazard. Supplemental oxygen should be given during transport from the operating room to the recovery room. Respiratory monitoring should be particularly aggressive in the recovery room and should include pulse oximetry or arterial blood gas monitoring, or both. Patients should not be discharged to the ward until they have been shown capable of maintaining adequate oxygenation, and it may be appropriate to use long-term oxygen therapy on the ward. After intra-abdominal operations, arterial hypoxemia may last 4–6 days⁹⁴ and is of greater magnitude with vertical than with horizontal incisions. Postoperative hypoxemia can be minimized by having patients sit in bed. There is some evidence that the intraoperative and postoperative use of regional anesthesia techniques reduces the incidence of postoperative respiratory complications.^{36,92}

Immobilization

Obese patients have a high incidence of postoperative deep vein thrombosis and pulmonary emboli. The use of low-dose heparin or intermittent leg compression prophylaxis may be appropriate. The use of regional anesthesia techniques may decrease the incidence of deep vein thrombosis and pulmonary emboli.³⁶

Analgesia

Obese patients may have less need for postoperative analgesics than normal-weight patients.⁹⁵ For previously stated reasons, the use of opioid analgesics can be hazardous in obese patients. Moreover, the routine use of intramuscular injections may not result in predictable blood levels of the opioid. If opioids are used, they should be delivered directly into the intravascular compartment using devices such as patient-controlled analgesia (PCA) machines. An anecdotal report implies that PCA may be hazardous in patients with obstructive sleep apnea,⁹⁶ but PCA has been effectively and safely used in the morbidly obese.^{97,98}

If an epidural catheter was placed for operative anesthesia, it may be used as the route for injecting either local anesthetic or opioid to provide postoperative analgesia. The use of local anesthesia³⁶ or opioids⁹² is associated with faster postoperative recovery and a lower incidence of respiratory complications than the use of conventional opioid techniques. The doses of either local anesthetic or opioid necessary to provide postoperative epidural analgesia are similar to those in normal-weight patients. Epidural opioid analgesia may result in delayed respiratory depression, and, because of the difficulty of maintaining or securing the airway in obese patients, those receiving epidural opioids should probably be nursed in a closely monitored environment (e.g., an intensive care unit) until the potential for such a complication has passed.

GASTROINTESTINAL DISORDERS

Functional Anatomy and Physiology

The mouth and pharyngeal musculature are under voluntary control as boluses of food and fluid are swallowed and delivered to the esophagus. Such boluses are lubricated by saliva, which amounts to approximately $1200 \text{ ml} \cdot \text{day}^{-1}$.⁹⁹

Esophagus

The esophageal musculature is under involuntary control and is innervated by the vagus nerve and a sympathetic component derived from segments T6–10. Waves of esophageal contraction pass boluses of food down to the gastroesophageal junction, which relaxes to allow them to enter the stomach.

At the gastroesophageal junction, reflux is prevented by a number of means, including the esophagus acting as a flap valve and the diaphragmatic crura pinching off the esophagus. The major barrier to gastroesophageal reflux is now believed to be the lower esophageal sphincter (LES). The LES is histologically similar to the rest of the esophagus but is functionally quite different. It may be identified by gastroesophageal manometry, in which a series of transducers is drawn from the stomach back through the gastroesophageal junction into the esophagus. The LES appears as an area of increased pressure (Fig. 37-3). It is usually 2–3 cm long and extends above and below the diaphragm. Peak pressure occurs just above the diaphragm and varies with respiration. The LES relaxes on swallowing, in contrast to the rest of the esophagus, which exhibits peristalsis.

Figure 37-3. The pressures found by lower esophageal manometry, illustrating the relationship of the lower esophageal sphincter to the diaphragm. Note also the effect of increasing intra-abdominal pressure causing a concurrent rise in lower esophageal sphincter pressure. (Reprinted with permission from Colton BR, Smith G: The lower esophageal sphincter and anaesthesia. *Br J Anaesth* 56:37, 1984.)

The tendency for esophageal reflux is related to some degree to LES tone but more to the barrier pressure, that is, the difference between the LES pressure and the gastric pressure. Thus, if intragastric pressure is sufficiently high, it may surmount the LES to produce reflux. However, in health, the LES pressure usually rises in response to a rise in intragastric pressure. The LES tends to relax during pregnancy; thus, the tendency for reflux to occur is greater at that time. Patients with hiatal hernia may have a normal LES pressure, although in such patients the LES is nearly always above the diaphragm. Patients with gastroesophageal reflux tend to have lower barrier pressures, ranging from low to near normal, rather than exhibiting a distinct cutoff point. The LES is innervated by both vagal and sympathetic nerves, but the role of the innervation is uncertain; vagal denervation does not affect resting tone or active function. Clinical circumstances associated with reduced LES tone include pregnancy, obesity, and hiatal hernia. Patients with gastroesophageal reflux may also have reduced LES tone. A number of drugs may increase or decrease LES tone (Table 37-2).

| Increase | Decrease | No Change |
|------------------|---------------------------|----------------|
| Metoclopramide | Atropine | Propranolol |
| Domperidone | Glycopyrrolate | Oxprenolol |
| Prochlorperazine | Dopamine | Cimetidine |
| Cyclizine | Sodium nitroprusside | Eranitidine |
| Edrophonium | Ganglion blockers | Atracurium |
| Neostigmine | Thiopental | ?Nitrous oxide |
| Histamine | Tricyclic antidepressants | |
| Suxamethonium | Halothane | |
| Pancuronium | Enflurane | |
| Metoprolol | Opioids | |
| Antacids | ?Nitrous oxide | |

Table 37-2. LOWER ESOPHAGEAL SPHINCTER EFFECT OF DRUGS USED IN ANESTHESIA

Stomach

The stomach has various functions. As a distensible receptacle, it allows the storage of large amounts of food and fluids (it may accept 1–1.5 l of fluid with minimal rises in intragastric pressure). As a chamber, it is the site for mixing of ingested food and gastric secretions, and where digestion begins; as a system, it expels small and manageable amounts of gastric contents into the duodenum.¹⁰⁰

The proximal part of the stomach is functionally a receptacle, exhibiting little mobility and in which little mixing occurs. Mixing occurs primarily in the distal stomach, with electrical activity originating from a “pacemaker,” usually located near the midpoint of the greater curvature. The electrical activity and resulting mechanical activity spread circumferentially and longitudinally toward the pylorus. Pyloric relaxation occurs in response to the waves of gastric activity, permitting expulsion of small amounts of gastric contents into the duodenum. In health, gastric emptying occurs at a rate that closely approximates an exponential curve, although varying from this curve when the stomach is full or nearly empty.

The rate of gastric emptying can be influenced by physiologic factors such as the type of intake—liquids leave the stomach more quickly than solids—and by the volume, pH, and osmotic qualities of the gastric contents.¹⁰⁰ The customary 4-hour preoperative fast does not guarantee that the stomach is empty, and evidence is accumulating that modest feeding or intake of small amounts of fluid during the preoperative period may be associated with lower volumes of gastric contents and may shorten the usual NPO waiting period before elective surgery (see [Chapter 21](#)).¹⁰¹ Certain groups of patients tend to have a high resting gastric content volume, including the pregnant, the obese, and the bedridden ([Table 37-3](#)). Pathologic states associated with high resting gastric content volume include pain, shock, and trauma. Laparotomy slows the rate of gastric emptying for approximately 24 hours, although this is probably the result of a combination of the mechanical effects of bowel handling and the postoperative use of opioids. A number of drugs may influence the rate of gastric emptying (see [Table 37-3](#)).

| | Accelerate | Delay |
|---------------|---|--|
| Physiologic | Gastric distention Neuroticism | Food Acid High osmotic pressure Posture Pregnancy Shock |
| Pathologic | Thyrotoxicosis | Trauma and pain Myocardial infarction Pyloric stenosis Crohn's disease Celiac disease Diabetic autonomic neuropathy |
| Pharmacologic | Metoclopramide Neostigmine Propranolol Sodium bicarbonate Cigarette smoking | Anticholinergics Tricyclic antidepressants Albuminum hydroxide Alcohol Isoprenaline Opioid analgesics |

Table 37-3. SOME FACTORS INFLUENCING GASTRIC EMPTYING RATE

Gastric secretions are produced at a rate of nearly 2000 ml · day⁻¹. They have a pH of 1.0–3.5, are isotonic with extracellular fluid, and consist predominantly of hydrochloric acid, with a higher potassium content than extracellular fluid. The pH of gastric contents may be raised by the administration of antacids or H₂-blocking drugs.

Duodenum

In the duodenum, secretions of the pancreas and the biliary tract are mixed with the gastric contents. Secretions of the pancreas and biliary tract are predominantly alkaline, with pH values in the region of 7.8–8.3 and daily volumes of 1200 and 700 ml, respectively. The pH of the resultant mix of gastric contents and duodenal secretions is a function of the respective volumes and pH of the gastric contents and the pancreatic and biliary tract secretions.

Small Intestine

At rest, the activity of the small intestine is governed by the migrating myoelectric complex. This complex has two components, electromyographic and manometric. Four phases may be seen: Phase I, the slow-wave electrical activity of the quiescent intestine; Phase II, characterized by slow-wave activity with some spikes, accompanied by periodic intestinal contractions; Phase III, characterized by intense spiking accompanied by electrical slow waves with vigorous mechanical contractions; and Phase IV, which reverts from Phase III to Phase I and is associated with rapid subsidence of contractions.

When food is taken, the migrating myoelectric complex is disrupted and there is contractile activity throughout the whole intestine. Postprandial intestinal activity can be divided into a cephalic phase, which may be abolished by vagotomy, a gastric phase, which is promoted by gastric distention, and an intestinal phase, which is provoked by perfusion of the intestine with nutrients.

The mode of control of small intestinal activity is not known with certainty. The parasympathetic system plays a role because parasympathetic stimulation results in increased activity, and suppression of the parasympathetic system results in decreased activity. The sympathetic nervous system also plays a role because sympathetic suppression causes an increase in activity and stimulation causes a decrease in activity, with the changes mediated by both catecholamines and dopaminergic receptors. However, with bowel denervation, there appears to be little change in activity, and it is likely that humoral secretions, especially pancreatic polypeptides and somatostatin, play a major role in mediating activity. Small intestinal activity is suppressed for 24–48 hours after laparotomy and may also be decreased by peritonitis and a reduction in serum potassium levels.

The small intestine secretes 2000 ml · day⁻¹ of fluid with a pH of 7.0–8.0. The small intestine is the site of most of the absorption of fluid and nutrients in the gastrointestinal (GI) tract. It is presented with 5500 ml · day⁻¹ of fluid (2000 ml from the stomach, 1500 ml from the pancreas and biliary tract, and 2000 ml from the small intestine), but passes on only 500 ml to the colon. Thus, the net turnover of fluid in the small intestine is of the order of approximately 5000 ml · day⁻¹. The absorptive abilities of the small intestine are impaired for approximately 36 hours after laparotomy.

Colon

Approximately 500–700 ml of bowel content is presented to the colon each day. The colon expels only 100–200 ml · day⁻¹; therefore, its function is predominantly absorptive. Colonic motility is controlled by a pacemaker located in the transverse colon. Three types of activity can be observed: (1) antiperistalsis from the transverse colon to the cecum, which permits maximal exposure of the feces for absorption of fluid; (2) peristalsis, which pushes feces forward to the distal parts of the colon; and (3) a powerful peristaltic movement that is responsible for the evacuation of fecal content; this movement proceeds anally in a series of large mass movements.

Parasympathetic neural control of the colon as far as the splenic flexure is furnished by the vagus nerve; beyond that point, it is furnished by the sacral parasympathetic outflow. The sympathetic supply is from segments T6–10. Parasympathetic stimulation increases motility, whereas sympathetic stimulation decreases activity. Administration of neostigmine increases both activity and tone, whereas morphine decreases them.¹⁰²

Splanchnic Blood Flow

Splanchnic oxygenation can be influenced by changes in the blood oxygen-carrying capacity (such as anemia) and by changes in blood flow to the bowel. In normal circumstances of a normal cardiac output, splanchnic blood flow remains relatively stable, being regulated by the splanchnic vascular resistance through mechanisms similar to those regulating hepatic blood flow. Splanchnic vascular resistance is largely regulated by the sympathetic nervous system, with sympathectomy decreasing splanchnic vascular resistance, α -adrenergic stimulation promoting vasoconstriction, and β -adrenergic stimulation promoting vasodilation. Dopamine may act in the splanchnic vascular bed through two receptors, with α -adrenergic vasoconstriction predominating over the mild vasodilation produced by β -adrenergic stimulation. Parasympathetic stimulation results in an increase in blood flow and an increase in motor activity.

In stress states, a number of humoral agents may influence splanchnic blood flow, including catecholamines, vasopressin, and angiotensin II. With hemorrhage, splanchnic vascular resistance rises, presumably as a teleologic mechanism to permit the diversion of cardiac output to organs more vital to survival. A modest hemorrhage of 10–15% of circulating blood volume, which does not affect systemic arterial pressure, may markedly impair splanchnic blood flow. The restoration of circulating volume does not result in a rapid restoration of splanchnic blood flow, which may remain decreased for several hours. Although blood loss and hypotension are not particularly critical for the blood supply to the stomach and small bowel, which have a liberal vascular supply, such circumstances may be associated with an increased rate of colonic anastomotic dehiscence.

A number of perioperative factors may alter splanchnic blood flow. After trauma, there may be an increase in splanchnic blood flow, but laparotomy alone produces little change. Morphine decreases splanchnic vascular resistance and therefore increases splanchnic blood flow. There is an almost linear relationship between splanchnic blood flow and PaCO_2 , with hypocapnia decreasing flow and hypercapnia increasing flow. Most inhaled anesthetics decrease splanchnic blood flow.¹⁰³ Regional anesthesia with high levels of sympathetic blockade results in an increase in splanchnic blood flow owing to a decrease in splanchnic vascular resistance, both as a consequence of the sympathectomy itself and of the fall in catecholamine levels associated with sympathetic blockade. However, if such a sympathectomy results in a fall in cardiac output, splanchnic blood flow may fall. Sympathectomy does not influence the changes in splanchnic blood flow produced by changes in PaCO_2 .¹⁰⁴ Neostigmine reduces mesenteric blood flow by 30–50% in association with the exaggerated motor activity of the intestine. Such decreases in blood flow may be somewhat ameliorated by the prior administration of atropine.

General Considerations for Anesthesia and the Gastrointestinal Tract

Regardless of the target of the surgery in the GI tract, a number of factors bearing on patient evaluation and management must be taken into consideration.

Airway Management and Protection

The oral, pharyngeal, and hypopharyngeal areas may be distorted by a number of pathologic processes, including tumor, infection, obstruction by an ingested foreign body, thermal or chemical damage, and nonmalignant variations on normal anatomy such as pharyngeal pouches. Thus, it is necessary to evaluate the patient carefully with respect to the site, type, and magnitude of the distortion and the pathologic process producing the airway abnormality. The choice of airway management and method of securing the airway should be based on clinical findings, supplemented as necessary by investigations such as direct or indirect laryngoscopy, soft tissue radiography, and computed tomography or magnetic resonance imaging of the abnormal area (see [Chapter 23](#)).

A major consideration in anesthesia for surgery on the GI tract is the prevention of inadvertent airway soiling by aspiration of GI contents during induction and maintenance of anesthesia. During routine anesthesia, the incidence of regurgitation of gastric contents is remarkably low; the incidence in adults and children is less than 1:1000.¹⁰⁵ Aspiration is most likely to occur during the induction of anesthesia, when the airway is not securely protected by an endotracheal tube and when active vomiting is most likely.

The consequences of regurgitation and subsequent aspiration of gastric contents into the airway depend on the character and volume of the aspirate. Solid matter produces an anatomic obstruction of the airway, and fluid of neutral pH produces the clinical picture of near drowning, whereas the aspiration of even small amounts of acidic fluid may be associated with the aspiration syndrome (Mendelson syndrome). The incidence of the latter is estimated at 0.05%.¹⁰⁵ It is generally accepted that a gastric content in excess of 25 ml with a pH of less than 2.5 implies a special risk for producing an aspiration syndrome if such fluid is aspirated. However, there is also opinion that acid aspiration syndromes can be produced by aspirates with a higher pH. Therefore, it is incumbent on anesthesiologists to attempt to reduce the volume and increase the pH of any gastric contents.

If the volume of gastric contents is suspected to be high, it may be reduced by emptying the stomach with a nasogastric tube or by inducing vomiting with apomorphine, although neither can guarantee complete gastric emptying. Gastric emptying can also be facilitated by using drugs to increase gastric motility. Several factors that influence gastric emptying are listed in [Table 37-3](#). Application of any of these techniques does not absolve the anesthesiologist of the responsibility of taking other precautions to prevent regurgitation and possible aspiration of GI tract contents.

A major thrust in reducing the potential for acid aspiration syndrome has been to raise the pH of gastric contents. This may be done effectively with particulate antacids such as aluminum hydroxide or magnesium trisilicate. However, such drugs may cause lung damage if they are aspirated; thus, it is preferable to use nonparticulate antacids such as sodium citrate (0.3 mmol). Drugs that reduce acid secretion, such as the H_2 blockers (e.g., ranitidine, famotidine), or proton pump inhibitors (e.g., omeprazole, lansoprazole), effectively raise the pH.^{50,51,106} Some anticholinergics, particularly glycopyrrolate, also reduce gastric acidity. Metoclopramide is of benefit because it increases gastric motility and increases LES tone.¹⁰⁶

Studies of the acid aspiration syndrome have shown that a high proportion of patients who have this problem have an LES dysfunction. Thus, it is important to maintain LES function. Circumstances associated with a lowered LES tone are discussed in an earlier section; drugs that raise LES tone are listed in [Table 37-2](#).

Before induction of anesthesia, the risk of regurgitation and pulmonary aspiration may be reduced by the following measures:

- Avoiding airway instrumentation at inadequate levels of anesthesia
- Reducing the volume of the stomach content
- Using nasogastric tubes
- Inducing vomiting
- Accelerating gastric emptying with drugs such as metoclopramide
- Raising the gastric content pH with clear antacids and H_2 blockers
- Increasing LES tone with metoclopramide

Once the anesthesiologist has attempted to reduce the likelihood of regurgitation and aspiration, the airway should be secured coincident with the induction of anesthesia by the expeditious passage of an endotracheal tube. Although conventional wisdom holds that application of cricoid pressure (Sellick maneuver) should accompany induction of anesthesia in the patient with a “full stomach,” in fact, application of cricoid pressure is associated with a relaxation of the gastroesophageal sphincter.¹⁰⁷

Fluid and Electrolyte Balance

Patients with GI disease may be in fluid or electrolyte imbalance for a number of reasons, some of which are listed in the following (see [Chapter 9](#)).

1. *Inadequate intake.* Patients awaiting surgery are often kept NPO for varying periods before surgery. This is especially likely to be a problematic factor in children, small adults, and patients in a hot environment or with pyrexia, in whom insensible fluid losses may be high. In the chronically ill patient, there may be a long period of inadequate intake, or oral intake may be prevented by anorexia or GI tract obstruction.
2. *Sequestration of water and electrolytes into abdominal structures,* such as the bowel lumen, bowel wall, and peritoneum, in patients with inflammatory bowel disease or intestinal obstruction.
3. *Extracorporeal loss of fluid* such as from vomiting, diarrhea, loss through fistulae, nasogastric suction, or diuretics.

Frequently, the etiology of the fluid deficit is an amalgam of these three causes. The magnitude of the fluid and electrolyte deficit reflects the duration of the problem and the site of the fluid loss. Deficient intake and salivary loss, for example, in a patient with a pharyngeal tumor, is primarily water loss with minimal electrolyte loss.

Loss of fluid that is primarily gastric contents (which, in a patient with pyloric stenosis, may reach $2000 \text{ ml} \cdot \text{day}^{-1}$) results in a hypochloremic alkalosis and hypokalemia. Not only is potassium lost in the gastric fluid, it is excreted by the kidney in response to the alkalosis.

If fluid is lost externally from the lower GI tract, the resulting deficit is predominantly a metabolic acidosis and hypochloremia. The loss may be up to $3000 \text{ ml} \cdot \text{day}^{-1}$.

When small bowel obstruction occurs, a complex series of events takes place. The segment of bowel proximal to the obstruction dilates and contains gas (primarily swallowed gas) and fluids. The fluids result from bowel contents upstream and an increase in small bowel secretion with a decrease in fluid absorption. As bowel dilation increases, fluid is lost into the bowel wall and peritoneal cavity. Progressive dilation and edema of the bowel or of a volvulus may lead to impaired bowel blood supply, with potential bowel necrosis and perforation. In these circumstances, further rapid fluid loss occurs and the patient may contract bacterial toxemia or septicemia. The usually encountered abnormalities include hemoconcentration, a fall in circulating blood volume, and a fall in total body potassium.

Large bowel obstruction tends to occur more slowly and manifests less dramatically than small bowel obstruction. The effects of the obstruction depend on the competence of the ileocecal valve. If the valve is competent, the closed obstruction results in large bowel dilation, particularly of the right colon and cecum, with the potential for progression to impairment of colonic blood supply and necrosis and perforation. However, if the ileocecal valve is not competent, the bowel contents reflux into the small bowel, ultimately resulting in feculent vomiting. The speed of progression of symptoms in large bowel obstruction tends to be slower than in small bowel obstruction, but the fluid and electrolyte disturbances may be just as severe, with similar intravascular and extracellular fluid consequences.

Diarrhea may result from impaired intestinal absorption of water and electrolytes, from abnormal bowel motility, or from an increase in the osmotically active substances in the bowel lumen. The fluid and volume deficit reflects the hypotonic, potassium-containing nature of the stools and tends to produce a hypokalemic metabolic acidosis.

Preoperative evaluation of the patient's fluid and electrolyte deficit includes assessment of clinical parameters such as skin turgor, peripheral circulation, heart rate, blood pressure, and urine output. Useful laboratory studies include hematocrit, serum electrolytes, and blood urea nitrogen. If necessary, invasive monitoring such as central venous pressure and pulmonary artery pressure measurements should be used further to assess the patient's vascular volume. The speed with which resuscitation and rehydration should be accomplished depends on the urgency of the surgical procedure. Small bowel obstruction, which may rapidly progress to bowel ischemia and perforation, necessitates urgent operation. Therefore, resuscitation should be swift and aggressive and aimed at rendering the patient fit for operation in a brief time. Resuscitation for large bowel obstruction or for a more chronic fluid loss, from whatever source, may be accomplished in a somewhat more leisurely fashion. The type of fluid resuscitation depends on the volume of loss and the clinical and laboratory findings.

Malabsorption and Malnutrition

The GI tract is responsible for absorbing all nutrients; therefore, bowel abnormalities may be associated with malabsorption of nutrients and consequent malnutrition. The malabsorption may be of one element only, but more commonly it is of multiple elements and is usually associated with chronic rather than acute disease.

Gastric lesions and gastric resections are commonly associated with a poorly understood iron deficiency anemia and with megaloblastic vitamin B₁₂ deficiency anemia owing to either lack of intrinsic factor or overgrowth of vitamin B₁₂-consuming bacteria in a blind loop. A deficiency of bile salt secretion impairs fat absorption, leading to steatorrhea and deficiencies of the fat-soluble vitamins A, D, and K and of calcium. Pancreatic insufficiency may lead to protein and fat malabsorption with steatorrhea and fat-soluble vitamin deficiency. Intestinal malabsorption may occur owing to motility disorders, a reduction in absorptive area, mucosal abnormalities, or bacterial overgrowth. The severity of the malabsorption and malnutrition is related to the magnitude, site, and duration of the disease and the magnitude of the decrease in absorptive surface. Malabsorption is usually of protein, fats, and vitamins; carbohydrate absorption is relatively well preserved.

Malnutrition may also result from loss of bowel contents through fistulae or from intestinal loss of protein into the bowel lumen in diseases such as regional enteritis, ulcerative colitis, and allergic enteropathies.

Although the correction of malnutrition in the preoperative period is relatively unimportant for acute diseases, it may be extremely important in chronic disease states. Experience with preoperative elemental diets or hyperalimentation has shown that correction of malnutrition improves both wound healing and the overall outcome of surgical procedures for chronic bowel diseases. Adequate postoperative nutrition is also important to improve healing and to reduce the incidence of complications. After abdominal operations, most patients have increased needs for calories and protein, particularly patients with major abdominal infections (see [Chapter 56](#)).

Special Anesthesia Considerations for Bowel Surgery

Use of Nitrous Oxide

The solubility of nitrous oxide in blood is 34 times that of nitrogen. In consequence, nitrous oxide in the bloodstream enters gas-containing body cavities much faster than the nitrogen in those cavities can be removed by the circulation. If this occurs in the bowel, the gas-containing bowel distends.¹⁰⁸ The amount of distention depends on the following factors:

1. The amount of gas within the bowel. In health, the bowel contains approximately 100 ml of gas, most of which is swallowed; therefore, distention is relatively unimportant. However, with obstruction or aerophagy, the bowel may contain much larger amounts of gas, and the potential for expansion is much greater.
2. The duration of administration. During the initial administration of nitrous oxide, there is a linear increase in bowel gas cavity size. By approximately 100 minutes after the commencement of administration of nitrous oxide, bowel gas cavity size increases by 75–100%, and, at that time, the ratio of bowel nitrous oxide to end-tidal nitrous oxide is approximately 0.5.
3. The concentration of nitrous oxide. If the alveolar concentration is only 50%, the maximum possible increase in bowel gas is twofold. At 80%, the increase could potentially be fivefold.¹⁰⁸

The distention of bowel by nitrous oxide may produce a number of problems. In a critical situation with an already distended bowel (e.g., in bowel obstruction), the increases in size and intraluminal pressure may tip the balance toward bowel ischemia and necrosis. More commonly, the increase in size causes intraoperative difficulties for the surgeon, especially during abdominal closure. Therefore, although use of nitrous oxide for most abdominal procedures is appropriate, it is best to avoid nitrous oxide when the bowel contains significant quantities of gas. In such circumstances, it is probably safe to use nitrous oxide, limiting its concentration to 50% for a brief time (e.g., 10–15 minutes), at the start of an operation to facilitate induction of anesthesia with a volatile drug. The nitrous oxide should be withdrawn thereafter and anesthesia should be maintained with oxygen and a volatile drug—a technique that leads to little or no increase in the size of gas-containing cavities.

Neostigmine

Parasympathetic activity results in increased bowel peristalsis. Thus, drugs that increase parasympathetic effects (e.g., cholinesterase inhibitors such as neostigmine) also increase bowel activity. In normal bowel, neostigmine increases the frequency and magnitude of the pressure waves, particularly in the colon, and this effect is magnified in diseased bowel. Such effects may be reduced by the presence of anesthetic drugs or the previous administration of atropine or glycopyrrolate.¹⁰⁹ There is anecdotal evidence that the administration of neostigmine to patients with a large bowel anastomosis may lead to an increased incidence of anastomotic disruption, but this has never been verified experimentally.

Specific Disease States

Esophageal Perforation. Patients with this anomaly may be extremely ill, fluid depleted, and septic. They may have pneumomediastinum, pneumothorax, and pleural

effusions. The patient's inability to swallow may complicate airway management.

Acute Pancreatitis. This entity is commonly associated with chronic alcohol ingestion; thus, the patient usually is compromised by the effects of alcoholism. The patient may be malnourished with impaired liver function and possibly an alcohol withdrawal syndrome. More acute problems include a fluid deficit, hypocalcemia, hyperglycemia, pleural effusions, and the adult respiratory distress syndrome.

Pancreatic Cysts and Pseudocysts. These cysts are usually a consequence of acute or chronic pancreatitis. Patients are usually malnourished and often septic.

Crohn's Disease. Patients with Crohn's disease are chronically ill, malnourished, and dehydrated owing to bowel obstruction, malabsorption, or loss of fluids and nutrients through fistulae. They are often very ill, taking large doses of steroids or immunosuppressive therapy.

Ulcerative Colitis. This chronic disease often results in electrolyte and fluid imbalance, vitamin B₁₂ and folate deficiency, and extracolonic manifestations such as arthritis, iritis, and hepatitis. Operations in the quiescent phases are often undertaken for precancerous lesions. Acute problems that may necessitate urgent operation include hemorrhage, bowel perforation, bowel obstruction, and toxic megacolon. Patients undergoing operations in the acute phase are often very ill, taking large doses of steroids, and undergoing extensive operations (e.g., total colectomy or total proctocolectomy). Careful resuscitation and intensive monitoring may be required.

Carcinoid Tumors. Although carcinoid tumors may occur at other anatomic sites, the GI tract is the source of most of them.^{110,111 and 112} The tumors are usually small and frequently multiple. Most carcinoid tumors originate in the intestine, although approximately 20% can originate in the lung. Of those in the intestine, 50% occur in the appendix, 25% in the ileum (these are usually the source of metastatic tumors), and 20% in the rectum. The hormones secreted by nonmetastatic carcinoid tumors reach the liver by way of the portal vein and are usually inactivated there. However, once metastases to the liver have occurred, the hormones secreted by the hepatic metastases may have direct access to the systemic circulation, to produce the symptoms and signs of the *carcinoid syndrome*. Approximately 35% of patients with carcinoid tumors and metastases have symptoms of the carcinoid syndrome. The classic presentation of the carcinoid syndrome is not evident in all patients, and the presentation of the disease varies considerably between patients. Typical symptoms include cutaneous flushing, abdominal pain, vomiting, diarrhea, hypertension, hypotension, bronchospasm, and hyperglycemia.

Carcinoid tumors produce a variety of hormones, and the symptoms produced in each case probably depend on the hormone(s) secreted. A summary of the hormones secreted, their physiologic effects, and suggested treatments is given in [Table 37-4](#).

| | Physiologic Effect | Treatment | | |
|-----------|---|------------------------|-----------------------|---|
| | | Antibody Antagonist | Stimulus Depletion | Receptor Blockers |
| Serotonin | Vasoconstriction Vasodilation Increased motility Dysrhythmias Tachycardia | Prochlorperazine | Telavastin | Methylergide Cyproheptadine Ketanserin |
| Gastrin | Vasodilation Hypotension Bronchospasm | Serolis Aprepit | | |
| Histamine | Vasodilation E ₁ + extracellular smooth muscle contraction E ₂ + extracellular smooth muscle relaxation | | | H ₁ antagonists Dexchlorpheniramine |

Table 37-4. HORMONES RELEASED BY CARCINOID TUMORS AND THEIR MANAGEMENT

The drug of choice for treatment of patients with carcinoid syndrome is the synthetic somatostatin analog octreotide.¹¹² Somatostatin suppresses release of serotonin and other vasoactive substances from the carcinoid tumor. Octreotide, with a half-life of approximately 160 minutes, has greatly improved preoperative and intraoperative management of carcinoid syndrome. Octreotide can be given subcutaneously in effect-titrated concentrations of 50–500 µg, 8-hourly, for prophylaxis, or 10–100 µg slowly iv 1 hour before surgery. During an intraoperative carcinoid crisis, it can be administered slowly iv in doses of 10–100 µg · h⁻¹ or 100 µg · h⁻¹ by iv drip, until symptoms cease. With the exception of steroids used for bronchospasm, other drugs used for carcinoid syndrome (e.g., theophyllines for bronchospasm, aprotinin for flushing and hypotension, and cyproheptadine, methysergide, and ketanserin) are drugs of second choice and should be used only if octreotide has failed. Octreotide should be administered 100 µg subcutaneously, three times a day, for two weeks before surgery. If octreotide is discontinued after surgery, it should be weaned over a period of 1 week and not stopped abruptly.

Although carcinoid tumors are relatively rare, patients with carcinoid tumors who present for surgery are usually the worst affected and pose a number of problems. Carcinoid heart disease occurs in approximately one third of the patients, but its etiology is somewhat uncertain. The pathologic findings are predominantly right-sided fibrinous plaques deposited on the right ventricular wall and on the tricuspid valve, producing incompetence or, less frequently, stenosis or deposition on the pulmonary valve. Such plaques are rarely found on the left side of the heart. Invasive or noninvasive cardiologic evaluation is necessary to determine the magnitude and the effects of heart disease.

It is difficult to give blanket recommendations for the management of all patients with carcinoid syndrome because it is likely that the extent and proportion of hormonal secretion and the hormones' effects will vary from person to person. When anesthetizing a patient with a carcinoid syndrome, it may be possible to get clues to likely intraoperative events from the previous history, although this is not necessarily so (e.g., 50% of the patients with intraoperative bronchospasm may have no previous history).

Choices of preoperative and intraoperative medication should be those that have low potential for provoking mediator release. Preoperative anxiety can trigger a carcinoid episode. Premedication with benzodiazepines, which do not release histamines, and antihistamines for any potential histamine release, is recommended. Perioperative factors that can trigger the release of carcinoid mediators (anxiety, hypothermia, hypercapnia, hypotension, hypertension) and drugs that can cause histamine release should be avoided. At induction of anesthesia, 100 µg of octreotide should be given iv. The induction of anesthesia should be smooth to avoid catecholamine release and is best performed with propofol or etomidate. Thiopental, with its potential for histamine release, is relatively contraindicated. Fentanyl and its derivatives, with their cardiovascular stability and non-histamine-releasing properties, are the opioids of choice. Morphine can cause histamine release and should be avoided. To facilitate tracheal intubation, nondepolarizing muscle relaxants are preferred because succinylcholine can cause histamine and peptide release from the liver. The use of succinylcholine should be limited to emergencies in which other agents are not considered suitable. Because of the potential for rapid and dramatic changes in systemic blood pressure, it may be wise to establish intra-arterial blood pressure monitoring before induction of anesthesia and to continue it after surgery. Central venous pressure and urinary output should be monitored because hypotension can be caused by both hypovolemia and mediator release from the carcinoid tumor. In patients with cardiac dysfunction, a pulmonary artery catheter or transesophageal echocardiographic monitor should be considered.

Anesthesia can be maintained with fentanyl or its derivatives, a nondepolarizing muscle relaxant, and an inhalation agent. Nitrous oxide, isoflurane, and sevoflurane are acceptable choices. Acceptable alternatives include continuous propofol infusion and spinal or epidural anesthesia. Regional anesthetic techniques require great care because sympathomimetic drugs, such as ephedrine, can trigger mediator release from carcinoid tumors.

Intraoperative hypotension is the most serious complication of the "carcinoid crisis" because it cannot be treated directly with sympathomimetics. The treatment of choice is fluid therapy and iv octreotide infused slowly. Hypertensive carcinoid crises can be treated by increasing the concentration of volatile anesthetic or with octreotide infusion. Bronchospastic carcinoid crises have been successfully treated with an iv bolus of octreotide (200 µg) and nebulized ipratropium bromide. Blood glucose levels should be closely monitored and hyperglycemia treated with an insulin infusion.

After surgery, the patient should be closely monitored for at least 24 hours because the effects of carcinoid mediators can continue after the tumor has been removed. Octreotide should be weaned slowly over a week.

* By rearranging the BMI equation (BMI = weight [kg]/height² [m]) to BMI × height² (m) = weight (kg), various body weights may be calculated for the person. Thus, a patient with a true body weight of 139 kg and a height of 1.77 m has a BMI of 139/1.77² = 44.4. At IBW, BMI = 25, and at low body weight (LBW), BMI = 30. Thus, for this patient, IBW = 25 × 1.77² = 78 kg and LBW = 30 × 1.77² = 94 kg. Intermittent positive-pressure ventilation at a rate of 12 ml · kg⁻¹ at the LBW at a rate of 8–10 breaths · min⁻¹ achieves a PaCO₂ of approximately 30 mm Hg.⁷⁸

HISTORICAL PERSPECTIVES

The modern age of laparoscopic surgery was ushered in with the incorporation of a miniature video camera attached to the eyepiece of the laparoscope, allowing multiple assistants to view the operative field from the same vantage point.¹ Gynecologic laparoscopic surgery has been routinely performed since the 1970s. In 1987, Philippe Mouret described the first laparoscopic cholecystectomy in France; the first series was reported by Perissat *et al.*,² and the technique was introduced into the United States in 1988 by Reddick and Olsen.³ Improved instrumentation allowed laparoscopic cholecystectomy to revolutionize upper abdominal surgery in the 1990s. Currently, laparoscopic gastroesophageal, hepatobiliary, colorectal, and solid-organ renal/splenic procedures, as well as herniorrhaphy, are routinely performed using minimal-access techniques.

Laparoscopic surgical techniques have been rapidly accepted by surgeons worldwide, with published reports describing the benefits of less postoperative pain, reduced hospital stay, and an earlier return to work.⁴ Until the late 1980s, morbidity and mortality were accepted as unavoidable aspects of the therapeutic process. The current realization that less invasive methods of treatment may reduce the risks of death and morbidity has given rise to the concept of *minimally invasive therapy* with the general aim to “minimize the trauma of the interventional process whilst still achieving a satisfactory therapeutic result.”⁵ A United Kingdom report commissioned by the Department of Health⁶ to assess the implications of minimally invasive therapy did not favor the term *minimally invasive surgery*, with its connotation of increased safety and minor procedures, preferring instead the term *minimal-access surgery*. The key feature of this technology-dependent surgery is that it produces significantly less trauma than does the conventional means of gaining access. The technology required is expensive, and its adoption has major implications for patient services, hospital design, operating room equipment, surgical specialty alignment, and training.⁷

Public perception that laparoscopic techniques are superior has led to the poorly controlled and audited introduction of laparoscopy-based surgical procedures. The percentage of cholecystectomies that are laparoscopic procedures has climbed from 0% in 1987 to 80% in 1992.⁸ A State of New York Department of Health⁹ memorandum reported 158 adverse incidents involving laparoscopic cholecystectomy between August 1990 and March 1992. Seventy-two percent of these incidents required remedial open surgical repair of the injury/complication. As the demand grew for laparoscopy-based procedures, the demand for training also increased. Approximately 15,000 general surgeons were trained in new laparoscopic techniques in the United States between 1990 and 1992.⁸ The Society of American Gastrointestinal Endoscopy Surgeons suggested guidelines for the credentialing, training, and determination of competence in laparoscopy techniques for their members.¹⁰

For more than a century, surgeons have upheld the legacy of William Halsted, who believed that each surgical advance should be based on thoughtful observation, laboratory experimentation, and carefully planned clinical trials. The evolution of laparoscopic cholecystectomy, however, has represented a departure from traditional surgical development. The National Laparoscopic Surgery Registry was established in the United States in 1990 with the support of independent educational grants to help evaluate the acquisition of technical skills, the outcome analysis of new laparoscopic procedures, and cost–benefit assessments. The initial mission of the Registry was to collect, organize, and disseminate clinical data relevant to laparoscopic cholecystectomy, but has been expanded to include all endocavity surgical procedures.¹¹

The development and potential for advanced laparoscopic surgery, beyond laparoscopic cholecystectomy and diagnostic laparoscopy, were reviewed by Hunter.¹² Current limitations include a two-dimensional video image and the requirement for specialized surgical instrumentation. The laparoscopic port acts as a fulcrum that restricts the freedom of movement of the instruments.¹ The development of three-dimensional imaging and expected introduction of flexible laparoscopes and robotics in the future will herald a new age in interventional surgery.^{1,13} The implications for anesthesia will be far reaching. The physiologic effects of prolonged CO₂ insufflation into an endocavity combined with variations in positioning have a major impact on cardiopulmonary function, particularly in American Society of Anesthesiologists (ASA) Class III or IV patients.¹⁴ Introduction of “gasless laparoscopy” using an abdominal wall lifting device may obviate the requirement for pneumoperitoneum.¹⁵

CARDIAC AND THORACOSCOPIC PROCEDURES

Thoracoscopic Procedures

The history of thoracoscopic surgery has been reviewed.¹⁶ Jacobaeus, in 1910, introduced therapeutic thoracoscopy by using the cystoscope in the pleural space to diagnose and treat patients with tuberculous effusions. Thoracoscopy is now commonly used in the diagnosis and treatment of pleuropulmonary disease.

The thoracoscopic management of pneumothorax and bullous lung disease was reviewed by Hazelrigg.¹⁷ Thoracoscopy allows visualization of the causal lung lesion, its removal, and subsequent pleurodesis. Blebs may be resected using a ligature or linear stapler and thoracoscopic pleural abrasion or apical pleurectomy used to achieve pleurodesis. Open surgical procedures for idiopathic spontaneous pneumothorax are rapidly being replaced by analogous thoracoscopic procedures. Graeber and Jones¹⁸ reviewed the application of thoracoscopic techniques in the management of traumatic thoracic injuries. After initial stabilization, they recommend thoracoscopic evaluation under general anesthesia through a double-lumen endobronchial tube in the operating room. Videothoracoscopy proved to be an accurate and safe procedure in the assessment of diaphragmatic injuries, control of continuing chest wall bleeding, and the early evacuation of clotted hemothorax.

Video-Assisted Thoracic Surgery

Video-assisted thoracic surgery (VATS) presents new challenges for the surgeon and anesthesiologist. Potential advantages include less postoperative pain, improved postoperative pulmonary function, shorter hospitalization, and earlier return to work. Applications of VATS ([Table 38-1](#)) include lobectomy, pneumonectomy, esophagectomy, and pericardial resection. More innovative applications include implantation of the implantable cardioverter–defibrillator,¹⁹ excision of mediastinal masses, transthoracic endoscopic sympathectomy for the treatment of upper limb hyperhydrosis and painful causalgias,^{20,21} and splanchnicectomy (celiac plexus block) for intractable pain from pancreatic cancer and pancreatitis.²² VATS has been reported in the management of multiple diseases of the thoracic spine, including disc herniation, disc space abscesses, and spinal deformities.²³

Table 38-1. VIDEO-ASSISTED THORACIC SURGERY

Early experience with video-assisted thoracoscopic lobectomy has been reported by Kirby *et al.*²⁴ A successful VATS lobectomy was accomplished *via* two thoracoscopy ports and a 6–8-cm “access” thoracotomy in 35 of 44 patients included in the study. Conversion to open thoracotomy was indicated in five patients because of dense pleural adhesions, difficulty dissecting the interlobar pulmonary artery, or a combination of these factors. The mean operative time for thoracoscopic lobectomy was 153 ± 26 minutes, and no major intraoperative complications were reported. The mean hospital stay was 5.7 ± 1.6 days. The authors concluded that VATS lobectomy was technically feasible and potentially safe. Walker *et al.*²⁵ reported their experience with video-assisted thoracoscopic pneumonectomy and found that the lung was easily delivered through a small submammary incision. Adoption of VATS lobectomy and pneumonectomy has enabled curative surgery to be attempted as an alternative to compromise therapy in elderly patients.²⁶

Anesthetic Implications

Anesthetic techniques for thoracoscopy were reviewed by Horswell.²⁷ Most VATS are performed under general anesthesia with one-lung ventilation (OLV) provided through a double-lumen endobronchial tube placed in the left mainstem bronchus and verified bronchoscopically (Fig. 38-1).

Figure 38-1. Thoracoscopic surgery.

Anesthesia is maintained by a combination of intravenous (iv) and inhaled agents. A radial artery cannula is usually placed for continuous blood pressure measurement and blood gas analysis.²⁸ Continuous pulse oximetry and end-tidal carbon dioxide tension (PETCO₂) are measured. Postoperative pain is managed by patient-controlled opioid analgesia, nonsteroidal anti-inflammatory drugs (NSAIDs), or regional techniques. VATS-assisted placement of paravertebral catheters during thoracoscopic procedures has been reported in the management of postoperative pain.²⁹

The double-lumen endobronchial tube has evolved as the technique of choice for most cases of OLV, which creates an obligatory right-to-left transpulmonary shunt of blood flow through the nonventilated, nondependent lung. Consequently, OLV results in a much larger alveolar–arterial oxygen tension difference and a greater risk of intraoperative hypoxemia than two-lung ventilation.

The distribution of pulmonary blood flow and ventilation is influenced by the lateral decubitus position, and the anesthetized, paralyzed, closed/open chest conditions. Creation of an artificial pneumothorax by CO₂ insufflation has been advocated in an effort to provide complete nondependent lung collapse and optimal surgical conditions. Using an animal model, Jones *et al.*³⁰ evaluated the hemodynamic response to varying insufflation pressures in eight mechanically ventilated pigs undergoing thoracoscopy. Significant hemodynamic compromise followed CO₂ insufflation. Cardiac index (CI), stroke volume, and left ventricular stroke work index (LVSWI) decreased 36%, 34%, and 49%, respectively, compared with baseline measurement at an insufflation pressure of 5 mm Hg. At an insufflation pressure of 15 mm Hg, mean arterial blood pressure (MABP) decreased 64%, CI decreased 81%, and LVSWI decreased 95% compared with baseline. The hemodynamic parameters returned to within 5% of baseline values when negative intrapleural pressure was restored by suction. The authors concluded that routine CO₂ insufflation during thoracoscopy could not be recommended because of significant hemodynamic compromise.

Patients with severe bilateral chronic lung disease who previously may not have been candidates for thoracotomy may be considered for VATS. Barker *et al.*³¹ described the anesthetic management of 22 such patients who underwent long periods of OLV during thoracoscopic laser ablation of emphysematous bullae. Thirteen patients in this series were receiving long-term supplemental oxygen and six patients were wheelchair bound. Despite this degree of respiratory impairment, OLV with 100% O₂ was instituted for a mean of 170 ± 53 minutes. Intraoperative hypoxemia was managed with differential lung ventilation and positive end-expiratory pressure as required. Only one patient failed to tolerate OLV. Elective postoperative ventilation was recommended.

An overview of the emerging practice of thoracoscopy and VATS was provided by the Video Assisted Thoracic Surgery Study Group.³² This group has collected data on 1820 patients from more than 40 institutions who have undergone a thoracoscopic procedure in an effort to define the role for this new technique. Lung nodules (47.5%) and pleural effusions (19.4%) represent the most frequent indication, and most commonly performed procedures were wedge resection (49%) and operation in the pleural space. Conversion to thoracotomy occurred in 24% of procedures. Half of these conversions were because of the need for more extensive resection, but other indications included inability to find the lesion, too large a lesion or difficult location, adhesions, equipment failure, and bleeding. Complications included prolonged air leak for more than 5 days (4.7%), atelectasis (1.9%), dysrhythmia (1.6%), bleeding requiring transfusion (2.0%), and pneumonia (1.9%). Rubin *et al.*³³ in an investigation of patients undergoing VATS or thoracotomy for limited diagnostic and therapeutic procedures, found that the VATS patients had significantly shorter hospitalizations (4.8 ± 2.7 versus 7.8 ± 4.6 days), fewer days of narcotic use for pain control (3.4 ± 2.1 versus 6.1 ± 3.6 days), and similar operating times compared with patients undergoing traditional thoracotomy.

Cardiac Procedures

Since the mid-1990s, minimally invasive cardiac surgery has evolved to avoid cardiopulmonary bypass (CPB; with its inherent risks), median sternotomy, or both. The media, patient preferences, and commercial developments (fiberoptic imaging technology) that made minimally invasive cardiac surgery possible have fueled this change.

Cardiovascular disease affects approximately one in four Americans, with approximately one million deaths per year.³⁴ The increasing numbers of elderly patients undergoing cardiac surgical procedures has major implications for health care costs.³⁵ To contain costs and minimize the major risks of conventional cardiac surgery, including median sternotomy (mediastinitis, sternal dehiscence, chest wall instability, wound pain) and deleterious effects of CPB (stroke, neuropsychological dysfunction, myocardial infarction, renal dysfunction and bleeding diatheses), less invasive direct procedures have been introduced³⁶ (Fig. 38-2).

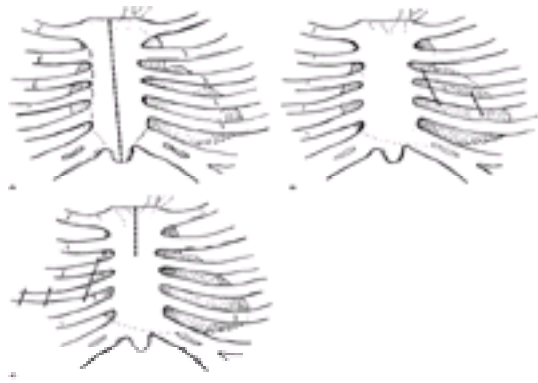

Figure 38-2. Schematic illustration of standard coronary artery bypass, minimally invasive direct coronary artery bypass (MIDCAB), and micromitral incision locations. (A) Standard median sternotomy for coronary artery bypass surgery. (B) MIDCAB incision. (C) Minimally invasive valve surgery. A right lateral minithoracotomy incision is made and a thoracoscope with or without other minimally invasive instruments is introduced to facilitate mitral valve repair. A partial sternal incision may be used to access either valve.

Minimally invasive direct coronary artery bypass grafting (MIDCAB) is an alternative method of revascularization for certain categories of coronary artery disease.³⁷ The strategy is to use a small incision, thus avoiding median sternotomy, or to make an anastomosis on the beating heart without CPB, or both.³⁸ Port-access minimally invasive cardiac surgery uses a system of cannulae and catheters to provide CPB and myocardial protection without accessing the heart through a median sternotomy. In contrast, the strategy in valvular heart surgery is to avoid the median sternotomy. However, all valve procedures currently require CPB.

Benetti and colleagues³⁹ highlighted developments in minimally invasive cardiac surgery techniques between 1978 and 1990. In 1975, Ankeney⁴⁰ reported a series of 143 patients undergoing coronary artery bypass graft surgery without CPB and the same year Trapp and Bisarya⁴¹ reported a series of 63 patients. Buffolo *et al*⁴² reported their series of 1274 patients in 1996 and concluded that the operation can be performed with an acceptable mortality rate of 2.5%. In addition, all types of arterial conduits can be used and the incidences of neurologic complications (1.1%) and dysrhythmias (5.5%) were lower than with conventional coronary artery bypass grafting with CPB (3.8% and 12.6%, respectively).⁴² In contrast to MIDCAB, minimally invasive valve surgery is in its relative infancy, with the first such repair performed by Chitwood *et al*⁴³ in 1996. Cosgrove and Sabik⁴⁴ at the Cleveland Clinic subsequently described and popularized a minimally invasive approach for aortic valve replacement.

The largest experience of minimally invasive cardiac surgery relates to coronary artery bypass surgery. The advantages of MIDCAB include early extubation, hospital discharge, and return to a functional level⁴⁵ (Table 38-2).

| |

| 7. Promotes earlier return to functional capacity |

Table 38-2. ADVANTAGES OF MINIMALLY INVASIVE CARDIAC SURGERY

Diegeler and colleagues⁴⁶ reported an immediate and 6-month angiographic graft patency rate of at least 90% in a series of patients undergoing MIDCAB. The limited clinical experience of minimally invasive valve surgery prohibits firm conclusions about the utility and benefit of this technique. However, Weinschelbaum *et al*⁴⁷ reported that the minimally invasive approach was a useful technique in patients undergoing first-time valve surgery.

Surgical Techniques

Minimally invasive coronary artery bypass is particularly suitable for patients with isolated proximal left anterior descending coronary artery (LAD) disease or right coronary artery disease and minimal left ventricular impairment.⁴⁸ In addition, Del Rizzo *et al*⁴⁹ reported that high-risk patients (advanced age, urgent operation, impaired left ventricular function, redo operation) are also suitable candidates and have significantly lower mortality rates and intensive care unit (ICU) stays compared with predicted rates for similar patients undergoing conventional coronary artery bypass surgery. Relative contraindications include acute myocardial ischemia at the time of the procedure, a small LAD (luminal diameter <1.5 mm), and cardiac arrhythmias (atrial fibrillation). An intramyocardial or calcified LAD represents an absolute contraindication.

Minimally invasive coronary artery bypass is performed using one of two types of approaches,⁵⁰ a series of small holes or “ports” in the chest (referred to as PACAB, PortCAB, or port-access coronary artery bypass) or a small incision directly over the coronary artery to be bypassed (*i.e.*, MIDCAB). The latter may be used with a port access approach.

Port-Access Coronary Artery Bypass. Port-access coronary artery bypass currently uses CPB *via* the femoral vessels. Bypasses are performed using instruments passed through the ports during cardiac standstill. As with abdominal laparoscopic surgery, the cardiac surgeon typically views the operative field on a video monitor. More recently, a specially designed port-access system has been introduced by a group from Stanford in conjunction with Heartport (Redwood City, CA). Port-access coronary artery bypass surgery was initially attempted under thoracoscopic guidance, but small incisions are now used to allow direct anastomosis to the coronary arteries, similar to the MIDCAB procedure. This system is used for both minimally invasive coronary artery bypass and mitral valve surgery.

Minimally Invasive Direct Coronary Artery Bypass. MIDCAB uses a small incision directly over the coronary artery to be bypassed. The small incisions used most commonly for the left coronary circulation include a mini-anterior mediastinotomy, a minithoracotomy, and a mini- or partial sternotomy. Right coronary artery disease may also be treated by MIDCAB using a gastroepiploic artery graft, through a small subxiphoid incision. All of the approaches are suitable for off-pump coronary artery bypass grafting. Diegeler and colleagues⁴⁶ compared four techniques for minimally invasive coronary artery bypass surgery and found that MIDCAB using a minithoracotomy, without CPB, was the preferred technique for one-vessel graft procedure to the LAD or right coronary artery. The port-access system with CPB was reserved as a second option for young patients requiring multiple-vessel grafting to the left coronary circulation (LAD or circumflex arteries). For either the MIDCAB or port-access techniques, the procedure is converted to a standard median sternotomy and CPB in less than 5% of cases, when the artery lies inside the heart muscle and cannot be easily located.

Minimally invasive procedures for performing aortic/mitral valve repair or replacement involve small (~10 cm) parasternal or partial sternal access incisions. Patients are placed on CPB by cannulating either the common femoral artery and vein, or the right atrial appendage and the common femoral artery. Visualization of the mitral valve using this approach is described as superior to that obtained with the conventional median sternotomy, in contrast to the view obtained during aortic valve procedures, where the main advantage is avoidance of a full sternotomy.⁵¹

Anesthetic Considerations

Anesthetic techniques and monitoring strategies for minimally invasive cardiac surgery focus on detection and monitoring cardiac ischemia, maintaining perioperative

hemodynamic stability, ensuring adequate pain relief, and facilitating early extubation.

Standard patient monitoring includes direct arterial and central venous or pulmonary artery pressure recordings and, in some cases, pulmonary artery catheterization for continuous cardiac output (CO) and mixed venous oxygen saturation (SV_{O_2}) measurements. Transesophageal echocardiography (TEE) is used in some institutions to detect regional myocardial ischemia or to facilitate placement of coronary sinus catheters for retrograde cardioplegia administration during port-access coronary artery bypass grafting. The operating room is set up as for a conventional coronary artery bypass procedure with the CPB machine and perfusion team on standby. The patient is placed in the supine position with external defibrillator pads in place. Conversion from MIDCAB to conventional coronary artery bypass surgery may be indicated if the symptomatic ischemia develops in the patient, if the arterial conduit is inadequate, or if the coronary artery target is inaccessible.

Early extubation, within 1–4 hours after surgery (in the operating room or in the cardiovascular ICU), is a major priority. Short-acting anesthetic and sedative agents facilitate this process. A benzodiazepine premedication is given 1 hour before surgery. Induction agents include low-dose fentanyl, midazolam, and thiopentone, whereas fentanyl and inhalational agents are used to maintain anesthesia. A double-lumen tube is used in some institutions when minithoracotomy is the surgical approach. Otherwise, standard single-lumen endotracheal tubes are inserted.

Coronary artery bypass without CPB requires local occlusion of the coronary artery to be grafted during anastomosis. Snares are placed to occlude both antegrade and retrograde flow and the anastomosis is performed on the beating heart. Commercially available heart-stabilizing devices (Octopus) to facilitate the anastomosis of the graft to the coronary artery have made pharmacologic control of the heart rate, with β or calcium channel blockade, less of a management consideration. Variable periods of regional ischemia may occur during occlusion of the coronary arteries, and detection and treatment of this ischemia is an important component of anesthetic management. Ischemia may be manifested by hypotension, electrocardiogram ST segment elevation, elevated pulmonary capillary wedge pressure, reduced CO and SV_{O_2} , or TEE-detected new regional wall motion abnormalities. If such changes occur before grafting, the snares are released and the myocardium is reperfused and allowed to recover. Additional 5-minute occlusion periods have then been used to induce “ischemic preconditioning” with reperfusion for several minutes before reocclusion.⁵² Other strategies to ameliorate regional ischemia during anastomosis include nitroglycerin infusion or β blockade. If ischemia persists and the patient becomes hemodynamically unstable, other options include instituting femorofemoral CPB or conversion to the conventional procedure with aortocaval CPB. Ventricular dysrhythmias may occur after reperfusion of the myocardium. Treatment options include prophylactic lidocaine before reperfusion or defibrillation using external defibrillator pads. Careful attention to electrolyte and acid-base balance is important in the prevention and management of these dysrhythmias.

The severity of pain reported after minimally invasive cardiac surgery is poorly quantified.⁵³ MIDCAB without a median sternotomy may be less painful. However, trauma to the costal cartilages (with or without rib segment removal) may be more painful than a median sternotomy. Ineffective treatment of pain from minithoracotomy or mini-anterior mediastinotomy incisions causes an increase in catecholamine release with consequent tachycardia, increased myocardial oxygen demand and myocardial ischemia, perioperative cardiac morbidity, and delayed hospital discharge.⁵³ In addition, lung volumes may be reduced with atelectasis and ventilation-perfusion (V/Q) mismatch.⁵⁴ Postoperative analgesic techniques include iv opioids, thoracic epidural analgesia, intercostal nerve block, and NSAIDs. Randomized, controlled trials are warranted to determine the optimal techniques and agents.

INTRA-ABDOMINAL LAPAROSCOPIC PROCEDURES

Cholecystectomy

Laparoscopic cholecystectomy involves changes in patient position from Trendelenburg to reverse Trendelenburg (rT), and intraperitoneal CO₂ insufflation (Fig. 38-3).

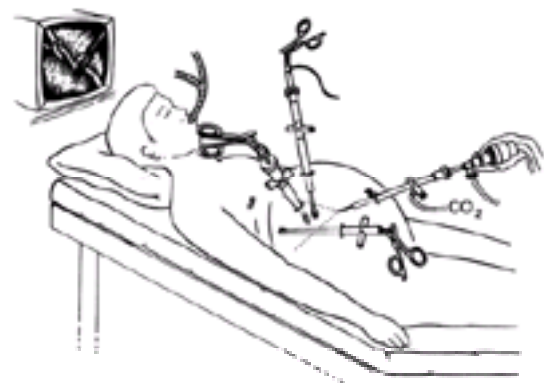

Figure 38-3. Laparoscopic cholecystectomy: patient positioning and equipment.

The laparoscopic approach combines the benefit of completely removing the gallbladder with the advantages of shorter hospital stays, more rapid return to normal activities, less pain associated with the small, limited incisions, and less postoperative ileus compared with the open laparotomy technique⁵⁵ (Table 38-3).

| |
|--|
| Comparison with traditional open cholecystectomy |
| Minimizes abdominal incision |
| Preserves diaphragmatic function |
| Potential benefits |
| Reduced adverse events |
| Pulmonary function preserved |
| Less postoperative ileus |
| Early ambulation |
| Economic benefits |
| Shorter hospital stay |
| Early return to work and normal activities |

Table 38-3. POTENTIAL BENEFITS OF LAPAROSCOPIC CHOLECYSTECTOMY

The Southern Surgeons Club,⁵⁶ in a prospective study of 1518 laparoscopic cholecystectomies performed by 59 surgeons in academic and private practice, defined a standard of care for the new procedure in 1991. Several other large series have also been reported from Europe⁵⁷ and North America.^{58,59} and ⁶⁰ Acute cholecystitis, obesity, and previous intra-abdominal surgery were initially considered to present difficult technical challenges. In late pregnancy, limited exposure was believed to compound the potential hazards of trocar insertion and the deleterious fetal effects of hypercarbia and pneumoperitoneum.

An impressive body of experience and literature has emerged in the 1990s confirming the safety and efficacy of laparoscopic cholecystectomy in the hands of experienced surgeons. Acute cholecystitis, despite concerns about technical difficulties with the associated edema, inflammation, and necrosis, is no longer considered a contraindication to laparoscopic cholecystectomy.⁶¹ The conversion rate, however, is high, especially in patients older than 65 years of age with a history of biliary disease and an acute gangrenous gallbladder.⁶² Although the incidence of symptomatic biliary disease in pregnancy is estimated at only 0.05%, the need for surgery in symptomatic patients is approximately 40%, and the risk of premature labor is inversely related to gestational age.⁶³ As with open cholecystectomy, conventional wisdom suggests delay until the postpartum period, if possible, when managing biliary colic in pregnancy. Case reports,⁶⁴ series,⁶⁵ studies,⁶⁶ and literature reviews⁶⁷ confirm that laparoscopic cholecystectomy can be safely performed in all trimesters of pregnancy, with acceptable maternal and fetal morbidity. The available data suggest that the safety and efficacy of laparoscopic cholecystectomy in pregnancy is increased by using the open Hasson technique for instrumentation; limiting intraabdominal pressure (IAP) during the pneumoperitoneum; using appropriate maternal and fetal monitoring; ensuring adequate maternal oxygenation and normocapnia; preventing aortocaval compression by left tilt; and using active antithromboembolism measures, including calf compression.

Careful audit of large series has highlighted problems unique to or more commonly associated with the laparoscopic approach in North American and Australia/New Zealand practice.^{68,69} Pre-existing umbilical and ventral hernia defects are major risk factors for postoperative trocar site hernia formation. Critics of laparoscopic surgery cite the increased incidence of tumor recurrence at the trocar sites after laparoscopic cholecystectomy in patients incidentally found to have carcinoma of the gallbladder. There is considerable controversy regarding the appropriateness of laparoscopy in the treatment of known malignant disease. However, data suggest that gallbladder cancer is an aggressive malignancy and abdominal wall implantation is not increased with laparoscopic surgery, but is more likely a manifestation of the aggressive nature of the tumor.⁷⁰ Bile duct injuries are more common after laparoscopy compared with open cholecystectomy.⁷¹ Furthermore, such injuries after laparoscopic cholecystectomy tend to be more extensive and higher in the duct system than those after open cholecystectomy, thus reducing the chance of a successful outcome from reconstruction. Roy *et al*⁷² undertook a case series review of 21 patients who sustained bile duct injuries during laparoscopic cholecystectomy in two tertiary care centers over 2 years. Misidentification of the common duct, resulting in accidental division or resection, and obstruction by hemoclips were the most common injuries. Pain, jaundice, and bile collections were the typical presenting features of injuries that became evident after laparoscopic cholecystectomy. Twenty of the 21 patients required Roux-en-Y hepaticojejunostomy for definitive treatment.

Miscellaneous Intra-abdominal Procedures

The adoption of therapeutic endoscopy has triggered the single largest change in surgical practice for many decades. Proponents of the endoscopic approach claim that the minimally invasive aspect should decrease postoperative morbidity and allow the patient to return to normal activity and work earlier than after a conventional open procedure.

Mellinger and Ponsky⁷³ highlighted the minimally invasive surgery literature in 1996. The list of procedures now commonly performed endoscopically has grown rapidly with gastric, antireflux, colonic, and renal surgery following appendectomy and inguinal hernia repair (Table 38-4).

Cholecystectomy
 Vagotomy
 Hiatal hernia repair
 Diaphragmatic hernia repair
 Appendectomy
 Colectomy
 Inguinal hernia repair
 Nephrectomy
 Adrenalectomy

Table 38-4. LAPAROSCOPIC INTRA-ABDOMINAL SURGICAL PROCEDURES

Raiser *et al*⁷⁴ reviewed the current status of minimally invasive antireflux surgery. They emphasized the importance of preoperative evaluation—endoscopy, biopsy, manometry, pH monitoring—in guiding patient selection for the most appropriate procedure, and in avoiding unnecessary or inappropriate operative misadventures. A laparoscopic Nissen fundoplication may prove a cost-effective technique for patients with gastroesophageal reflux on long-term medical management, provided complication rates are comparable and surgical results are enduring. Interest in laparoscopic hernia repair continues, although conflicting reports have been published regarding its putative advantages over traditional surgical techniques. The laparoscopic surgical technique has evolved from external intraperitoneal onlay, to transabdominal preperitoneal, to totally extraperitoneal. The laparoscopic techniques involve the use of general anesthesia, and the associated higher operative costs and complication rates may not offset the potential benefits of less postoperative pain.⁷⁵ Laparoscopic approaches to solid abdominal organs, especially the spleen, kidney, and adrenal gland, continue to be described. A comparative study of laparoscopic and open splenectomy reported by a group from the University of California at San Francisco noted equivalent blood loss, complication rates, transfusion requirements, and hospital costs.⁷⁶ Longer operative times, earlier return to regular diet, and shorter hospital stay were features of the laparoscopic group. Goletti and Buccianti⁷⁷ reported a mean operative time of 109 minutes and a median postoperative stay of 3 days in their series of 25 patients undergoing laparoscopic adrenalectomies.

Despite the significant advances in surgery over the past century, the diagnosis of acute appendicitis continues to present problems for clinicians. In 20% of patients with appendicitis, the diagnosis was missed initially, and in 15–40% percent of those undergoing emergency operations for suspected appendicitis, the appendix was normal.⁷⁸ The laparoscopic appendectomy technique, in a prospective, randomized study, was associated with longer duration of surgery, shorter hospital stay, and no differences in terms of time to return to activity and work compared with conventional open surgery.⁷⁹ Case reports, with associated literature reviews and editorial comments, highlighted concerns about trocar site recurrence after laparoscopic colectomy for colorectal cancer.^{80,81} Preliminary experimental data confirmed a significantly increased incidence of diffuse carcinomatosis, even when the procedure was performed for locally noninvasive tumors.⁸²

PHYSIOLOGIC CHANGES AND COMPLICATIONS

Significant data have been accumulated on complications associated with laparoscopy.⁸³ The complications unique to laparoscopic cholecystectomy, reviewed by Strasberg and colleagues,⁸⁴ include bile duct injury and disruption of major blood vessels. Other problems relate to the cardiopulmonary effects of pneumoperitoneum, systemic CO₂ absorption, extraperitoneal gas insufflation, and venous gas embolism (Table 38-5).

RESPIRATORY SYSTEM
 • Hypoxemia
 • Increased airway resistance
 • Decreased functional residual capacity
 • Increased dead space ventilation
 • Increased minute ventilation
 • Increased oxygen consumption
 • Increased carbon dioxide production
 • Increased venous gas embolism

CARDIOVASCULAR SYSTEM
 • Hypertension
 • Tachycardia
 • Myocardial ischemia
 • Decreased stroke volume
 • Increased systemic vascular resistance
 • Increased pulmonary vascular resistance
 • Increased pulmonary artery pressure
 • Increased pulmonary capillary pressure
 • Increased pulmonary artery pressure
 • Increased pulmonary capillary pressure
 • Increased pulmonary artery pressure
 • Increased pulmonary capillary pressure
 • Increased pulmonary artery pressure
 • Increased pulmonary capillary pressure

Table 38-5. LAPAROSCOPIC SURGERY: SUMMARY OF POTENTIAL PHYSIOLOGIC CHANGES

Trocar Insertion

The establishment of a pneumoperitoneum during laparoscopy is essential for most laparoscopists before a trocar and laparoscope can be introduced into the peritoneal cavity. To achieve a pneumoperitoneum, a Veress needle is introduced into the peritoneal cavity and CO₂ gas is insufflated. Injuries have been reported to occur as the Veress needle or trocar is introduced blindly through the abdominal wall before insertion of the laparoscope (Fig. 38-4). Such injuries have included bleeding from abdominal wall vessels, gastrointestinal tract perforations, hepatic and splenic tears, major vascular trauma, avulsion of adhesions, omental disruption, and herniation at the trocar insertion site.⁸⁵ Near the level of the umbilicus, both the medial vessels (superficial and inferior epigastric) and lateral vessels (superficial and deep circumflex iliac) are at risk for injury.⁸⁶ To avoid injuries associated with blind Veress needle and trocar insertion, Hasson⁸⁷ has advocated a minilaparotomy technique for pneumoperitoneum creation. In this open technique, the first or primary trocar is inserted through a minilaparotomy incision, and the potential complications of blind Veress needle and trocar insertion are avoided.

Figure 38-4. Laparoscopic cholecystectomy: surgical incision sites.

Gees and Holden⁸⁸ retrospectively reviewed 2201 laparoscopic procedures performed in Columbus, Ohio between 1992 and 1995. There were three major vascular injuries—the left common iliac vein, the right common iliac artery, and the left internal iliac artery—for a combined incidence of 0.14%. Noga *et al*⁸⁹ highlighted the role of the anesthesiologists in the early diagnosis of retroperitoneal hematoma, a potentially fatal complication laparoscopic surgery.

Patient Position

During laparoscopic surgery, the patient is positioned to produce gravitational displacement of the abdominal viscera away from the surgical site. Gravity has profound effects on the cardiovascular and pulmonary systems. The head-down tilt of 10–20 degrees commonly used both in gynecologic procedures and for the initial trocar insertion in laparoscopic cholecystectomy is accompanied by an increase in central blood volume⁹⁰ and a decrease in vital capacity and diaphragmatic excursion,⁹¹ whereas the rT position favors improved pulmonary dynamics⁹² but reduced venous return.^{93,94} These changes associated with positioning may be influenced by the extent of the tilt,⁹⁵ the patient's age, intravascular volume status, and associated cardiac disease,^{96,97} anesthetic drugs administered, and ventilation techniques. The potential for inadvertent right mainstem bronchial intubation and hypoxemia associated with Trendelenburg positioning was highlighted by Wilcox and Vandam.⁹⁸ A subsequent case report confirmed this possibility.⁹⁹ The proposed mechanism is that the endotracheal tube, firmly secured at its proximal end to the mandible, does not always move along with the trachea as the diaphragm causes cephalad displacement of the lung and carina.¹⁰⁰ In one report, prolonged laparoscopic surgery in the Trendelenburg position was complicated by brachial plexus injury.¹⁰¹

Creation of Pneumoperitoneum

Pneumoperitoneum creation involves the intraperitoneal insufflation of CO₂ through a Veress needle while the patient is in a 15–20-degree Trendelenburg position. The potential difficulties that may be encountered during creation of pneumoperitoneum are outlined in the following.

Technical Difficulties

Extraperitoneal insufflation of CO₂ is one of the most common complications of laparoscopy. The incidence of this complication has been reported to vary from 0.4 to 2%.¹⁰² Such extraperitoneal insufflation may cause subcutaneous or retroperitoneal emphysema, prolonging surgery or causing its abandonment. Subcutaneous emphysema may occur if the tip of the Veress needle does not penetrate the peritoneal cavity before insufflation of gas. This may cause the insufflating gas to accumulate in the subcutaneous tissue or between the fascia and the peritoneum. Lew *et al*¹⁰³ reported extensive subcutaneous emphysema, which involved the neck, chest, and abdomen and extended to the groin, attributed to subcutaneous insufflation of CO₂ from a poorly stabilized Veress needle.

Extraperitoneal insufflation has been associated with higher levels of CO₂ absorption than intraperitoneal insufflation and may be the cause of a sudden rise in PETCO₂ during the procedure.¹⁰⁴

Pneumomediastinum and Pneumothorax

Pneumothorax is a rare but potentially life-threatening complication of pneumoperitoneum. The history, pathogenesis, and management of such clinical situations were reviewed by Prystowsky and colleagues.¹⁰⁵ This complication occurs primarily on the right side. Insufflated gas may track around the aortic and esophageal hiatuses of the diaphragm into the mediastinum and then rupture into the pleural space. However, an anatomic basis for passage of gas into the thoracic cavity through a diaphragmatic defect is more likely. Commonly, these weak points or defects occur at the pleuroperitoneal hiatus or foramen of Bochdalek, the outer crus, or the esophageal hiatus. Pneumothoraces have been reported in association with subcutaneous emphysema and pneumomediastinum, whereas an isolated tension pneumothorax has been reported during laparoscopic cholecystectomy after trocar insertion and intraperitoneal CO₂ insufflation.¹⁰⁶ A congenital defect of the diaphragm (patent pleuroperitoneal canal) through which the insufflated gas passes into the thoracic cavity has been suggested as the underlying mechanism. Alternatively, a ruptured bleb or bulla could have produced the tension pneumothorax independent of the pneumoperitoneum.

Hasel *et al*¹⁰⁷ reported three cases in which extravasation of CO₂ during laparoscopic cholecystectomy resulted in subcutaneous emphysema associated with pneumomediastinum, pneumoscrotum, pneumothorax, and ocular emphysema. It was assumed that intraperitoneal CO₂ traversed into the mediastinum through a defect in the diaphragm, and to the scrotum along the spermatic cord through the inguinal canal. Excessively high IAPs during CO₂ insufflation may have contributed to these complications, which resolved uneventfully within 24 hours.

Undetected pneumothorax/pneumomediastinum can be life threatening. The diagnosis should be considered in the presence of increased airway pressure, hemodynamic compromise, oxygen desaturation, or unexpected hypoxemia-hypercarbia. Subcutaneous emphysema of the neck, chest wall, and face should alert the anesthesiologist to the possibility of such associated complications. As soon as this possibility is suspected, a chest radiograph should be obtained to rule out a pneumomediastinum or pneumothorax. If the hemodynamic status is stable and if there is clinical evidence of a tension pneumothorax, chest tube decompression and abdominal deflation are indicated before obtaining a chest radiograph. Once the chest drain is in a satisfactory position, the abdomen can be insufflated and the procedure continued if the patient remains stable. If the pneumothorax is recognized near the end of the operation and the patient is stable, the surgery can be completed without therapeutic intervention. Once the abdomen is deflated, the CO₂ in the pleural cavity is rapidly resorbed, obviating the necessity for a chest tube.

Cardiovascular Effects

The extent of cardiovascular changes associated with creation of the pneumoperitoneum depends on the interaction of factors that include positioning of the patient,¹⁰⁸ the IAPs obtained during insufflation,¹⁰⁹ and the neurohumoral effects of absorbed CO₂.¹¹⁰ Preoperative cardiorespiratory status,¹⁴ the intravascular volume,¹¹¹ and the anesthetic agents used may also be significant.

The physiologic changes associated with laparoscopy and pneumoperitoneum in gynecologic surgery have been well described.^{112,113} This patient population in general comprises healthy women undergoing short procedures in the Trendelenburg position. In comparison, abdominal laparoscopic surgery has been recommended for elderly and infirm patients who may not tolerate conventional surgery,^{114,115} although the technique requires complicated positioning and increased operating time.⁶

The hemodynamic effects of CO₂ insufflation and rT positioning were comprehensively reviewed by Wahba *et al*¹¹⁶ in a meta-analysis of North American and United Kingdom literature. The dynamic physiologic changes that occur during laparoscopic abdominal surgery appear to have a phasic component. Joris *et al*¹¹⁷ used flow-directed pulmonary artery catheters to assess the effects of CO₂ insufflation to an IAP of 14 mm Hg in healthy patients undergoing laparoscopic cholecystectomy. CI was reduced by 35–40% from baseline after induction of anesthesia and rT positioning, and further reduced to 50% of its preoperative value 5 minutes after the beginning of CO₂ insufflation. CI gradually improved after 10 minutes of CO₂ insufflation. Other studies support this phasic change in hemodynamic function.^{118,119} However, some investigators have documented an unchanged CI during insufflation of CO₂.^{120,121}

The filling pressures of the heart, central venous pressure, and pulmonary artery occlusion pressure (PAOP) initially are reduced after induction of anesthesia and

venous pooling in the rT position. After CO₂ insufflation, the right- and left-sided filling pressures substantially increase.^{14,117,122,123} The mechanical effects of insufflated CO₂ may explain some of these changes. Modern laparoscopic insufflators automatically terminate the gas flow when a preset IAP of 10–15 mm Hg is reached. The insufflated CO₂ compresses both the venous capacitance system and the arterial resistance vessels. The mechanical effect on the venous system involves transiently increased venous return followed by impedance.¹²⁴ However, the increase in IAP has been claimed to cause a proportionate increase in intrathoracic pressure, and this probably also contributes to the documented rise in central venous pressure and PAOP.^{125,126}

The compressive effects on the arterial vasculature result in a dramatic increase in calculated systemic vascular resistance (SVR), particularly during the initial phase of CO₂ insufflation. MABP also rises substantially, reflecting the increased afterload with an associated deterioration in CI.^{14,117,118} The magnitude of CI reduction is directly proportional to the insufflation pressure. Westerband *et al.*,¹¹⁸ using impedance cardiography, reported a 30% reduction in CI and a 79% increase in SVR immediately after peritoneal insufflation to 15 mm Hg. The safe upper limit of IAP insufflation was studied in an animal model investigating stepwise increases in IAP of 8, 12, and 16 mm Hg. The threshold pressure that had minimal effects on hemodynamic function was found at an IAP of 12 mm Hg. The authors recommend this pressure limit to avoid cardiovascular compromise during pneumoperitoneum.¹⁰⁹

In a series of 13 otherwise healthy patients, Cunningham *et al.*¹⁰⁸ found that left ventricular function, as determined by TEE, was preserved after CO₂ insufflation and patient position changes, despite variations in left ventricular loading conditions. However, CO₂ insufflation was associated with increases in left ventricular end-systolic wall stress, concomitant with increases in systemic arterial pressure. In addition, left ventricular end-diastolic volume decreased after rT positioning, indicating reduced venous return. Left ventricular ejection fraction was maintained throughout the study period in this investigation of otherwise healthy patients. However, it might reasonably be speculated that the aforementioned changes in left ventricular loading conditions might have had deleterious consequences in a patient population with significant cardiovascular disease.

Safran *et al.*¹⁴ investigated ASA Class III–IV patients with severe heart disease. CO decreased and SVR and MABP increased after CO₂ insufflation. Significant reductions in $\bar{S}\bar{V}O_2$ and oxygen delivery were noted in 50% of their patients. Feig and colleagues¹²⁷ documented significant increases in SVR, MABP, PAOP, and LVSWI occurring with insufflation pressures up to 15 mm Hg in 15 ASA Class III–IV patients. Persistent refractory acidemia and hypercarbia complicated four cases in the study. Two patients had significant cardiac arrhythmias requiring treatment during insufflation. Hypercarbia and respiratory acidosis may cause a decrease in myocardial contractility and a lowering of the arrhythmia threshold, particularly if the myocardium is already sensitized by the use of volatile anesthetic agents. Hypercarbia is reported to increase CO, MABP, heart rate, and plasma epinephrine and norepinephrine levels.¹²⁸ Because the direct effects of hypercarbia include arteriolar dilatation and myocardial depression, the overall change in cardiovascular function is thought to be mediated by the catecholamine release.

A number of case reports have described acute hypotension, hypoxemia, and cardiovascular collapse associated with laparoscopy.^{129,130} Postulated causes included (1) hypercarbia, which may induce dysrhythmias; (2) reflex increases in vagal tone due to excessive stretching of the peritoneum; (3) compression of the inferior vena cava, leading to decreased CO; (4) hemorrhage; and (5) venous gas embolism. The clinical conditions associated with venous CO₂ embolism during laparoscopy have also been described.^{131,132} Venous CO₂ embolism in these cases was associated with profound hypotension, cyanosis, and asystole after creation of pneumoperitoneum. Beck and McQuillan¹³¹ noted a sudden decrease in PETCO₂ after 1 hour of surgery in a fatal case of embolism. The authors suggested that CO₂ could enter a tributary of the portal system during attempts at establishing the pneumoperitoneum. Rapid CO₂ exsufflation was reported to have precipitated acute hypotension, bradycardia, and hypoxemia.¹³³ Derouin and colleagues,¹³⁴ using TEE, observed CO₂ gas embolism in 11 of 16 patients studied (5 during peritoneal insufflation and 6 during gallbladder dissection). Cerebral arterial CO₂ embolism has been reported in a patient with an atrial septal defect.¹³⁵

Renal and Hepatic Blood Flow

Intra-abdominal pressure, hypercarbia, and patient position may influence renal and hepatic blood flow. Head-up position and intraperitoneal pressure greater than 12 mm Hg compromised hepatic and renal blood flow in an experimental animal study.¹³⁶ The level and duration of IAP were responsible for elevations in serum bilirubin and hepatic aminotransferases during laparoscopic surgery.¹³⁷ Although no symptoms appeared in patients with normal hepatic function, patients with severe hepatic failure should probably not be subjected to prolonged laparoscopic procedures.

During pneumoperitoneum, the plasma concentrations of dopamine, vasopressin, epinephrine, norepinephrine, renin, and cortisol rise significantly.^{138,139,140} and ¹⁴¹ Of particular importance is the time course of vasopressin and norepinephrine elevation. The plasma concentration–time course profile parallels that of the change in CI, MABP, and SVR,^{138,140} suggesting a possible cause–effect relationship. It is probable that hypercarbia and pneumoperitoneum cause stimulation of the sympathetic nervous system and release of catecholamines.¹⁴¹ The phasic restoration in CI may be a result of the direct arteriolar vasodilatory effects of CO₂ and the effects of anesthetic agents on the SVR. Overall, the hemodynamic effects of pneumoperitoneum are generally well tolerated by healthy people but require careful evaluation in compromised patients.

Respiratory Function

Carbon Dioxide Homeostasis

Peritoneal gas insufflation is essential to facilitate exposure, visualization, and manipulation of intra-abdominal contents. Although nitrous oxide has been used for diagnostic gynecologic procedures, it is flammable when electrocautery is used. Helium has not been accepted because of its insolubility in blood in the case of embolic phenomena.¹⁴² CO₂ has evolved as the insufflation gas of choice for laparoscopic surgery because of its efficacy and safety during electrocautery and laser surgery and its capability for pulmonary excretion.¹²¹

Carbon dioxide insufflation into the peritoneal cavity increases arterial CO₂ tension, which is managed by increasing minute ventilation. The absorption of CO₂ from a closed cavity depends on its diffusibility and perfusion of the walls of that cavity, and not on the rate of insufflation of the gas into the cavity.¹⁴³ Mullet *et al.*¹⁴⁴ hypothesized that the rate of CO₂ diffusion into the body depends on the duration and the site of CO₂ insufflation. They examined PETCO₂ and pulmonary CO₂ elimination during CO₂ insufflation under general anesthesia for gynecologic laparoscopy (intraperitoneal for 43 minutes), laparoscopic cholecystectomy (intraperitoneal for 125 minutes), and pelviscopy (extraperitoneal for 45 minutes). PETCO₂ and pulmonary CO₂ elimination increased in parallel from the 8th to the 10th minute after the start of CO₂ insufflation. A plateau was reached 10 minutes later in patients having intraperitoneal insufflation, whereas PETCO₂ and pulmonary CO₂ elimination continued to increase slowly throughout CO₂ insufflation during pelviscopy.

Wittgen *et al.*¹⁴⁵ compared 20 healthy patients undergoing laparoscopic cholecystectomy with 10 ASA Class II–III patients. Compared with the healthy group, there were significant decreases in pH and increases in PaCO₂ during pneumoperitoneum in the ASA III group, and this group also had significantly higher minute ventilation and peak inspiratory pressures than baseline values. Increasing minute ventilation in most cases maintains PaCO₂ within normal limits but inevitably leads to some increase in airway pressure. However, in ASA Class III or IV patients, PaCO₂ may remain elevated despite adjusting minute ventilation to normalize PETCO₂.¹²⁷ Preoperative evaluation with pulmonary function tests demonstrating forced expiratory volumes less than 70% of predicted values and diffusion defects less than 80% of predicted values can identify patients at risk for development of hypercarbia and respiratory acidosis after pneumoperitoneum. Hall *et al.*¹⁴⁶ reported a case of acute profound hypercarbia occurring late in the procedure caused by CO₂ insufflation and first detected by capnography.

Intraoperative Changes

Respiratory function changes occurring during laparoscopic cholecystectomy may differ from those reported during gynecologic laparoscopic procedures, probably because of the intra-abdominal nature of the surgery and the prolonged insufflation times required. Functional residual capacity (FRC) and lung compliance decrease with assumption of the supine position and cephalad shift of the diaphragm and with induction of general anesthesia.¹⁴⁷ However, the insufflation of intraperitoneal CO₂ may exacerbate these changes. Lung and chest wall mechanical impedance increase with increasing IAP.¹⁴⁸ The increase depends on body configuration and is greater in a head-down position. These changes should be considered in patients for whom increases in impedance may be critical, such as obese patients and those with pulmonary disease.

Hypoxemia during laparoscopic abdominal surgery can have many causes, including a reduction in compliance, which may lead to diminished FRC relative to closing volume and $\dot{V}O_2$ mismatch. Intraoperative hypoxemia is uncommon in healthy patients.^{149,150} Joris *et al.*¹¹⁷ found no significant increased intrapulmonary shunt despite reductions in CO and oxygen delivery in 20 healthy patients during laparoscopic cholecystectomy. We reported a case of intraoperative hypoxemia complicating

laparoscopy in an obese patient with sickle hemoglobinopathy.¹⁵¹ Hypoxemia may be caused by regurgitation and aspiration of gastric contents. Duffy¹⁵² reported gastric regurgitation in 2 of 93 fasted patients undergoing laparoscopic gynecologic surgery. Similarly, during laparoscopic cholecystectomy, there are several factors that predispose to regurgitation, including the initial steep head-down tilt, insufflation of intraperitoneal gas, and mechanical pressure exerted on the abdomen by the surgical team. The hazards of intraoperative pneumothorax are described earlier.

Postoperative Changes

There have been few prospective, randomized studies comparing laparoscopic and open cholecystectomy. Pulmonary dysfunction after open cholecystectomy is multifactorial and has been characterized as a restrictive pattern with a decrease in vital capacity and FRC. The common denominator is division of the abdominal musculature, which produces incisional pain, diaphragmatic dysfunction, and impairment of ventilatory mechanics. It has been suggested that laparoscopic surgery may reduce postoperative pulmonary complications by avoiding the restrictive pattern of breathing that usually follows upper abdominal surgery.

Schauer *et al*¹⁵³ observed that, compared with patients undergoing open cholecystectomy, the laparoscopic procedure was associated with 30–38% less impairment of pulmonary function, including FRC, forced expiratory volume in 1 second (FEV₁), maximum forced expiratory flow, and total lung capacity. Joris and colleagues¹⁵⁴ differentiated the influence of site of surgery, parietal trauma, intraoperative patient position, and pneumoperitoneum on pulmonary function and, by extension, clarified their roles in the pathophysiology of postoperative pulmonary dysfunction in women of normal body mass index and free of cardiopulmonary disease. Reductions in effort-dependent measures of pulmonary function—FEV₁, peak expiratory flow rate, and vital capacity—were less than those usually associated with “open” cholecystectomy, and return to normal function was more rapid. Although the incidence of surgical trauma to the gallbladder is almost identical with open and laparoscopic techniques, the advantage of the latter may relate to the minimal trauma to the abdominal wall.¹⁵⁵ Postoperative residual pneumoperitoneum *per se* may not explain the diaphragmatic dysfunction observed after laparoscopic cholecystectomy. Visceral afferents originating in the gallbladder area or somatic afferents arising from the abdominal wall, which exert an inhibitory action on phrenic discharge, may be the cause of this diaphragmatic dysfunction. Erice *et al*¹⁵⁶ concluded that the internal site of surgical intervention is the crucial variable determining diaphragmatic inhibition after they observed a decrease in maximum transdiaphragmatic pressure with laparoscopic cholecystectomy and not laparoscopic hernia repair.

ANESTHETIC MANAGEMENT

A number of reviews have highlighted the anesthetic considerations for laparoscopic cholecystectomy, including anesthetic technique, intraoperative opioid and nitrous oxide administration, and appropriate monitoring.^{157,158} The choice of anesthetic technique for upper abdominal laparoscopic surgery is mostly limited to general anesthesia because of patient discomfort associated with creation of pneumoperitoneum and the extent of position changes associated with the procedure. Cuffed endotracheal tube placement minimizes the risk of acid aspiration if reflux occurs. Controlled ventilation is recommended because several factors may induce hypercarbia, including depression of ventilation by anesthetic agents, absorption of CO₂ from the peritoneal cavity, and mechanical impairment of ventilation by the pneumoperitoneum and the initial steep Trendelenburg position.

After induction of anesthesia, a urinary catheter and nasogastric tube are placed. Bladder catheterization is undertaken to decompress the bladder and thus avoid trauma to intra-abdominal contents at the time of trocar insertion. Gastric decompression may also reduce the risk of visceral puncture, as well as improving laparoscopic visualization and facilitating retraction of the right upper quadrants.¹⁵⁹ Data reported by Goodale and colleagues¹²⁴ suggest that the increased IAP with pneumoperitoneum causes venous stasis. Measures to reduce stasis, such as pneumatic compressive stockings, may be indicated during these procedures. In general, local or regional anesthetic techniques have not been advocated for laparoscopic cholecystectomy or other upper abdominal laparoscopic procedures.

Anesthetic Agents

Limited data are available concerning the impact of anesthetic management on postoperative outcome after laparoscopic cholecystectomy. Rose *et al*¹⁶⁰ prospectively documented intraoperative critical observations and adverse outcomes in the recovery room for the first 101 patients undergoing laparoscopy at their institution. They compared the anesthetic management and outcome with patients undergoing open cholecystectomy. Intraoperative hypothermia (35°C nasal/oral) and hypotension (systolic blood pressure <80 mm Hg) were documented in 6.2% and 12.9%, respectively, of patients undergoing laparoscopic cholecystectomy, compared with 2.9% and 3.4% for open cholecystectomy. Of the laparoscopic cholecystectomy patients, 31.4% had skin temperature recordings of 35°C in the recovery room.

Most authors studying laparoscopic techniques have used balanced anesthetic techniques with oxygen, nitrous oxide, volatile anesthetic agents, relaxants, and opioids. Opioid or cholinergic agents have been reported to cause spasm of the sphincter of Oddi,¹⁶¹ which can be antagonized by several drugs, including naloxone,¹⁶² glucagon,¹⁶³ and nalbuphine.¹⁶⁴ The advent of parenteral perioperative NSAIDs and the tendency for less postoperative pain associated with the laparoscopic approach may obviate perioperative narcotic administration.

Pain after laparoscopic surgery may result from tissue injury, nociceptor sensitization, and activation of central pathways. Michaloliakou *et al*¹⁶⁵ used wound infiltration with local anesthesia and NSAIDs to attenuate peripheral pain and opioids for central pain modulation. This preoperative multimodal analgesic regime was associated with less postoperative pain, nausea, and vomiting and faster recovery and discharge.

Intraperitoneal administration of local anesthetics has been reported to reduce postoperative shoulder pain after minor gynecologic laparoscopic procedures. Experiences with intraperitoneal local anesthetic administration after laparoscopic cholecystectomy have ranged from significant reduction in postoperative pain during the first 48 hours with 10 ml of 0.5% bupivacaine,¹⁶⁶ to no effect in reducing postoperative pain, improving lung function, or attenuating metabolic endocrine responses with 20 ml 0.25% bupivacaine.¹⁶⁷ Joris and colleagues¹⁶⁸ investigated the time course of parietal (abdominal wall), visceral, and shoulder pain after laparoscopic cholecystectomy. Visceral pain accounted for most of the discomfort after laparoscopic cholecystectomy and was not attenuated by intraperitoneal administration of 80 ml 0.125% bupivacaine.

Postoperative nausea and vomiting are among the most common and distressing symptoms after laparoscopic surgery.¹⁶⁹ Ondansetron, a highly potent and selective 5-hydroxytryptamine type 3 (5-HT₃) receptor antagonist, has proved to be an effective oral and iv prophylaxis against postoperative emesis.¹⁷⁰

Use of Nitrous Oxide

The use of nitrous oxide during laparoscopic surgery is controversial because of concerns over its ability to produce bowel distention during surgery and to increase postoperative nausea. The effects of nitrous oxide on bowel distention during surgery and bowel function after surgery were studied in 150 patients undergoing elective colonic surgery.¹⁷¹ There was no difference between the air–oxygen group and the nitrous oxide–oxygen group in duration of anesthesia, distention of the bowel, and postoperative bowel function. The safety and efficacy of nitrous oxide specifically during laparoscopic cholecystectomy were investigated by Taylor *et al*.¹⁷² There were no significant differences between the groups receiving air and nitrous oxide with respect to operating conditions or bowel distention. More important, there were no time-related changes in either variable during the course of surgery. Finally, the incidence of postoperative nausea and vomiting was similar in both treatment groups. However, a meta-analysis performed by Divatia and colleagues¹⁷³ noted that the omission of nitrous oxide reduced the risk of postoperative nausea and vomiting by 28%. In the subgroup analysis, the maximum effect of nitrous oxide omission was seen in female patients.

In summary, there is no conclusive evidence demonstrating a clinically significant effect of nitrous oxide on surgical conditions during laparoscopic cholecystectomy or on the incidence of postoperative emesis. With the caveats previously described, nitrous oxide therefore may still be a useful adjuvant during general anesthesia for this procedure.

Monitoring

Standard monitoring techniques are required for all patients undergoing laparoscopic surgery. PETCO₂ is most commonly used as a noninvasive substitute for PaCO₂ in evaluating the adequacy of ventilation during laparoscopic cholecystectomy. Wahba and Mamazza¹⁷⁴ studied 28 otherwise healthy patients undergoing elective laparoscopic cholecystectomy to determine the increase in minute ventilation required to maintain the preinsufflation arterial CO₂ tension and whether PETCO₂ could safely be used as an index of PaCO₂ and, therefore, of the adequacy of ventilation during pneumoperitoneum. Increasing minute ventilation by 12–16% maintained the PaCO₂ close to the preinsufflation levels. PETCO₂ was not a satisfactory noninvasive index of PaCO₂ if it exceeded 41 mm Hg and if large volumes of CO₂ were insufflated. Otherwise, PETCO₂ proved to be a reasonable approximation of PaCO₂ in these patients free from cardiopulmonary disease. In contrast, patients with preoperative cardiopulmonary disease demonstrated significant increases in PaCO₂ not reflected by comparable increases in PETCO₂ during insufflation.¹⁴⁵

PaCO₂ may be underestimated by PETCO₂ if there is a reduction in CO or an increase in \dot{V}/\dot{Q} mismatch, and occasionally PETCO₂ may overestimate PaCO₂.¹⁷⁵ In

patients with significant cardiopulmonary disease, it would seem prudent to monitor PaCO₂ levels at times during the procedure to avoid problems with hypercarbia and acidosis. Preoperative pulmonary function test results with low forced expiratory and vital capacity volumes and high ASA grouping can predict those patients at risk for development of hypercarbia and acidosis during laparoscopic cholecystectomy, but patient age and duration of surgery do not seem to be influencing factors.¹⁷⁶

Invasive hemodynamic monitoring may be required in ASA Class III–IV patients to monitor the cardiovascular response to insufflation and institute therapy. Because the CO is inversely proportional to the insufflation pressure in the abdomen, gradual insufflation should be monitored by the anesthesiologist and a limit of 8–12 mm Hg set as maximal inflationary pressure. Limiting the rT tilt may attenuate the reduction in CO during pneumoperitoneum.¹⁷⁷ Refractory persistent hypercarbia, acidosis, or a reduction in S_VO₂ may necessitate exsufflation of pneumoperitoneum or lowering of the insufflation pressure.¹⁷⁷ Finally, a decision to convert to an open procedure may be an important option in those patients with significant hemodynamic compromise.

SUMMARY

Minimally invasive therapy aims to minimize the trauma of any interventional process but still achieve a satisfactory therapeutic result. The development of “critical pathways,” rapid mobilization, and early feeding have contributed to the goal of shorter hospital stay. This concept has been extended to include laparoscopic cholecystectomy and laparoscopic hernia repair.¹⁷⁸ Reports have been published confirming the safety of same-day discharge for most laparoscopic cholecystectomy patients.¹⁷⁹ The minimal-access nature of the surgical insult and the lack of opioid administration may minimize postoperative hypoxemia and sleep disturbance.¹⁸⁰ However, we caution against overenthusiastic ambulatory laparoscopic cholecystectomy based on the rational, but unproven, assumption that early discharge will lead to occasional delays in diagnosis and management of postoperative complications. A New South Wales group in Australia has reported a 1.37% incidence of ICU admissions after 725 general surgical procedures.¹⁸¹ Surgical complications were associated with delayed diagnosis and longer ICU admissions.

Endoscopic-assisted intra-abdominal procedures recently introduced include appendectomy, herniorrhaphy, adhesiolysis, antireflux and acid-reducing procedures, and intestinal resections. Case reports of bile duct injuries after laparoscopic cholecystectomy and unusual modes of colorectal, renal, and gallbladder carcinoma recurrence after laparoscopic-assisted surgery confirm the need for rigorous prospective study of these new procedures.

Intraoperative complications of laparoscopic surgery are mostly due to traumatic injuries sustained during blind trocar insertion and physiologic changes associated with patient positioning and pneumoperitoneum creation. General anesthesia and controlled ventilation comprise the accepted anesthetic technique to reduce the increase in PaCO₂. Investigators have documented the cardiorespiratory compromise associated with upper abdominal laparoscopic surgery, and particular emphasis is placed on careful perioperative monitoring of ASA Class III–IV patients during insufflation. Setting limits on the inflationary pressure is advised in these patients. Anesthesiologists must maintain a high index of suspicion for complications such as gas embolism, extraperitoneal insufflation and surgical emphysema, pneumothorax, and pneumomediastinum.

Postoperative nausea and vomiting are among the most common and distressing symptoms after laparoscopic surgery. A highly potent and selective 5-HT₃ receptor antagonist, ondansetron, has proven to be an effective oral and iv prophylaxis against postoperative emesis in preliminary studies. Opioids remain an important component of the anesthesia technique, although the introduction of newer, more potent NSAIDs may diminish their use. A preoperative multimodal analgesic regimen involving skin infiltration with local anesthesia, NSAIDs to attenuate peripheral pain, and opioids for central pain may reduce postoperative discomfort and expedite patient recovery and discharge. There is no conclusive evidence to demonstrate clinically significant effects of nitrous oxide on surgical conditions during laparoscopic cholecystectomy or on the incidence of postoperative emesis. Laparoscopic cholecystectomy has proven to be a major advance in the treatment of patients with symptomatic gallbladder disease.

The liver occupies the epicenter of a diverse spectrum of vital physiologic functions and plays an essential role in maintaining perioperative homeostasis. For example, the liver moderates hypotensive responses to acute losses of blood via its reservoir function, and helps to prevent the development of coagulopathies through its synthesis of clotting factors and the degradation of fibrinolytic substances. Predictable termination of the pharmacologic effects of many anesthetic agents depends on hepatic clearance mechanisms. In addition, the liver nourishes the essential organs, helping to sustain them during the fasted state. Moreover, it defends the body against invading microorganisms, maintains immunologic surveillance, and modulates inflammatory processes. Such vital functions are often unappreciated when the liver is healthy.

The liver is a remarkably resilient organ, with an unparalleled regenerative capacity and substantial physiologic reserves. These reserves, however, enable insidious diseases, such as hepatitis C, to silently destroy a majority of the liver. Few, if any, symptoms develop and many patients remain unaware of their condition until irreversible hepatic damage has occurred. Identifying patients with marked limitations of hepatic reserve but no overt hepatic dysfunction is important and requires a careful preoperative history and physical examination. These patients are often at increased risk for perioperative complications and postoperative liver dysfunction, particularly when undergoing major operative procedures. Unfortunately, when the pathogenesis of postoperative hepatobiliary disorders is unclear, the anesthetic often gets the blame.

As therapies for stabilizing chronic hepatic diseases continue to improve, an increasing number of patients with moderate-to-severe liver disease will be presenting for surgery. Certain operative procedures (e.g., laparotomy), when performed in patients with severe liver disease, have been associated with rates of morbidity and mortality that are stunning. For example, a British study documented a 30-day mortality rate after laparotomy of 31%, and reported that all patients with viral or alcoholic hepatitis died, as did most of those with ascites.¹ In a subsequent U.S. study, the 30-day mortality rate approached 83% in patients with severe hepatic disease and ascites, and reached 91% when their prothrombin time (PT) was prolonged by more than 2.5 seconds.² Because patients with hepatic dysfunction may be

at extremely high risk for perioperative complications, anesthesiologists must understand the interactions between liver disease, surgical procedures, and anesthetic interventions, so that we can formulate and orchestrate therapeutic plans to optimize patient outcome.

HEPATIC ANATOMY

The liver is the largest gland in the human body, accounting for nearly 2% of the total body mass of an adult and about 5% of a newborn's mass.³

Lobes Versus Segments of the Liver

Physicians of prior eras viewed the liver as a bilobed organ, with right and left lobes separated by the falciform ligament (a peritoneal fold connecting the diaphragm and anterior abdominal wall). Contemporary anatomic classifications include lobar and segmental systems. The former system derives from topographic anatomy of the liver and specifies four distinct lobes (left, right, caudate and quadrate; [Fig. 39-1](#)), whereas the latter (French or Couinaud) relates to physiologic anatomy ([Fig. 39-2](#)). Couinaud partitions the liver into eight functionally independent segments, each with its own vascular inflow, vascular outflow, and biliary drainage. This system enables hepatic resections along segmental planes, which prevents major disruptions of hepatobiliary function and facilitates the preservation of vital tissue and extirpation of nonviable tissue.⁴ By coupling segmental concepts with innovative imaging techniques, radiologists can construct precise, three-dimensional models of a patient's liver to pinpoint the proximity of lesion(s) to critical intrahepatic structures. Such information simplifies surgical decision making, enhances the resectability of a variety of lesions, and improves outcomes for patients undergoing hepatic operations for neoplasms or trauma.⁵

Figure 39-2. Segmental division of the liver according to Couinaud's nomenclature. (Reprinted with permission from Parks RW, Chryso E, Diamond T: *Br J Surg* 86:1121, 1999.)

Vascular Supply of the Liver

The liver receives about 25% of the cardiac output, and therefore has an average blood flow of between 100 and $130 \text{ ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$. The hepatic artery delivers one-fourth of this flow but nearly one-half (45–50%) of the oxygen supply; the portal vein provides three-fourths of the hepatic flow and roughly one-half (50–55%) of the oxygen. Because portal venous blood has already perfused the preportal organs (stomach, intestines, spleen, and pancreas) ([Fig. 39-3](#)), it is partially deoxygenated and enriched with nutrients and other substances absorbed from the gastrointestinal tract.

Figure 39-3. Schematic representation of splanchnic circulation. (Reprinted with permission from Gelman S: *Effects of anesthetics on splanchnic circulation*. In Altura BM, Halevy S [eds]: *Cardiovascular Action of Anesthetics and Drugs Used in Anesthesia*, p 127. Basel, Karger, 1986.)

The hepatic artery arises from the celiac axis ([Fig. 39-3](#)) and has abundant collateral circulation. The portal vein forms by the anastomosis of the superior mesenteric and splenic veins and has numerous tributaries ([Fig. 39-1](#)), which are normally of little importance. When patients develop portal hypertension, however, these normally rudimentary connections form large portosystemic shunts, permitting portal venous blood to return to the heart without traversing the liver. These shunts produce many of the pathologic findings and severe complications of portal hypertension (*e.g.*, esophageal varices).

Intrahepatic Circulation

As the hepatic artery and portal vein approach the porta hepatis, each bifurcates into left and right branches. These branches enter the liver, arborize in parallel, and diminish in caliber as they penetrate the hepatic parenchyma. At the end of their intrahepatic journeys, these vessels become terminal hepatic arterioles and terminal portal venules ([Fig. 39-4](#)).

Figure 39-4. Relationship of branches of the portal vein (PV), hepatic artery (HA), and bile duct (BD). Notice the peribiliary capillary plexus that envelops the bile ducts. These three structures constitute a portal triad, which is a transverse section of a portal canal. (Reprinted with permission from Jones AL: Anatomy of the normal liver. In Zakim D, Boyer T (eds): Hepatology: A Textbook of Liver Disease, 3rd ed, p 3. Philadelphia, WB Saunders, 1996.)

Most terminal vessels drain directly into the hepatic sinusoids, delivering substrates to, and removing products from, the neighboring liver cells. Before emptying into the sinusoids, some hepatic arteriolar blood flows through the peribiliary capillary plexus, which plays a major role in bile secretion and absorption (Fig. 39-4).

A sinusoid is typically 7–15 μm wide, but its width may increase to 180 μm under certain physiologic conditions. The pressure within the sinusoids is normally 2–3 mm Hg above central venous pressure. Sinusoids have a large reservoir capacity, are highly compliant, and have an extremely low resistance.

Blood egresses from the distal end of a sinusoid through a terminal hepatic venule, and immediately enters a central vein (Fig. 39-5). It then flows through sublobular veins to progressively larger tributaries that ultimately form one of the three major hepatic veins (right, middle, and left). A short extrahepatic segment joins each major vein to the inferior vena cava (IVC). If thrombosis of the major hepatic veins occurs (Budd-Chiari syndrome), the small posterior caudate veins become important for draining hepatic blood into the IVC.

Figure 39-5. Schematic view of liver lobule: The central vein (CV) lies in the center of the figure surrounded by anastomosing cords of block-like hepatocytes. About the periphery of this schema are six portal areas (PA) consisting of branches of the portal vein, the hepatic artery, and the bile duct. (Reprinted with permission from Jones AL: Anatomy of the normal liver. In Zakim D, Boyer T (eds): Hepatology: A Textbook of Liver Disease, 3rd ed, p 3. Philadelphia, WB Saunders, 1996.)

Hepatic Microanatomy: Classic Liver Lobule Versus Acinar Lobule

The classic lobule is roughly a hexagonal prism of liver tissue. A central vein courses longitudinally through the prism's center and runs parallel to six vertically aligned portal canals that define the angles of the hexagonal structure (Fig. 39-5). Each canal contains connective tissue, lymphatics, nerves, and a portal triad (terminal branches of portal vein, hepatic artery, and bile duct). Viewed in transverse section, a lobule is an array of anastomosing cords of cuboidal hepatocytes, separated by vascular channels (lacunae) that radiate from the six portal areas and converge on a central vein at the middle of the hexagon. A lacunar labyrinth permeates the entire lobule, except for the most peripheral portion, where a limiting plate of hepatocytes forms a near continuous wall. This wall separates the interior of the lobule from the portal canals. Only tiny terminal branches of the hepatic artery, portal vein, and bile duct can penetrate the occasional fenestrae within the limiting plate.

Human livers, unlike those of several other species, lack well-defined interlobular connective tissue. Therefore, classic lobules are difficult to visualize in human livers. The quest to identify their boundaries led to the discovery of circumferential terminal hepatic arterioles, portal venules, and bile ductules. Reasoning that these encircling vessels supply segments of contiguous classic lobules that lie between two central veins (*i.e.*, terminal hepatic venules; Fig. 39-6), Rappaport developed the acinus lobule (acinus) concept.

Figure 39-6. Blood supply of the simple liver acinus. The oxygen tension and the nutrient level of the blood in sinusoids decrease from Zone 1 through Zone 3. Note that the lower left side of the figure also depicts Zones 1, 2 and 3 in a portion of an adjacent acinar unit. BD = bile duct; HA = hepatic artery; PV = portal vein; CV = central vein. (Reprinted with permission from Jones AL: Anatomy of the normal liver. In Zakim D, Boyer T (eds): Hepatology: A Textbook of Liver Disease, 3rd ed, p 3. Philadelphia, WB Saunders, 1996.)

The acinar concept partitions all liver cells supplied by a terminal branch of the portal vein and hepatic artery into three concentric circulatory zones, based on their proximity to the afferent vessels (Fig. 39-6). Blood enters the center of the acinus and flows centrifugally to the central veins. Zone 1 cells are closest to the portal axis and are therefore the first to receive blood. The oxygen content and nutritive value of the blood progressively decrease as blood flows from Zone 1 to Zone 3. Blood perfusing Zone 3 cells (acinar periphery) has already exchanged gases with, and collected waste products from, cells of Zones 1 and 2.

This unique microvascular arrangement allows for metabolic heterogeneity among the various zones. Cells of Zone 1 are amply equipped with mitochondria and contain the highest concentrations of Krebs cycle enzymes; they are ideally suited for oxidative metabolism and synthesis of glycogen. Zone 1 cells are of primary importance in the bile synthetic pathway that is dependent upon the plasma concentration of bile, being the first cells to encounter this readily absorbable detergent. On the other hand, cells of Zone 3 play the larger role in the bile salt-independent formation of bile.

Zone 3 cells are relatively anaerobic and well suited to regulate the rates of metabolic reactions that use molecular oxygen and produce reactive oxygen species. They have an abundance of smooth endoplasmic reticulum, reduced nicotinamide adenine dinucleotide phosphate (NADPH), and reduced cytochrome P-450, and play a

major role in the metabolism of drugs, chemicals, and toxins. The anaerobic milieu of Zone 3, however, is also its Achilles' heel because these cells are exquisitely susceptible to injury from circulatory disturbances that cause ischemia or hypoxia (e.g., hypotension, hypoxemia, severe anemia) and to toxic products of biotransformation. Thus, a decreased capacity of the liver to metabolize drugs and endogenous substances may be an early manifestation of hepatic dysfunction. Centrilobular necrosis is more likely to occur than periportal necrosis when pathophysiologic processes critically lower the oxygen supply-to-demand ratio in the liver by decreasing oxygen delivery or by increasing its extraction by cells of Zone 1 and Zone 2.

Innervation of the Liver

An anterior and a posterior plexus innervate the portal and pericapsular regions of the liver. The anterior plexus conveys postganglionic sympathetic nervous system (SNS) fibers from the celiac plexus (ganglia T7–T10), left-sided vagal fibers, and fibers from the right phrenic nerve. The anterior plexus communicates with the posterior plexus near the portal vein and bile ducts. SNS fibers innervate the hepatic arteries.

Disruption of neurotransmission through the anterior plexus can modify hepatobiliary physiology, producing alterations in the accumulation of hepatic fat and in the composition of secreted bile. Distension of the liver capsule or gallbladder causes referred pain, conveyed to the right shoulder or scapula via the third and fourth cervical nerves.

Hepatic Lymphatic System

The primary site of hepatic lymph formation is the perisinusoidal space of Disse (located between hepatocytes and the sinusoidal endothelium). This lymph travels through the periportal space of Mall (between the limiting plate and portal connective tissue), permeates the connective tissue, and drains into the lymphatic vessels of the portal canal. About 80% flows through progressively larger channels, ultimately reaching the collecting lymphatics, which exit the porta hepatis and empty into the thoracic duct at the cisterna chyli. The remaining 20% leaves the liver either via small lymphatic networks near the hepatic veins and IVC or in vessels that pierce the diaphragm and anastomose with retrosternal lymphatics. Hepatic lymph nodes are located in the porta hepatis, celiac region, and near the IVC. Small increases in hepatic venous pressure can drive an excess of intravascular fluid into the lymphatics, leading to its transudation through the hepatic capsule and into the peritoneal cavity (ascites).

REGULATION OF HEPATIC BLOOD FLOW

The hepatic circulation is regulated by mechanisms that are both intrinsic⁶ and extrinsic to the liver. Intrinsic mechanisms help to provide a constant supply of blood and oxygen to the liver. In doing so, these mechanisms stabilize the hepatic clearances of many endogenous substances and drugs, and contribute to the maintenance of venous return and cardiac output.⁶ Extrinsic mechanisms, which include a complex constellation of neural and humeral reflexes, moderate the hemodynamic consequences of major circulatory derangements. For example, when hypovolemia and hypotension occur, extrinsic reflexes are activated, resulting in the prompt deployment of the liver's blood reservoir and rapid diversion of its blood flow to essential, extrahepatic tissues, including the heart and brain.

Intrinsic Circulatory Regulation

Hepatic Arterial Buffer Response

Because the liver lacks the ability to directly regulate portal venous flow, intrinsic regulatory mechanisms operate almost exclusively by modulating hepatic arteriolar tone. The hepatic arterial buffer response—the most important of these mechanisms—causes hepatic arterial flow to vary reciprocally with changes in portal venous flow. The greatest reduction in arterial flow achievable by the buffer response occurs when portal venous flow doubles. Conversely, the buffer response produces an approximately twofold increase in arterial flow following severe reductions of portal venous flow, as occurs after placement of a portal–caval shunt or ligation of the superior mesenteric artery.⁶ Thus, at least in theory, if portal venous flow were to decrease by more than 50%, the arterial buffer response would be unable to fully prevent a decrease in hepatic blood flow, although it could be expected to totally preserve hepatic oxygenation. (Because the hepatic artery supplies 25% of the liver's blood flow and 50% of its oxygen, a doubling of the arterial flow would yield 50% of the normal total blood flow and 100% of the normal oxygen supply.)

The hepatic buffer response appears to be mediated via adenosine. Presumably, this potent arteriolar dilator is synthesized at a constant rate (independent of oxygen supply or demand) and continuously secreted in the vicinity of the terminal hepatic arterioles and portal venules.⁶ If flow through the portal vein decreases, less of the perivascular adenosine is “washed out,” leading to its accumulation around hepatic arterioles. The result is a greater degree of arteriolar dilation and an increase in hepatic arterial flow. Conversely, an increase in portal venous flow would lower the peri-arteriolar concentration of adenosine, and thereby decrease hepatic arterial flow.

Hepatic Flow Autoregulation

The hepatic arterial system also undergoes flow autoregulation (constant pressure, variable flow) when the liver is very active metabolically (postprandial) but not during the fasted state. The metabolic state modifies the composition of portal venous and systemic blood, thereby influencing hepatic blood flow. Decreases in pH and O₂ content, or increases in PCO₂ of the portal blood promote increases of hepatic arterial flow.⁷ Postprandial hyperosmolarity can increase both hepatic arterial and portal venous blood flow, but this effect would not be relevant in fasted patients. Thus, hepatic flow autoregulation is not an important mechanism during most anesthetics, given that they occur in fasted patients.

Extrinsic Circulatory Regulation

Extrinsic factors regulate blood flow through the portal vein by modulating the tone of arterioles in the preportal splanchnic organs (Fig. 39-3). Portal vein pressure (normally 7–10 mm Hg) therefore reflects both splanchnic arteriolar tone and intrahepatic resistance to portal flow. Portal venules (presinusoidal sphincters) affect the distribution of blood flow to the sinusoids; however, the hepatic venules (postsinusoidal sphincters) control venous resistance in the liver. Extrinsic mechanisms modulate this venular tone, with the sympathetic nervous system being the primary physiologic regulator. Stimulation of α₁-adrenergic receptors increases venular tone, leading to decreases in hepatic blood flow and a reduction of blood volume in the sinusoids.

Hepatic arteriolar tone is the main determinant of resistance in the hepatic arterial tree. Blood flow through the liver decreases with stimulation of certain arteriolar receptors (α₁-adrenergic or type 1 dopaminergic) and increases with activation of others (β₂-adrenergic receptors). As mentioned earlier, local and intrinsic mechanisms also modulate arteriolar tone, producing changes in arterial flow that are reciprocal to changes in portal flow (arterial buffer response). Thus, when the arterial buffer response is intact, changes in portal venous flow will induce compensatory alterations in hepatic arterial flow.

Humoral Regulators of Hepatic Blood Flow

Myriad humoral substances alter liver blood flow, including gastrin, glucagon, secretin, bile salts, angiotensin II, vasopressin, and catecholamines. Of the systemic hormones, epinephrine is most likely to attain concentrations that produce vasoactive effects. Both α- and β-adrenergic receptors exist in the hepatic arterial bed, whereas the portal vasculature has only α receptors. An injection of epinephrine directly into the hepatic artery causes vasoconstriction (α-adrenergic effect), followed by vasodilation (β₂-adrenergic effect). When injected into the portal bed, epinephrine produces only vasoconstriction. During activation of the sympathetic nervous system, the hepatic circulatory effects of epinephrine and norepinephrine would far exceed those of dopamine. Dopamine probably has little if any importance as a physiologic modulator of the hepatic circulation. Glucagon induces a graded, long-lasting dilation of hepatic arterioles; it also antagonizes arterial constrictor responses to a wide range of physiologic stimuli, including stress-induced sympathoadrenal outflow. Angiotensin II markedly constricts both hepatic arterial and portal beds, and significantly reduces mesenteric outflow; the result is a substantial decrease in total hepatic blood flow. Vasopressin also intensely constricts splanchnic vessels, markedly reducing flow into the portal vein. This action accounts for the efficacy of vasopressin to alleviate portal hypertension; of lesser importance is its ability to dilate intrahepatic portal vessels, which further lowers portal pressure.

MAJOR PHYSIOLOGIC FUNCTIONS OF THE LIVER

Blood Reservoir

The liver is a vital reservoir of whole blood in humans. It contains nearly 25–30 ml of blood per 100 g tissue, which represents 10–15% of a person's total blood volume. The autonomic innervation of the liver coupled with neurohumoral input from the systemic circulation allows for rapid, precise control of the reservoir volume. Intense sympathetic nervous system stimulation (e.g., pain, hypoxia, hypercarbia) abruptly decreases hepatic blood flow and blood volume; 80% of the hepatic blood volume

(approximately 400–500 ml) can be expelled within a matter of seconds.

Anesthetics that suppress sympathetic nervous system outflow impair the reservoir function, and predispose to circulatory decompensation when significant decreases of intravascular volume occur without immediate replacement. Severe liver disease exacerbates hypotensive effects of hypovolemia by impairing vasoconstrictor responses to catecholamines. A total failure of vasoconstriction not only incapacitates the splanchnic reservoir, but also prevents the redirection of blood flow from skeletal muscle beds and splanchnic tissues to the heart and brain.

Regulator of Blood Coagulation

The liver helps maintain normal blood clotting function in numerous ways. It synthesizes all of the coagulation factors except VIII clotting factor, VIII vWF (endothelial), and IV (Ca). Through the synthesis of bile acids and the enterohepatic circulation, the liver ensures absorption of orally administered vitamin K; it uses this vitamin to bioactivate several clotting factors (II, VII, IX, and X). The liver also modulates platelet production through the synthesis of thrombopoietin, which stimulates bone marrow precursor cells to differentiate into platelet-generating megakaryocytes. Moreover, hepatic clearance of fibrinolytics and tissue plasminogen activators is necessary to prevent or control fibrinolytic states.

Endocrine Organ

The liver has important endocrine functions. It synthesizes and secretes essential hormones, including insulin-like growth factor-1 (IGF-1), angiotensinogen, and thrombopoietin. IGF-1, formerly called somatomedin, is the immediate stimulus for growth of the body. Thrombopoietin stimulates the bone marrow to produce platelets. Angiotensinogen, a precursor of angiotensin II, is intricately involved in the regulation of fluid and electrolyte balance in the body. The liver is also essential for the transport and metabolism of a variety of hormones including insulin, thyroxine, and estrogen.

Erythrocyte Breakdown and Bilirubin Excretion

Excretion of bilirubin, a breakdown product of heme, requires an intact biliary system. After reticuloendothelial cells phagocytize damaged erythrocytes and separate the protein portion of hemoglobin from the heme moiety, they convert heme to biliverdin and reduce this compound to bilirubin. Upon release into the blood, bilirubin binds tenaciously to albumin. Hepatocytes avidly extract bilirubin from albumin, conjugate it with glucuronic acid, and then actively excrete these conjugates into bile canaliculi; only a small portion of the conjugated bilirubin enters the plasma. Bacteria in the gut convert most of the conjugated bilirubin to urobilinogen. The intestinal mucosa reabsorbs some urobilinogen, which reaches the liver via the mesenteric blood. The liver efficiently extracts this molecule and returns it to the intestine (enterohepatic circulation); the kidneys excrete only about 5% of the urobilinogen produced. Exposure to air oxidizes urobilinogen to urobilin in the urine or to stercobilin in the feces.

The liver also scavenges free hemoglobin from blood, helping to conserve body iron. It synthesizes haptoglobin, which forms complexes with dimers of free intravascular hemoglobin. Receptors on hepatocytes remove these complexes from plasma and thereby prevent the loss of hemoglobin dimers in the urine. The decomposition of hemoglobin in plasma yields free oxidized heme (metheme). Hemopexin, another liver-derived protein, complexes with metheme; hepatocytes extract these hemopexin–metheme complexes from plasma and retain the iron.

Regulator of Intermediary Metabolism

The liver is the penultimate metabolic organ and is highly specialized to meet the energy requirements of the body. It expends nearly 20% of the energy and O₂ used by the body, while accounting for only about 2% of the total body mass. To feed itself, the liver prefers fatty acids to glucose.

Carbohydrate Metabolism

Normal hepatic function is important for maintaining euglycemia (glucose buffer function). Multiple metabolic pathways contribute to glucose homeostasis, including glycogen synthesis and degradation, conversion of galactose to glucose, and the *de novo* synthesis of glucose via gluconeogenesis. Important substrates for gluconeogenesis include lactate and amino acids. As prolonged fasting depletes hepatic and muscle stores of glycogen, the continued production of glucose requires muscle catabolism to provide the liver with amino acids (Cori cycle). Some amino acids, such as alanine, undergo oxidative deamination in the liver and are readily converted to glucose via gluconeogenesis. Others, including branched-chain amino acids (leucine, valine, and isoleucine), are not very useful in this capacity because they are relatively resistant to deamination or transamination by the liver.

Lipid Metabolism

During the fed state, with oxidative substrates in abundance, the liver transforms carbohydrates, proteins, and dietary lipids to fatty acids. It esterifies these acids with glycerol metabolites to yield triglycerides and phospholipids. Excess lipids attach to hepatically synthesized or reprocessed apoproteins to create lipoproteins, which are transported to adipocytes. The liver synthesizes a variety of important lipids including precursors and derivatives of cholesterol that provide the molecular framework of steroid hormones and bile acids. Bile salts form the micelles required to absorb essential lipids from the gut (e.g., fat-soluble vitamins: D, E, and K). In the fasted state, the liver converts triglycerides and fatty acids to ketone bodies (e.g., acetoacetate) via beta-oxidation. Rather than using these ketones for its own nourishment, the liver exports them to sustain other tissues (e.g., brain, muscle, and kidney).

Amino Acid Metabolism

The liver synthesizes the nonessential amino acids either *de novo* or through a variety of pathways involving transamination or deamination reactions. Such reactions are essential in the catabolism of amino acids and are required for the elimination of nitrogenous waste products. Deamination of glutamine yields glutamic acid plus ammonia (NH₃). The urea cycle combines NH₃ with CO₂ to form urea, which the kidney excretes. Thus, a normal or low concentration of urea nitrogen in blood (BUN) provides no assurance that a patient has adequate renal function if the liver is failing. Decreased activities of urea cycle enzymes (secondary to zinc deficiency) may contribute to the development of hepatic encephalopathy.

Synthesis of Important Proteins

The liver produces a vast assortment of proteins with important extrahepatic functions. These proteins include blood clotting factors, hormones, acute phase proteins, and most of the plasma proteins, with a few notable exceptions (e.g., immunoglobulins). Albumin accounts for nearly 10% of the protein synthesized by the liver. It constitutes about 60% (34 g · dl⁻¹) of the total plasma protein pool and is the major determinant of the colloid oncotic pressure of plasma. Albumin also performs significant carrier functions: it transports unconjugated bilirubin to the liver for excretion; serves as a secondary carrier for thyroxine, cortisol, and heme; and is the only plasma protein that transports free fatty acids. Furthermore, albumin binds to, and therefore affects the responses to, a variety of pharmacologic agents.

Tissue injury and inflammation activate macrophages, which release cytokines (e.g., tumor necrosis factor, interleukins) that can stimulate the hepatic synthesis of a variety of acute phase proteins while decreasing the production of albumin. (This may explain why plasma albumin levels generally decrease in all types of chronic diseases.) One of the acute phase proteins, ceruloplasmin, is an important transporter of copper, which also functions as an oxidase and perhaps as a free-radical scavenger. Estrogens stimulate ceruloplasmin synthesis via interactions with steroid receptors on hepatocytes, accounting for the substantial elevations of plasma ceruloplasmin that occur in pregnancy and in women taking estrogen-containing oral contraceptives.

Host Defender

Sinusoidal and perisinusoidal cells of the liver defend the body against microbial invaders, and modulate inflammatory and immune responses to foreign materials. Pit cells, sparsely located in the perisinusoidal space, possess natural killer and neuroendocrine activities. The ubiquitous Kupffer cells police the channels between the portal and systemic circulation, effectively clearing gut-derived toxins and antigens. These cells are aggressively involved in immune surveillance, participating in phagocytosis, cytolysis, antigen presentation to T cells, and perhaps regulation of T-cell proliferation. Kupffer cells produce a variety of inflammatory mediators and cytokines that initiate and modulate both local and systemic effects of hepatic injury. Impairment of Kupffer cell function may be an important harbinger of sepsis or multiorgan systems failure, particularly in the setting of severe gastrointestinal pathology or splanchnic ischemia.

Pharmacokinetics

The liver influences the plasma concentration and systemic availability of most orally and parentally administered substances. Through its synthesis of drug-binding

proteins, the liver affects the partitioning of drugs into the various compartments of the body (apparent volume of distribution, V_d). Plasma proteins, especially albumin (preferentially binds acidic and neutral molecules) and α_1 -acid glycoprotein (high affinity for alkaloids), act as sponges or sinks to decrease concentrations of free (unbound) drug. Consequently, changes in concentrations of plasma proteins often modify dose–response relationships of drugs. At times, hepatic diseases will be associated with simultaneous decreases of certain plasma proteins and increases of others, which may contribute to confusion about the impact of such diseases on pharmacokinetics. A large decrease in albumin, for example, would be expected to enhance pharmacologic responses to drugs that are normally highly bound to albumin (*i.e.*, leftward shift of dose–response curve). Conversely, an elevation of other plasma proteins (*e.g.*, α_1 -acid glycoprotein) may reduce the delivery of certain medications to the relevant receptors, thereby attenuating the pharmacologic response to any given dose of the drug (*i.e.*, rightward shift of dose–response curve).

Hepatic clearance is the sum of all processes by which the liver eliminates a drug from the body. The three major factors that determine a compound's hepatic clearance are its rate of delivery to the liver (liver blood flow), its intrinsic metabolic clearance (ratio of V_{max} to K_m), and its biliary excretion. Biliary excretion is a major mechanism for clearing peptides and proteins, whereas metabolic processes are primarily responsible for eliminating smaller molecules. Thus, the effects of liver disease on the hepatic clearance of a drug or endogenous substance depend both on the molecule's physicochemical properties and on the degree of impairment of hepatocellular and cholestatic function.⁸

Hepatic metabolic clearance occurs via phase 1 and phase 2 reactions. These reactions typically alter drugs in a manner that facilitates their elimination via renal or biliary mechanisms. In general, phase 1 reactions (oxidation, reduction, *N*-dealkylation) modify structural features of molecules to render them more hydrophilic, whereas phase 2 reactions increase hydrophilicity by conjugating compounds with endogenous molecules that are water-soluble. Products of phase 1 transformations often become substrates for phase 2 reactions. Phase 1 reactions, which involve a wide range of cytochrome P-450 isozymes, are much more susceptible to inhibition by advanced age or hepatic diseases than are phase 2 reactions.

The inherent ability of the liver to metabolize a drug is referred to as intrinsic metabolic clearance.⁸ Intrinsic clearance, which reflects the fraction of the delivered drug load that is metabolized or extracted during a single pass through the liver, provides the basis for classifying drugs as high-, intermediate- or low-clearance compounds. High-clearance drugs (*e.g.*, lidocaine, diphenhydramine, or metoprolol) are so efficiently metabolized that their hepatic clearance approaches the rates at which they traverse the liver (*i.e.*, total hepatic blood flow; Fig. 39-7). In other words, hepatic blood flow determines the liver's ability to eliminate high-clearance drugs. Low-clearance drugs (*e.g.*, diazepam or antipyrine), however, are metabolized at rates that are usually far below their flow rates through the liver (Fig. 39-7); therefore, their hepatic clearances are relatively independent of liver blood flow. Factors that increase the free fraction of drugs are much more consequential for low- than for high-extraction drugs. The clearance of low-extraction drugs increases almost linearly as the free fraction increases (Fig. 39-8). In contrast, a single pass through the liver metabolizes almost all of a high-clearance drug, irrespective of its extent of binding to plasma proteins (nonrestrictive binding).

Figure 39-7. Relationship between hepatic clearance (*ordinate, on left*) and liver blood flow (*abscissa*) as determined by the extraction ratios (ER) of the drug (*ordinate, on right*). Hepatic clearances of compounds with low extraction ratios are nearly independent of liver blood flow whereas the clearances of compounds with high extraction ratios vary almost directly with changes in hepatic blood flow. The *arrows* indicate the normal physiologic range of liver blood flow. (Reprinted with permission from Wilkinson GR, Shand DG: A physiological approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Figure 39-8. Relationship between hepatic extraction and fraction of unbound drug in blood: increasing free fraction (more unbound drug) usually produces increased extraction. This phenomenon is of greater importance for low-extraction drugs (with almost a direct linear change in extraction ratio with increasing free fraction) than for high-extraction drugs because the latter are almost completely cleared, regardless of extent of binding (nonrestrictive binding). The hepatic clearance (CL) reflects the changes in extraction ratio (E) if blood flow (Q) is constant ($CL = Q \cdot E$). (Reprinted with permission from Wilkinson GR, Shand DG: A physiological approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Significant liver disease decreases the clearances and prolongs the terminal half-lives of most drugs eliminated by the liver. Nonetheless, the complex and poorly quantifiable effects of hepatic dysfunction on drug disposition may render pharmacokinetic, and even pharmacodynamic, predictions precarious. The rational selection of medications for patients with severe liver dysfunction mandates a careful risk–benefit analysis that integrates both pharmacodynamic and pharmacokinetic concerns. At times, cirrhotic patients with coexisting diseases will be better served by a hepatically cleared medication (superior efficacy, fewer untoward effects) than by one whose clearance is primarily extrahepatic. In such cases, careful titration of medications is imperative to achieve the desired pharmacologic responses with minimal adverse effects.

ASSESSMENT OF HEPATIC FUNCTION

Laboratory Evaluation of Hepatic Function

A broad array of laboratory and clinical tests are available to evaluate the hepatobiliary system (Table 39-1).⁹ The majority of the so-called liver function tests (LFT) do not actually measure functions of the liver. Rather, they serve to detect hepatobiliary injury or suggest a general category of disease, such as hepatitis, biliary obstruction, or steatosis.

| | Bilirubin (Direct/Indirect) | Functional Disturbance | Causes |
|-----------------------------------|--------------------------------|---|--|
| Aspartate aminotransferase | Normal | Increased (may be normal or decreased in advanced stages) | Normal (may be increased in advanced stages) |
| Alanine aminotransferase | Normal | Normal | Increased |
| Bilirubin | Unconjugated | Conjugated | Conjugated |
| Bilirubin | Normal | Decreased | Normal (may be decreased in advanced stages) |
| Gamma-glutamyl transaminase | Normal | Decreased (may be normal in early stages) | Normal (may be prolonged in advanced stages) |
| Bile acid esters | Normal | Normal (may be decreased in advanced stages) | Normal |
| Indocyanine green (ICG) clearance | Normal | Normal | Normal or reduced |

From Gelman S. *Intensive Care and the Liver*. In: *Textbook of Liver Disease*, 3rd ed. Philadelphia, Lippincott-Raven, 1997.

Table 39-1. BLOOD TESTS AND THE DIFFERENTIAL DIAGNOSIS OF HEPATIC DYSFUNCTION

Increased serum activities of aspartate aminotransferase (AST, formerly SGOT [serum glutamic oxaloacetic transaminase]) and alanine aminotransferase (ALT, formerly SGPT [serum glutamic pyruvic transaminase]) reflect hepatocellular injury and occur in almost all types of hepatic disease. Small increases (less than 3-fold) are consistent with steatosis or chronic viral hepatitis. Larger increases (3 to 22-fold) suggest acute hepatitis or exacerbations of chronic hepatitis (alcoholic hepatitis). The largest increases (greater than 20-fold) indicate massive hepatocellular necrosis and usually result from toxic reactions to drugs (including anesthetics) or other chemicals, circulatory shock, or severe viral hepatitis.

Changes in ALT or AST, however, do not necessarily reflect the severity or even the presence of hepatocellular injury. For example, decreases of ALT or AST in patients with severe hepatitis may indicate that the liver is either recovering from the disease or being destroyed by it, with few remaining hepatocytes to release these enzymes into the circulation. Moreover, AST or ALT may increase in the absence of liver disease, reflecting injuries to tissues such as heart or skeletal muscle. ALT resides primarily in the liver, and is therefore more specific than AST as a marker of hepatic injury; AST exists in a variety of organs including liver, heart, skeletal muscle, kidney, and brain.

Lactate dehydrogenase (LDH) activity serves as a test for hepatic injury. A marked increase of LDH may indicate hepatocellular necrosis, shock liver, or hemolysis combined with liver disease. However, LDH increases in many nonhepatic diseases and is therefore of little value as a diagnostic test for liver disease.

Glutathione S-transferase (GST) is a sensitive and specific test for detecting drug-induced hepatocellular damage.¹⁰ Because of the rapid release of GST into the circulation following hepatic injury and its short plasma half-life (90 minutes), monitoring of plasma GST concentrations can provide detailed information about the time course of an injury, from onset to resolution. Unlike the aminotransferases, which are highly localized in the periportal region (Zone 1), GST is most abundant in centrilobular (Zone 3) hepatocytes.¹¹ This distinction is important because the centrilobular region contains the hepatocytes that are most susceptible to injuries from circulatory disturbances and toxic products of drug metabolism. Following such injuries, increases of GST may be disproportionately greater than increases of serum aminotransferases.

Alkaline phosphatase (AP) is a highly sensitive test for assessing the integrity of the biliary system. However, AP is not specific for hepatobiliary disease; alkaline phosphatase isozymes are present in bone, placenta, kidney, leukocytes, intestine, and liver. Routine laboratory testing reveals transient, mild increases of AP in up to one-third of patients in the absence of hepatobiliary disease. During pregnancy, AP can nearly double just from placental release of the enzyme. Nonetheless, the greatest increases in AP result from cholestatic disorders. In patients with fulminant hepatic failure, a low AP-to-serum bilirubin ratio portends a poor prognosis.

5'-Nucleotidase (5'NT) activity in blood is a highly specific test for hepatobiliary injury. (It has largely replaced GGT [serum glutamyl transpeptidase], which is a more sensitive indicator of biliary tract disease but relatively nonspecific.) Although 5'NT is present in numerous tissues (liver, brain, intestine, heart, blood vessels, and endocrine pancreas), only hepatobiliary tissue releases 5'NT into the circulation; the release may require the detergent action of bile salts on plasma membranes. 5'NT is an excellent test for assessing the hepatic origin of an increased AP because it closely correlates with AP in those patients with liver disease.

Measurement of serum bilirubin—unconjugated (indirect), conjugated (direct reacting), and total—is central to the evaluation of hepatobiliary disorders.

Hyperbilirubinemia has a wide range of causes (Table 39-2). Serum concentrations of unconjugated bilirubin that are between 1 and 4 mg · dL⁻¹ generally indicate a disorder of bilirubin metabolism, such as excessive production, impaired transport into hepatocytes, or defective conjugation by hepatocytes. The concentration of unconjugated bilirubin will rarely exceed 5 mg · dL⁻¹ when hepatic function is normal, even if severe hemolysis occurs. Conjugated hyperbilirubinemia indicates the presence of intra- or extrahepatic cholestatic disease. If the biliary tract is completely obstructed, conjugated bilirubin levels may reach 35 mg · dL⁻¹; they rarely go higher because the kidney excretes conjugated bilirubin. A total bilirubin level that exceeds 35 mg · dL⁻¹ suggests biliary obstruction combined with renal failure, or severe hepatocellular disease plus hemolysis.

Table 39-2. CAUSES OF HYPERBILIRUBINEMIA

Assays of coagulation function or serum albumin concentration are the most widely used methods for evaluating hepatic synthetic function. Proper interpretation of these tests requires an understanding of a patient's clinical status. For example, decreasing plasma albumin concentrations indicate a worsening of hepatic function in patients who have chronic liver disease but no other cause of hypoalbuminemia (poor nutritional status, hormonal imbalance, nephropathy, and derangements of osmotic pressure). Plasma albumin, however, is an insensitive and unreliable marker for acute hepatic dysfunction because of its long plasma half-life (nearly 20 days). In contrast to measurements of plasma albumin, coagulation tests (e.g., prothrombin time [PT] or international normalized ratio [INR]; thromboelastography) are sensitive indicators of severe hepatic dysfunction whether patients have acute or chronic liver disease. Such tests, however, may not detect mild-to-moderate hepatic disease because the liver's capacity to synthesize clotting factors far exceeds the concentrations needed to maintain normal coagulation. Thus, a progressively increasing PT is usually ominous in liver-diseased patients, signaling the development of end-stage hepatic failure. Of course, a prolonged PT can be totally unrelated to liver disease, resulting instead from congenital deficiencies of coagulation factors or acquired conditions, such as consumptive coagulopathy, vitamin K deficiency, or ingestion of drugs that antagonize the prothrombin complex (coumarin).

Tests that measure hepatic blood flow and metabolic capacity can detect acute changes in hepatic circulation and function. The indocyanine green (ICG) method has been a standard technique for comparing effects of various anesthetics on hepatic blood flow. ICG is a nontoxic dye that binds avidly to plasma proteins. It is highly extracted by the liver following an intravenous injection; its extraction ratio (70–90%) exceeds that of bromsulphothalein (BSP) (50–80%). Although the liver excretes ICG into the bile without metabolizing it, some extrahepatic clearance occurs, which limits the accuracy of the ICG method. Modifying the method by measuring ICG concentrations in hepatic veins circumvents this limitation; however, this modification also increases the invasiveness of the ICG method. Flow-dependent tests of hepatic metabolic function may offer some advantages over ICG for detecting rapid or abrupt changes in hepatic function. One test involves injecting lidocaine intravenously and monitoring its rate of conversion to monoethylglycinexylidide (MEGX). This test, which can help identify patients whose hepatic blood flow is inadequate to meet the liver's metabolic demands, may be more sensitive than ICG as an indicator of poor prognosis in critically ill patients.¹² Additional metabolic tests for assessing hepatic function include antipyrine clearance from plasma (C14 aminopyrine breath test), caffeine clearance, galactose elimination, and the maximum rate of urea synthesis. As a general rule, such tests employ highly extracted drugs (e.g., lidocaine) to track changes in hepatic blood flow, and agents with low intrinsic

clearance to assess the metabolic capacity of the liver, as their hepatic elimination depends mainly on the functional mass of the liver.

Several other laboratory tests are crucial for accurate diagnosis of liver disease but provide no specific information about hepatic function. Included in this category are serologic profiles for viral hepatitis and measurements of plasma immunoglobulins, which may reveal autoantibodies or antibodies to anesthetic-induced neoantigens (discussed later).

Liver Biopsy

Liver biopsy continues to play a central role in the evaluation of patients with suspected liver disease because it provides the only means of determining the precise nature of hepatic injury (necrosis, inflammation, steatosis or fibrosis). Postoperatively, liver biopsy can be invaluable. It often helps resolve diagnostic dilemmas by revealing the type and extent of various chronic hepatic disorders, the identity and location of intrahepatic viral antigens, and patterns of acute hepatic injury characteristic of hepatotoxic drugs. Liver biopsy is also useful for evaluating the efficacy of therapy for liver disease. The presence of coagulopathy (e.g., PT that is 3 seconds greater than control, platelet count $<60,000 \text{ mm}^{-3}$), however, contraindicates liver biopsy.

HEPATITIS CAUSED BY HALOGENATED VAPORS

The recognition that halothane can cause significant hepatotoxicity prompted a dramatic decrease in its use in adult patients in the United States. This paved the way for the newer agents: enflurane (1972), isoflurane (1981), desflurane (1993), and sevoflurane (1995). Several hundred cases of halothane hepatitis have been reported since the introduction of halothane into clinical practice in the 1950s.¹³ This is many times more than the total number of cases attributed to all the other inhaled agents combined (Table 39-3). Thus far, enflurane has reportedly caused severe hepatic injury in approximately 50 cases,^{13,14} and isoflurane may have been responsible for another 6 cases.^{13,16} Three cases of hepatitis have been linked to sevoflurane use,^{17,18} and only a single report implicates desflurane as a possible cause of hepatitis.²⁰

| Agent | Year Introduced in United States | No. of Cases of Hepatitis | Percentage of Anesthetic Metabolized | Fluorocetyl Metabolites |
|-------------|----------------------------------|---------------------------|--------------------------------------|-------------------------|
| Halothane | 1958 | >500 | 20-46 | Yes |
| Enflurane | 1972 | ~50 | 25-45 | Yes |
| Isoflurane | 1981 | 6 | 12-2 | Yes |
| Desflurane | 1993 | 1 | 102 | Yes |
| Sevoflurane | 1995 | 3 | 2-5 | No |

Table 39-3. RELATIONSHIP BETWEEN METABOLISM OF VOLATILE HALOGENATED AGENTS AND ANESTHETIC-INDUCED HEPATITIS

Clinical Evidence That Halogenated Vapors Cause Hepatitis

Halothane

Several years elapsed between the clinical debut of halothane and the appearance of reports linking halothane anesthesia to severe liver damage. To determine the incidence of massive hepatic necrosis after halothane anesthesia, the Committee on Anesthesia of the National Academy of Sciences launched one of the largest epidemiologic studies ever completed: the National Halothane Study.²¹ This retrospective review of 856,600 anesthetics performed over a 4-year period (from 1959 through 1962) reported an incidence of fulminant hepatic necrosis of about 1 per 35,000 anesthetics. It is important to recall that the National Halothane Study was not designed to determine the incidence of halothane hepatitis; it included only cases in which massive hepatic necrosis terminated in death and did not investigate lesser degrees of hepatic injury.²² Based on more recent studies, the incidence of halothane hepatitis is probably somewhere between 1 in 3000 and 1 in 30,000.^{23,24,25} and ²⁶

Halothane hepatitis characteristically develops after minor, uneventful procedures of brief duration (<30 minutes), and does not become clinically apparent for several days after the anesthetic. The classic presentation includes fever, anorexia, nausea, chills, myalgias, and a rash, followed by the appearance of jaundice 3–6 days later. Overt jaundice indicates severe disease and portends a mortality rate that may be as high as 40%. Other indicators of poor prognosis include a short latency between the anesthetic and onset of symptoms, certain demographic factors (age >40 years, obesity), and severe hepatic dysfunction (PT >20 seconds, bilirubin concentration $>10 \text{ mg} \cdot \text{dl}^{-1}$).²⁷

The single most important risk factor for halothane hepatitis is prior exposure to halothane. Of the patients who develop jaundice after halothane, 71–95% have had at least one prior exposure to this agent.^{22,25,28,29,30,31} and ³² Severe reactions occur nearly 10 times more often in patients who have had multiple halothane anesthetics than in those having their first-ever halothane anesthetic.³³ The shorter the interval between the two most recent exposures, the more rapid is the onset of jaundice and the more serious the disease.

Demographic factors also provide important information about the risk of halothane hepatitis. Obese women appear to be more likely than their nonobese counterparts to contract halothane hepatitis. The disease may have a genetic basis.³⁴ Some ethnic groups (Mexican-American) seem to be at greater risk,³⁵ and chromosomal differences have been noted between patients who recovered from halothane hepatitis and halothane-treated patients who never had the disease.³⁶ For reasons that are not yet clear, age is also a significant risk factor. Approximately 50% of the cases of halothane-associated fulminant hepatic failure occur in patients older than 50,³³ whereas children are highly resistant to the development of halothane hepatitis.^{37,38} and ³⁹ The rare cases documented in children have involved multiple exposures to halothane.³⁷ Notably, neither pre-existing liver disease nor concomitant administration of medication has been identified as a risk factor for halothane hepatitis.

Enflurane

About a decade after the clinical introduction of enflurane, Lewis *et al*¹⁴ published a case-control study involving 24 cases of suspected enflurane hepatitis. The clinical, biochemical, and histopathologic profiles were similar to those seen in halothane hepatitis. Fever was the most common presenting feature (79%). Jaundice eventually occurred in 79% of the patients, with a latency of 8 days. A shorter latent period occurred in patients who had had prior anesthetics with either enflurane or halothane. Liver biopsy characteristically showed centrilobular necrosis, and 20% of the patients died from fulminant hepatic failure.

Eger *et al*¹⁵ re-evaluated these data by creating a syndrome score for each patient, based on a composite of variables, including fever, chills, nausea, rash, eosinophilia, death, and hepatic histopathology. These investigators found no differences between the syndrome scores of patients identified in the prior study as having “probable postanesthetic enflurane hepatitis” and patients whose postoperative hepatitis was attributable to other causes (such as sepsis or shock). Consequently, they argued that there is still no proof that enflurane causes hepatitis. This conclusion notwithstanding, the many unexplained cases of massive or submassive necrosis that have followed enflurane anesthesia^{40,41} and ⁴² provide presumptive evidence that the disorder exists. The risk factors for “enflurane hepatitis” appear to be the same as those for halothane hepatitis. According to Eger, even if all unexplained cases of hepatitis that have followed enflurane anesthetics were considered to be enflurane-induced, the incidence of enflurane hepatitis would be just 0.36 cases per million, about 1/200 that associated with halothane.

Isoflurane

It is plausible that isoflurane, on very rare occasions, can produce significant liver injury. Numerous reports describe severe, unexplained hepatic dysfunction following isoflurane anesthesia.^{16,43,44,45,46} and ⁴⁷ In many of the cases, the patients had had prior exposure to halogenated agents (e.g., halothane,⁴⁷ enflurane,⁴³ or isoflurane⁴⁸). The Food and Drug Administration (FDA), having received notification of 47 cases of suspected isoflurane-induced hepatic injuries that occurred between 1981 and 1984, convened a committee to investigate the cases. In most instances, the committee identified likely causes other than isoflurane, such as sepsis, hypoxia, biliary obstruction, nutritional deficiency, circulatory shock, viral hepatitis (including herpes virus), and antibiotic therapy (erythromycin estolate). Nonetheless, the issue remains controversial. A brief review published in the *American Journal of Gastroenterology* in 1996 states that there is “direct evidence that isoflurane can induce liver injury and should therefore be considered as a potential cause of serum transaminase elevations in any patient who is exposed to this anesthetic.”⁴⁶ This conclusion

contrasts with that of the FDA committee, which found no compelling evidence of a causal relationship between isoflurane anesthesia and severe hepatic dysfunction.⁴⁴

Sevoflurane

Although sevoflurane was first synthesized in the late 1960s, its commercial development was delayed because of concerns about the potential toxicity of its metabolites and breakdown products. Such concerns were mitigated by the apparent safety of sevoflurane in clinical trials, conducted initially in Japan and later throughout the world.⁴⁹ Sevoflurane was approved for clinical use in Japan in 1990. During the next few years, three case reports of sevoflurane-induced hepatitis appeared in the *Japanese Journal of Anesthesiology*^{17,18} and ¹⁹; two of those cases involved infants. By 1995, when sevoflurane became clinically available in the United States, more than 2 million Japanese patients had already received the anesthetic. Despite its extensive use in the American population and elsewhere in the world, there have been no additional reports of sevoflurane hepatitis.

Desflurane

To date, the literature provides only a single account of desflurane-induced hepatitis.²⁰ The case involved a healthy 65-year-old woman who developed pruritus, malaise, nausea, and polyarthralgia 12 days after a minor operation under desflurane anesthesia. Four days later she had a macular rash, dermal jaundice, epigastric pain, and laboratory evidence of significant hepatic dysfunction (serum ALT was 1886 IU, total bilirubin was 27 mg · dl⁻¹, and PT was 27 seconds, with negative serologies). She re-entered the hospital as a potential candidate for orthotopic liver transplantation (OLT); however, her condition gradually improved on conservative therapy. A blood sample collected on postoperative day 48 contained antibodies that reacted with trifluoroacetylated (TF-acetylated) liver microsomal proteins, providing circumstantial evidence for an immunologically mediated hepatitis.

Mechanisms of Anesthesia-Induced Hepatitis

Relationship Between Oxidative Metabolism and Immune Injury

The oxidative metabolism of the halogenated vapors relates to their potential to cause severe liver damage. Of the halothane taken up during anesthesia, 20–46% is metabolized,^{50,51} compared to 2.5–8.5% for enflurane,^{51,52} 2–5% for sevoflurane,^{53,54} 0.2–2% for isoflurane,^{51,55} and 0.02% for desflurane⁵⁶ (Table 39-3). Each of these anesthetics, with the exception of sevoflurane, is oxidized via cytochrome P-450 2E1 to yield highly reactive intermediates that bind covalently (acylation) to a variety of hepatocellular macromolecules (Fig. 39-9). Halothane anesthesia induces both neoantigens (arising via reaction of TF-acetyl chloride and hepatic proteins) and autoantigens (lacking TF-acetyl adducts).^{57,58,59,60} and ⁶¹ Presumably, the TF-acetyl moiety acts as a hapten and enhances the immune recognition of the carrier protein. In susceptible people, these altered hepatic proteins may trigger an immunologic response that causes massive hepatic necrosis.¹³

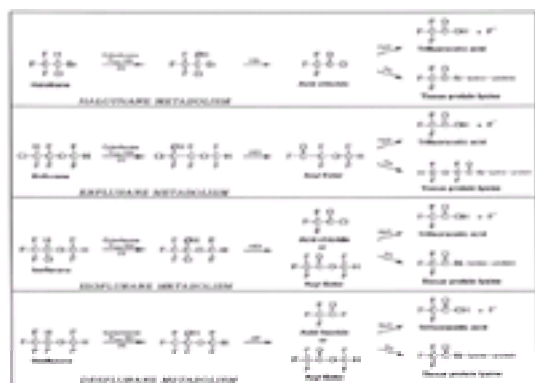

Figure 39-9. Proposed pathways of cytochrome P-450 2E1-catalyzed metabolism of halothane, enflurane, isoflurane, and desflurane that are involved in the production of highly reactive intermediates that acylate hepatic proteins. The acylated moieties of the liver proteins appear to function as haptens to elicit an immune response. Because there is no evidence that the metabolism of sevoflurane produces an acylating intermediate, sevoflurane metabolism is not included in this figure (see Fig. 39-10). (Reprinted with permission from Mushlin PS, Gelman S: Liver dysfunction after anesthesia. In Benumof JL, Saidman LJ (eds): *Anesthesia and Perioperative Complications*, 2nd ed, p 442. St Louis, Mosby, 1999; modified from Frink EJ Jr: *Anesth Analg* 81[suppl 6]:S46, 1995; Kenna JG, Jones RM: *Anesth Analg* 81[suppl 6]:S51, 1995.)

Halothane hepatitis has many features of an immunologic disease. It is idiosyncratic, affecting only a tiny fraction of those anesthetized with halothane. Neither the incidence nor the severity of the hepatitis correlates with the halothane dose administered. The disease has a latency of days, unlike the hepatic injury produced by severe hypoxia or a potent cytotoxin, which typically appears within hours of the hepatic insult. Moreover, the disease is usually accompanied by clinical laboratory findings that are characteristic of an immunologically mediated disorder. Such findings include peripheral eosinophilia,⁶² circulating immune complexes, organ nonspecific autoantibodies,⁶³ and antibodies that will bind to antigens isolated from halothane-treated animals (rabbits). Approximately 70% of the patients have antibodies that recognize neoantigens (TF-acetyl–modified epitopes), and 90% have antibodies that recognize autoantigens (non-TF-acetyl–modified epitopes). Therefore, preoperative testing for halothane antibodies might identify patients at risk for developing halothane hepatitis, whereas postoperative testing could help to determine if halothane anesthesia was the likely cause of unexplained postoperative hepatitis. Currently, however, no tests exist that are totally sensitive or specific for detecting the disease. The ELISA method of antibody detection has been reported to be approximately 75% sensitive and 88% specific.⁵⁹

Metabolites of Halogenated Vapors Other Than Halothane

Enflurane metabolism produces acyl adducts (difluoromethoxydifluoroacetyl halide) that are similar, but not identical, to those derived from halothane (TF-acetyl halide). Nonetheless, antibodies isolated from patients with halothane hepatitis can bind to hepatic proteins that contain enflurane-induced adducts (neoantigens).⁶⁴

Isoflurane metabolism also yields highly reactive intermediates (TF-acetyl chloride; acyl ester) that bind covalently to hepatic proteins (Fig. 39-9). The likelihood that isoflurane causes hepatitis via production of these intermediates appears to be extremely low, however, because just 0.2% of the isoflurane taken up into the body is actually metabolized. Only trace amounts of isoflurane-derived adducts are bound to hepatic proteins following isoflurane anesthesia.

Desflurane, which is similarly biotransformed to trifluoroacetyl metabolites, appears even less likely than isoflurane to cause immune injury because only 0.02–0.2% of a desflurane dose is metabolized (1/1000 that of halothane). Desflurane metabolites are usually undetectable in plasma, except after prolonged anesthetics with this agent. Furthermore, while antibodies from patients with halothane hepatitis clearly react with proteins isolated from halothane- or enflurane-treated rats, they do not appear to react with hepatic proteins from desflurane- or isoflurane-treated rats.¹³

Sevoflurane is metabolized more extensively than isoflurane or desflurane, slightly less than enflurane, and much less than halothane (see Table 39-3).^{54,65} The metabolism of sevoflurane (primarily via cytochrome P-450 2E1)⁵³ is rapid (1.5–2 times faster than enflurane), and produces detectable plasma concentrations of fluoride and hexafluoroisopropanol (HFIP) within minutes of initiating the anesthetic. The liver conjugates most of the HFIP with glucuronic acid, and the kidney excretes the HFIP-glucuronide (Fig. 39-10). An important distinction between sevoflurane and the aforementioned vapors is that sevoflurane produces neither highly reactive metabolites nor fluoroacetylated liver proteins.⁵⁴ At present, there is no evidence that any sevoflurane metabolites cause severe hepatic injury.⁶⁶

Figure 39-10. Cytochrome P-450 2E1-catalyzed biotransformation of sevoflurane produces inorganic fluoride and hexafluoroisopropanol (HFIP). The liver rapidly metabolizes HFIP to HFIP-glucuronide. Sevoflurane also undergoes breakdown in soda lime, yielding compound A, which is nephrotoxic but does not appear to be hepatotoxic. (Reprinted with permission from Mushlin PS, Gelman S: Liver dysfunction after anesthesia. In Benumof JL, Saidman LJ (eds): *Anesthesia and Perioperative Complications*, 2nd ed, p 442. St Louis, Mosby, 1999; modified from Frink EJ Jr: The hepatic effects of sevoflurane. *Anesth Analg* 81[suppl 6]:S46, 1995.)

Immune Crossover

The concept of immune crossover might explain cases of hepatitis that have been associated with anesthetics other than halothane. According to the immune theory, exposure to an anesthetic that generates fluoroacyl-derived antigens (neoantigens or autoantigens) can predispose to hepatitis from subsequent anesthetics that stimulate the formation of the same or similar antigens. Indeed, many patients who develop unexplained hepatitis after anesthetics with halothane,⁶⁷ isoflurane,⁴³ or sevoflurane,¹⁸ had prior enflurane anesthetics. Similarly, cases of unexplained hepatitis after isoflurane anesthesia have also occurred in patients with prior exposure to halogenated agents (e.g. halothane,⁴⁷ enflurane,⁴³ or isoflurane⁴⁸). Furthermore, the only patient ever reported to have desflurane hepatitis²⁰ had had two prior halothane anesthetics more than a decade before she received desflurane. About 7 weeks after the desflurane anesthetic, her blood contained antibodies that reacted with TF-acylated liver microsomal proteins. Did her earlier exposures to halothane sensitize her to desflurane hepatitis? Or could this actually have been a case of halothane hepatitis, triggered by the release of trace amounts of halothane from an anesthesia machine that contained residual halothane from prior anesthetics? Whether desflurane by itself actually causes hepatitis is unclear. Moreover, it is still unclear whether the above-mentioned associations are merely coincidental or represent true immune crossover between the various halogenated agents.

Conclusions

At present, the preponderance of evidence supports the TF-acetyl-hapten (immune) theory of anesthesia-induced hepatitis. Nonetheless, it is conceivable that the antigen-antibody responses that accompany anesthesia-induced hepatitis are the result of the hepatic injury, rather than its cause. Proponents of the hapten theory must reconcile the facts that most (if not all) patients anesthetized with halothane form the same or a similar set of TF-acylated liver proteins but few develop halothane hepatitis. Explanations for this disparity include the following possibilities: only a few of the TF-acyl proteins are actually immunogenic; the triggering of an immune response requires a critical threshold of TF-acylated proteins (antigenic threshold theory); and, only a tiny fraction of patients are genetically susceptible to the immunogenicity of these antigens.

HALOGENATED VAPORS CAUSE HEPATIC INJURIES OTHER THAN HEPATITIS

Mild hepatic injuries often occur after anesthetics with halogenated vapors. These injuries are typically asymptomatic and manifested only by minor abnormalities of LFTs.^{10,33,68} The incidence of these abnormalities appears to be related to the extent of an anesthetic's metabolism and the degree to which an anesthetic impairs hepatic perfusion and oxygenation. Whether such injuries predispose to halothane hepatitis is unclear.

Following halothane anesthetics, 20–50% of adult patients exhibit evidence of mild hepatic injury.^{10,33,68,69,70} and ⁷¹ Serum aminotransferases (ALT or AST) increase in about 25% of halothane-treated patients,³³ and may remain elevated for nearly 2 weeks after the anesthetic.^{69,70,71} and ⁷² GST, which is generally regarded as a more sensitive test than aminotransferases for detecting centrilobular injury,^{10,68,73} increases in almost 50% of adults who receive halothane and in approximately 20% of those who have enflurane anesthetics for minor operative procedures. Isoflurane anesthesia is less likely than either agent to produce enzyme elevations.¹⁰

Halothane anesthesia can also produce hepatic enzyme elevations in children. A prospective study of 25 children who received at least 10 halothane anesthetics in a single year revealed minor increases of enzymes in 5–11% of the children.⁷⁴ Similar elevations occurred in 3% of children who had had repeated halothane anesthetics at intervals of less than 28 days. Such findings indicate that children are much less susceptible than adults to both subclinical hepatic injury and hepatitis from halothane anesthesia.

Effects of Halogenated Vapors on Hepatic Blood Flow and Oxygen Delivery

Hepatic injury occurs whenever the liver's supply of oxygen is insufficient to meet its metabolic needs. The severity of the injury relates directly to the degree of ischemia or hypoxia, regardless of the cause, be it hemorrhage, halothane, or isoflurane.⁷⁵ Conditions that decrease hepatic oxygen consumption, including hypothermia or inhibition of metabolism pathways (e.g., by cimetidine), can protect the liver from hypoxic injury.⁷⁶

Halothane anesthesia significantly decreases hepatic blood flow and oxygen delivery in a variety of animal models, as well as in patients undergoing elective operations.⁷⁷ Studies in rats indicate that halothane anesthesia does not predictably cause dose-related hepatic injuries without employing special conditions, including those that stimulate the reductive metabolism of halothane (e.g., hypoxemic gas mixtures or phenobarbital pretreatment). However, such conditions also cause hepatic hypoxia, which creates confusion about the mechanism of the injury. Does it result primarily from the reductive metabolites of halothane or from halothane-induced decreases of oxygen delivery to a marginally hypoxic liver? Or does the injury stem from a combination of enhanced reductive metabolism and anesthesia-related decreases in hepatic oxygenation?

At least superficially, guinea pigs seem less complex than rats when it comes to studying halothane hepatotoxicity; halothane anesthesia by itself is sufficient to damage the guinea pig liver. This exquisite sensitivity to halothane presumably results from the unusually low hepatic arterial flow in guinea pigs (2–3% of the liver's total blood flow, versus 20–35% in other species). This low arterial flow renders guinea pigs unusually susceptible to hepatic injury from a variety of insults, including surgical stress and hemorrhage, as well as from anesthetic agents that are characteristically nontoxic (isoflurane, nitrous oxide). Both animal and human studies indicate that halothane is more likely than the other inhaled anesthetics to produce liver injury, probably because it causes the most cardiovascular and respiratory depression and the greatest reduction in hepatic arterial flow (see Fig. 39-11). Consequently, halothane is the most likely of the clinically used vapors to produce, or exacerbate, hepatic hypoxia when blood flow to the liver is critically limited and the adequacy of the oxygen supply-to-demand balance is in question.

Figure 39-11. Dose-dependent effects of inhaled anesthetics on hepatic arterial flow in chronically instrumented dogs in the absence of a surgical stress. Sevoflurane and isoflurane preserve hepatic arterial flow even at the higher minimum alveolar anesthetic concentration (MAC) levels. *Differs from sevoflurane and isoflurane at same MAC values ($p < 0.05$). †Differs from sevoflurane at same MAC value ($p < 0.05$). (Reprinted with permission from Frink EJ Jr: The hepatic effects of sevoflurane.)

Excluding halothane, enflurane decreases hepatic blood flow and splanchnic perfusion more than any other halogenated vapor in clinical use. It induces dose-dependent decreases in portal venous blood flow^{78,79} and either reduces⁷⁸ or does not change hepatic artery blood flow⁷⁹ (Fig. 39-11). Splanchnic perfusion decreases in parallel with decreases in mean arterial pressure (MAP) and cardiac output in patients anesthetized with enflurane.⁸⁰ Enflurane also increases splanchnic oxygen extraction and lowers both hepatic venous and mixed venous oxygen saturation.⁸⁰

Desflurane anesthesia decreases hepatic blood flow in both experimental and clinical settings. Administration of 1 MAC desflurane to patients prior to skin incision reportedly decreases hepatic blood flow by 30% (measured by ICG), similar to the decreases associated with 1 MAC of halothane or isoflurane.⁸¹ Studies in domestic pigs indicate that desflurane anesthesia produces dose-dependent reductions of mean arterial blood pressure, cardiac output, and hepatic blood flow. At 0.5 MAC, it decreases blood flow through the portal vein and superior mesenteric artery, and at 1 MAC, it also decreases hepatic arterial flow.⁸² Desflurane can markedly reduce oxygen delivery to the liver and small intestine without producing comparable reductions of hepatic oxygen uptake or hepatic and mesenteric metabolism. Therefore, desflurane anesthesia could decrease the oxygen reserve capacity of both the liver and small intestine.

Isoflurane is much less likely than halothane or enflurane to cause, or contribute to, hepatic injury. It undergoes minimal biodegradation,^{54,55} and preserves hepatic blood flow⁷⁷ and oxygen delivery even during laparotomy.⁸³ It actually protects the liver from carbon tetrachloride (CCl₄) toxicity, probably by inhibiting the cytochrome P-450 isozyme that metabolizes CCl₄ and possibly by dismutating halo-peroxyl radicals.^{84,85}

Sevoflurane anesthesia usually preserves blood flow and oxygen delivery to the liver, even in the presence of positive-pressure ventilation.⁸⁶ Patients having elective operations under sevoflurane anesthesia (1 or 2 MAC) experience significant reductions in mean arterial blood pressure, but maintain their hepatic blood flow (ICG clearance) at awake, preanesthetic levels. Experiments in chronically instrumented dogs indicate that sevoflurane produces dose-dependent increases of hepatic arterial flow that compensate for the dose-related decreases of portal venous flow.⁸⁷ At 2 MAC, sevoflurane produces a 33% decrease in portal flow and a 33% increase in hepatic arterial flow (mean arterial pressure and cardiac output decrease by 37% and 21%, respectively). By comparison, hepatic arterial flow decreases slightly with 2 MAC isoflurane,⁸⁷ moderately (approximately 30%) with 1 MAC of halothane or enflurane, and markedly with 1.5 MAC halothane. At 2 MAC, sevoflurane reduces portal flow more than isoflurane, but less than enflurane, and much less than halothane.⁷⁸ At 1.5 MAC, however, sevoflurane and isoflurane produce similar reductions of portal vein flow. Thus, sevoflurane appears to be the most effective of the inhaled anesthetics for maintaining both blood flow and oxygen delivery to the liver (Fig. 39-11).

Under a condition of marginal hepatic oxygen supply (hepatic artery ligation) in beagles, both sevoflurane and halothane decrease portal venous flow (electromagnetic flow meter) and hepatic oxygen supply more than isoflurane does. Hepatic oxygen uptake is reportedly higher with sevoflurane than halothane (3.7 vs. 2.7 ml · min⁻¹ · 100 g⁻¹ of liver), perhaps because halothane decreases hepatic metabolism and oxygen requirements more than sevoflurane does. Thus, the hepatic oxygen supply/uptake ratio may be lower with sevoflurane than with halothane anesthesia. Despite this, sevoflurane appears to better preserve hepatic function than halothane anesthesia (ICG clearance; 40 vs. 31 ml · min⁻¹),⁸⁸ even in the presence of hypoxia. The reason for this is unclear.

After minor operative procedures, sevoflurane anesthesia may produce slight elevations in blood concentrations of hepatic enzymes, which are comparable to those associated with isoflurane.⁸⁹ Sevoflurane anesthesia does not appear to cause significant postoperative hepatic dysfunction in patients undergoing major intra-abdominal operations.^{90,91}

In animal studies (beagles), sevoflurane (1.8 MAC) produces minor, transient elevations of hepatic enzymes, similar to those that result from enflurane or halothane.⁹² Multiple, prolonged sevoflurane anesthetics (up to 2 MAC, for 3 hours per day, 3 days per week) are well tolerated. Although aminotransferases and LDH increase within the first few weeks of sevoflurane administration, they subsequently return to normal. In an 8-week study in monkeys, sevoflurane anesthesia did not produce any gross pathologic, histopathologic, or ultrastructural abnormalities of the liver.⁹³

Several breakdown products of sevoflurane, including compound A [CF₂=C(CF₃)OCH₂F and fluoromethyl-2,2-difluoro-L-(trifluoromethyl) vinyl ether], result from the extraction of hydrogen fluoride by CO₂ absorbents at low fresh gas flows (see Fig. 39-10). Compound A clearly causes renal injury in animals and could possibly be nephrotoxic in humans.⁷⁷ However, no significant hepatic abnormalities occurred during a 2-week study in dogs and rats, despite repeated administrations of sevoflurane (closed-circle, soda lime absorbent).⁹⁴ There are no laboratory or clinical reports indicating that compound A itself causes hepatotoxicity.

Conclusions About Halogenated Vapors and Liver Injury

Guidelines for the clinical use of halothane should take into consideration the following issues and concerns.⁹⁵ (1) In children, halothane hepatitis is extremely uncommon, even after repeated exposures to halothane. (2) In adults, the disease rarely occurs after a single exposure to halothane; repeated anesthetics, however, especially in obese, middle-aged women, over a brief period (<6 weeks) substantially increase the risk of the disease. (3) No totally reliable test exists for detecting halothane hepatitis or susceptibility to the disease. (4) Halothane can markedly decrease hepatic blood flow and oxygen supply and often causes mild, transient liver injury. (5) Halothane anesthetics have medicolegal implications, which may plague anesthesiologists whenever unexplained hepatic dysfunction develops in the postoperative period.

Why use halothane at all? The main advantage of halothane over other agents appears to be its low cost. However, when potential medicolegal costs are factored into the equation, the cost-benefit analysis might actually favor the elimination of halothane from anesthesia practice.²⁷

Sevoflurane is less likely than either halothane or enflurane to induce liver injury, and no more toxic than either desflurane or isoflurane. Its metabolic products are less reactive, and therefore probably less injurious, than those resulting from halothane, enflurane, isoflurane, or even desflurane.⁹⁶ Sevoflurane better preserves hepatic blood flow and oxygen delivery than halothane, enflurane, or desflurane; its effects on hepatic perfusion and metabolic function are similar to those of isoflurane. It seems unlikely that sevoflurane will emerge as a clinically important cause of severe postoperative liver dysfunction.

Other than sevoflurane, desflurane is the least likely of the halogenated vapors to cause severe hepatic injury, based on the immune theory of anesthesia-induced hepatitis. Nonetheless, desflurane produces a greater reduction of hepatic blood flow and oxygen delivery than either isoflurane or sevoflurane. Hence, it may be more likely than the latter agents to cause liver injury in the setting of marginal hepatic oxygenation.

EFFECTS OF ANESTHETICS OTHER THAN HALOGENATED VAPORS ON HEPATIC FUNCTION

Nitrous Oxide

Cohen and co-workers⁹⁷ surveyed more than 60,000 dentists and chair-side assistants and found a higher prevalence of liver disease in professionals who were chronically exposed to nitrous oxide (N₂O); the prevalence was 1.7-fold higher in dentists and 1.6-fold higher in their assistants. The methodologic limitations of this study argue for cautious interpretation of the data. It is clear, however, that N₂O inhibits the enzyme methionine synthetase, which could produce toxic effects. Brief exposures to N₂O, at concentrations used clinically, are sufficient to produce time-related decreases in methionine synthetase activity in the livers of animals and humans.⁹⁸ Whether the resultant abnormalities in folate and methionine metabolism actually injure the liver is unclear.

Nitrous oxide by itself does not usually cause clinically significant changes in blood pressure and cardiac output. Hepatic circulation remains undisturbed when it is administered to conscious animals.⁹⁹ However, when used with a barbiturate to provide anesthesia during laparotomy, N₂O (30, 50 and 70%) induces dose-related decreases in both hepatic arterial flow and portal venous flow without altering hepatic oxygen consumption. In this setting, N₂O also increases mean arterial pressure, hepatic arterial resistance, and mesenteric vascular resistance. Taken together, these data suggest that N₂O can increase sympathetic nervous system activity, which decreases portal venous and hepatic arterial flows through stimulation of α -adrenergic receptors in the hepatic and mesenteric circulations.¹⁰⁰

Hepatic injury may at times result from a N₂O-related decrease in hepatic oxygen tension. Nitrous oxide appears to increase selectively the potential of halothane to cause mild hepatic injury. For example, in a study of urologic patients, halothane anesthetics (100% O₂, or 70% N₂O + 30% O₂), but not isoflurane anesthesia with 70%

N₂O (30% O₂), increased GST. The N₂O plus halothane group had a higher incidence than the halothane group of small, but significant, GST elevations 3–6 hours after anesthesia (35 vs. 24%, respectively).⁶⁸ The exact mechanisms of the GST increases are unknown, but the increases probably result from hepatic hypoxia caused by anesthesia-related decreases of hepatic blood flow and oxygen delivery. Another clinical investigation evaluated effects of inspired oxygen tension (including hyperbaric oxygenation) during halothane anesthesia on postoperative ALT levels; patients who received halothane at lower intraoperative oxygen tensions had the largest increases of ALT.¹⁰¹ These results suggest that increases in oxygen tension may protect the liver from halothane-induced hypoxic injury.

The aforementioned studies suggest that N₂O-containing anesthetics do not cause liver injury in the absence of impaired hepatic oxygenation.^{68,101} In another study, no hepatocellular injury resulted from up to 4 hours of anesthesia with 67% N₂O (in oxygen) and infusions of methohexital.¹⁰² Moreover, no hepatic dysfunction developed when patients with mild alcoholic hepatitis received N₂O–opioid or N₂O–enflurane anesthetics for peripheral or superficial operations.¹⁰³ There is no convincing evidence that nitrous oxide *per se* causes hepatotoxicity¹⁰⁴ in the absence of a precarious oxygen supply/demand ratio in the liver.

Nonopioid Sedative–Hypnotic Agents

Intravenous anesthetic agents, such as propofol, etomidate, and midazolam, have not been shown to significantly alter hepatic function in patients undergoing minor operative procedures. Although very large doses of thiopental (>750 mg) may cause hepatic dysfunction, usual induction doses have little effect on the liver.¹⁰⁵ Ketamine induction may produce a moderate increase in serum concentrations of some liver enzymes.⁷⁵ Patients anesthetized with ketamine infusions plus oxygen show a dose-dependent increase in biochemical markers of hepatic injury.¹⁰⁶ It is unclear whether ketamine causes liver dysfunction by exerting direct hepatotoxic effects, altering hepatic metabolism, or by increasing serum catecholamines, which can decrease hepatic blood flow and oxygen delivery. However, none of the intravenous agents commonly used to induce anesthesia appears to produce serious hepatotoxicity.

Opioids

Opioids and intravenous anesthetics *per se* have little effect on hepatic function, provided that they do not impair hepatic blood flow and oxygen supply.

Opioids increase the tone of the common bile duct (Fig. 39-12) and sphincter of Oddi, leading to increases in biliary tract pressure and biliary spasm. Consequently, opioids may trigger severe epigastric or abdominal pain, and biliary spasms. This may occur in approximately 3% of patients receiving opioids and can cause false-positive results on intraoperative cholangiography.¹⁰⁷ Also, increases in serum lipase and amylase concentrations may occur, and persist for up to 24 hours after administration of a μ -agonist. At equianalgesic doses, fentanyl and morphine cause larger increases in biliary pressure than meperidine¹⁰⁸ or pentazocine.^{109,110} Butorphanol¹⁰⁸ and nalbuphine¹¹¹ probably do not cause spasm of the sphincter of Oddi. Medications that can antagonize opioid-induced increases in biliary spasm include nitroglycerin, atropine, glucagon, and naloxone, as well as the volatile anesthetic agents.

Figure 39-12. Effects of opioids and placebo on common bile duct pressure, expressed as a percentage of pretreatment values. (Reprinted with permission from Radnay PA, Duncalf D, Novakovic M, *et al*: Common bile duct pressure changes after fentanyl, morphine, meperidine, butorphanol, and naloxone. *Anesth Analg* 63:441, 1984.)

Nonopioid Analgesics

Acetaminophen

Acetaminophen is widely prescribed for the treatment of postoperative pain, being used alone (Tylenol) or in combination with opioid analgesics, such as oxycodone (Percocet) and hydrocodone (Vicodin). Extremely large doses (suicide attempts) of acetaminophen are a well-known cause of fulminant hepatic failure, and it has recently become clear that analgesic doses can produce hepatotoxicity in susceptible individuals.¹¹² Daily doses in the range of 3–8 g may result in chronic liver injury.¹¹³ In chronic alcoholics or patients with poor nutritional status, doses as low as 2 g per day may produce serious liver injury.¹¹⁴ The American Liver Foundation has recommended that warning labels be placed on all acetaminophen-containing products to alert consumers of the potential for liver damage. Whenever acetaminophen hepatotoxicity seems probable, specific treatment (*N*-acetylcysteine) should be instituted without delay because it is highly effective with minimal risk to the patient.

Nonsteroidal Anti-inflammatory Drugs, Including Aspirin

Aspirin is a well-documented cause of a dose-related, reversible form of hepatotoxicity. This disorder may develop in days to weeks after initiation of high-dose aspirin therapy. Patients are usually asymptomatic, with mild-to-moderate increases of serum aminotransferase activities. Jaundice is uncommon, and severe clinical hepatitis is rare.

The FDA Arthritis Advising Committee concluded in 1992 that hepatotoxicity is a “class characteristic” of nonsteroidal anti-inflammatory drugs (NSAIDs). Major offenders in this regard have been diclofenac, sulindac, and phenylbutazone. Other offenders include piroxicam, ibuprofen, naproxen, and fenoprofen. The basis of hepatotoxicity from NSAIDs appears to be largely, but not entirely, idiosyncratic. Cross-sensitivity between different NSAID classes may occur.

NONPHARMACOLOGIC CAUSES OF PERIOPERATIVE LIVER DYSFUNCTION

Sepsis and Splanchnic Ischemia

The characteristic features of human sepsis occur in chronically instrumented, sedated sheep that receive a 24-hour infusion of *Escherichia coli* endotoxin. The earliest vascular abnormality is transient pulmonary arterial constriction, which is followed immediately by simultaneous, precipitous decreases in blood flow (to below 50% baseline values) through the celiac trunk, superior mesenteric artery, and portal vein. Hepatic arterial flow exhibits a biphasic response; an abrupt, transient decrease precedes a marked and sustained increase in flow. These early effects appear to be unrelated to systemic hemodynamics. The large increase in hepatic arterial flow occurs independently of changes in portal venous flow, suggesting a dysregulation of the physiologic hepatic arterial buffer response. This phenomenon may be the result of an increase in hepatic oxygen demand, to support phagocytosis and digestion of the sudden overload of bacterial endotoxins.¹¹⁵

Endotoxin also ablates the hepatic arterial buffer response and autoregulation in anesthetized pigs.¹¹⁶ Decreases in portal venous flow parallel and match decreases in cardiac output, without reciprocal increases in hepatic arterial flow. Selective inhibition of vascular endothelial function appears to mediate the impairment of the buffer response,¹¹⁷ and nitric oxide may moderate this effect. During endotoxic shock, nitric oxide induces arterial hypotension, dilates hepatic arterioles, and attenuates the increases in both portal and pulmonary resistances.¹¹⁶ The nitric oxide synthase inhibitor, *N*(G)-nitro-L-arginine methyl ester (L-NAME), markedly disrupts the hepatic circulation in experimental endotoxemia. This latter effect is rapidly and partially reversed by sodium nitroprusside.¹¹⁷ Thus, inhibition of NO synthetase might worsen outcome in endotoxic shock by causing a loss of local control of liver blood flow and markedly increasing resistance to venous return across both the liver and lungs.

Splanchnic ischemia impairs hepatic function and appears to increase morbidity and mortality in critically ill patients. A prospective study, conducted in ICU patients with evidence of inadequate tissue perfusion, suggests that measurements of hepatic metabolic function and tonometric assessment of gastric intramucosal pH (pH_{im})

better predict patient outcome than standard liver blood tests.¹² The investigators noted that the survivors and nonsurvivors had similar values of bilirubin, AST, alkaline phosphatase, PT, and indocyanine green clearance (ICG). In contrast, hepatic metabolism of lidocaine to monoethylglycinexylidide (MEGX) differed markedly between survivors and nonsurvivors (MEGX levels of $16 \text{ ng} \cdot \text{ml}^{-1}$ and $2.4 \text{ ng} \cdot \text{ml}^{-1}$, respectively). During the 3-day study period, MEGX levels in nonsurvivors had decreased from 20.6 to $2.4 \text{ ng} \cdot \text{ml}^{-1}$. Such data suggest that critically ill patients can rapidly develop severe hepatic dysfunction. This rapid deterioration may result from an imbalance between hepatic metabolic demand and liver blood flow, and portends a poor prognosis.

Hepatic Injury Associated with Low Arterial Oxygen Content, Hypotension, and Shock

The liver is exquisitely sensitive to hypoxia. In one study, patients with chronic lung disease whose blood oxygen content fell below $9 \text{ ml} \cdot \text{dl}^{-1}$ all developed liver injury, without developing overt myocardial or cerebral damage.¹¹⁸ Detrimental effects of oxygen deprivation on perioperative hepatic function can occur independent of anesthetic techniques.¹¹⁹

Passive congestion alone, no matter how severe or prolonged, seems to cause little if any damage to the liver,¹²⁰ even in patients with congestive heart failure. Hepatic dysfunction tends to be mild, and the prognosis primarily depends on the severity of the underlying cardiac or systemic illness. However, if moderate hypotension occurs, a hepatitis-like illness (ischemic hepatitis) may follow. Patients develop jaundice, systemic symptoms, and large increases of serum transaminases, which may persist for 3–11 days. Liver biopsy shows centrilobular necrosis with little or no inflammatory response.¹²¹

Patients with ischemic hepatitis typically have a history of inadequate systemic perfusion, along with marked increases of serum aminotransferases. The increases are usually of greater magnitude than those associated with viral hepatitis. Prolonged shock or sepsis can cause extreme liver injury; a hepatic lobe or the entire liver may become infarcted, even in the absence of portal venous or hepatic arterial occlusion.¹²⁰ The mechanism of ischemic hepatitis is unknown, but may involve free-radical production because hepatocytes contain very high concentrations of xanthine oxidase. (Ischemia and reperfusion increase xanthine oxidase activity; this enzyme catalyzes the oxidation of purines to uric acid and the associated reduction of O_2 to superoxide anion, which initiates toxic free-radical reactions.)

Surgery-Related Injury

Minor operations do not cause postoperative liver dysfunction in healthy patients. Even patients with marginal hepatic function usually tolerate peripheral procedures without hepatic complications, including those who receive halothane anesthesia.¹²² A randomized study in patients with mild alcoholic hepatitis compared spinal vs. general anesthesia (enflurane plus N_2O or N_2O plus opioid) and found no anesthesia-related differences in values of LFTs following peripheral or superficial surgery.¹⁰³

Major operations (especially laparotomy) are often associated with hepatic dysfunction or injury. The magnitude of the abnormality depends more on the type of operation than on a particular anesthetic technique.^{122,123} Nonetheless, hepatic dysfunction subsequent to major surgery is rarely of concern in healthy patients. By contrast, patients with advanced hepatic disease (marginal hepatic function) who undergo major operations, such as laparotomy, have extremely high postoperative morbidity and mortality.^{1,2,124,125} These patients are probably unable to tolerate the surgical stress, which contributes to decreased hepatic oxygen supply.

The surgical stress response includes the stimulation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone system, and the nonosmotic release of vasopressin; each of these neurohumoral responses can compromise the splanchnic circulation. These effects may persist for many hours or even days after surgery. Laboratory studies indicate that laparotomy induces marked mesenteric vasoconstriction and decreases gastrointestinal blood flow; acute hypophysectomy and administration of an angiotensin II antagonist can abolish these changes.¹²⁶ In addition to the surgical stress response, laparotomy by itself decreases blood flow through the intestine and the liver,¹²⁷ probably through traction and manipulation of the viscera.

Anesthetic agents might be expected to modify the effects of laparotomy on the liver because some of them (halothane or enflurane) cause much greater decreases of hepatic blood flow and oxygen supply than others (isoflurane or sevoflurane).^{83,128,129,130} and ¹³¹ Support for this idea comes from experiments conducted in phenobarbital-pretreated rats (microsomal enzyme induction) that were anesthetized with either thiamylal, halothane, enflurane, or isoflurane for various operative interventions, including hepatic artery ligation.¹³¹ Centrilobular necrosis occurred only in the rats anesthetized with halothane; the severity of the injury was related both to duration of anesthesia and to operative location. The hepatic damage that resulted from upper abdominal (sham for hepatic artery ligation) and lower abdominal operations was comparable, and exceeded that associated with peripheral surgery. Thus, the pathogenesis of laparotomy-induced hepatic injury appears to involve mesenteric vasoconstriction and reductions of hepatic and intestinal blood flow.

Laparoscopic Cholecystectomy

Acute cholecystitis occasionally develops in cirrhotic patients and requires surgical intervention. It is unclear whether a laparoscopic procedure is preferable to an open cholecystectomy because of the risk of intraoperative hemorrhage related to portal hypertension. A recent study compared complication rates and outcomes in cirrhotic patients ($n = 48$; Child-Pugh A or B severity) and noncirrhotic controls ($n = 187$) who underwent laparoscopic cholecystectomy for symptomatic cholelithiasis. No differences occurred in overall outcome, operation duration, or hospital stay. However, the group with cirrhosis required more transfusions and had a higher incidence of minor complications. Conversion to open cholecystectomy occurred in 8.3% of cirrhotic patients but in none of the controls (0/187). Thus, while laparoscopic cholecystectomy may appear safe in patients with mild-to-moderate cirrhosis and symptomatic gallstones, the overall complication rate is increased.¹³²

Procedures Requiring Cardiopulmonary Bypass

Cardiac failure itself does not usually lead to significant hepatic dysfunction, but jaundice and hepatocellular necrosis may occur if severe hypotension develops.¹³³ Cardiopulmonary bypass with low-flow states and nonpulsatile perfusion can aggravate pre-existing hepatic dysfunction. Administration of catecholamines to improve cardiac performance, either before or after bypass, may decrease hepatic oxygen delivery. Hypothermia during cardiopulmonary bypass probably limits the hepatic injury created by the abnormal hemodynamics.

Hypotension and hemorrhage decrease portal blood flow, but the hepatic arterial buffer response and pressure-flow autoregulation tend to preserve hepatic arterial flow and oxygen delivery. Perfusion at 28°C increases portal flow and slightly decreases hepatic arterial flow. A pump flow rate of $2.4 \text{ l} \cdot \text{min}^{-1} \cdot \text{m}^{-1}$ better maintains total blood flow to the liver than a rate of $1.2 \text{ l} \cdot \text{min}^{-1} \cdot \text{m}^{-1}$. Only at low pump rates does pulsatile flow appear to be more advantageous than nonpulsatile perfusion in terms of hepatic blood flow.¹³⁴

Liver Transplantation

One to three hours after transplantation, mean cardiac output remains elevated ($9.5 \text{ l} \cdot \text{min}^{-1}$) and hepatic blood flow represents 23% of cardiac output. The portal flow is disproportionately high, constituting 85% of total blood flow to the liver. Intentionally reducing the portal flow by 50% triggered a 30% increase in hepatic artery flow, indicating an intact hepatic arterial buffer response in the newly transplanted liver.¹³⁵

Hemolysis and Transfusion

Reabsorption of large surgical hematomas and transfusions of red blood cells are major causes of postoperative jaundice in the absence of overt hepatocellular dysfunction. At least 10% of transfused erythrocytes hemolyze within the initial 24 hours following a blood transfusion (bilirubin load is about 250 mg per unit transfused). A normal liver readily clears the bilirubin load that results from mild hemolysis. With severe hemolysis, the excessive bilirubin loads lead to unconjugated hyperbilirubinemia, which persists until the liver conjugates and excretes the excess bilirubin.

Excessive bilirubin loads can also result from severe hemolytic disorders, including hemoglobinopathies (e.g., sickle cell disease) or derangements of erythrocyte metabolism [glucose-6-phosphate dehydrogenase (G6PD) deficiency]. Thus unconjugated hyperbilirubinemia may be seen in the perioperative period as a result of exacerbations of sickle cell disease (via hypovolemia, hypoxia, hypothermia, stress) or G6PD deficiency (via sulfonamides, chloramphenicol, nitrofurantoin). Other causes of significant hemolysis include transfusion reactions and prosthetic cardiac valves.

HEPATIC AND HEPATOBILIARY DISEASES

Classification of Liver Diseases

For the purposes of the following discussion, liver diseases are divided into two large, heterogeneous groups: parenchymal diseases (e.g., viral hepatitis,

steatohepatitis, hepatic cirrhosis, and fulminant hepatic failure) and cholestatic diseases (e.g., intrahepatic and extrahepatic biliary obstruction).

Prevalence of Hepatobiliary Disease

More than 100 distinct hepatic diseases have been described. Currently, nearly 10% of the American population (25 million) have some form of hepatobiliary disease. Hepatitis B or C viral infections afflict more than 5 million Americans. About 50% of those with hepatitis C may develop cirrhosis, which currently accounts for between 13,000 to 15,000 deaths each year. Alcoholic liver disease remains a problem, becoming severe in 10–15% of those who consume large amounts of alcohol over a prolonged period.

Viral Hepatitis

Viral hepatitises are important causes of perioperative hepatic dysfunction. They can elude preoperative detection, especially during the incubation period, when the disease is asymptomatic. Heterotropic viruses are the ones that most commonly cause hepatitis: hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis D (HDV, delta), and hepatitis E (HEV). HDV is a defective but pathogenic agent that requires HBV for its replication.

Other important but much less common causes of viral hepatitis include cytomegalovirus (CMV), Epstein-Barr (EBV), herpes simplex, rubella, varicella zoster, measles, Coxsackie, and echoviruses. These viruses typically produce benign, anicteric disease, and often escape detection by surgical and anesthesia teams.^{136,137} However, in rare circumstances, particularly in immunocompromised patients, they cause acute hepatitis, fulminant hepatic failure, and death.

The differential diagnosis of viral hepatitis and anesthesia-induced hepatitis can be quite difficult. The clinical presentations may be similar, laboratory findings may be inconclusive, and liver biopsy results may fail to provide a basis for etiologic differentiation. A diagnosis of viral hepatitis is based on a constellation of findings suggestive of viral infection coupled with hepatocellular necrosis.¹³⁸ The clinical presentation of viral hepatitis generally includes four phases: An *early prodromal phase*, resembling serum sickness, with fever, arthralgias, arthritis, rash, and angioneurotic edema; a *preicteric phase*, with nonspecific constitutional symptoms including malaise, unusual fatigue, myalgias, anorexia, nausea, vomiting, occasional midepigastic or right upper quadrant pain, and diarrhea; an *icteric phase*, marked by the onset of jaundice, a decrease in fever, and lessening of constitutional symptoms; a *convalescent phase*, in which jaundice begins to subside, constitutional symptoms disappear, and a sense of well-being returns to the patient.

HAV infection (infectious hepatitis) is not associated with blood transfusion. Viremia is short-lived, and the incubation period is only 3–4 weeks long. There are no chronic carriers, and chronic liver disease does not occur. Fulminant hepatic failure is rare (0.14–2%) in the absence of pre-existing liver disease. Patients with hepatitis B who acquire an HAV infection typically have an uncomplicated clinical course. However, approximately 41% of patients with chronic hepatitis C who acquire an HAV superinfection go on to develop fulminant hepatitis, which has a fatality rate of 35%. In these cases, propensity to develop liver failure is unrelated to the severity of pre-existing liver disease.¹³⁹ An HDV superinfection markedly increases the potential for HBV to cause fulminant hepatic failure.

HCV (previously called non-A, non-B hepatitis), which was discovered in 1989, was the major cause of transfusion-related hepatitis until the 1990s. Reports from earlier decades indicate that approximately 7 weeks elapsed between a transfusion and the onset of clinical hepatitis. It is now clear that the incubation period for HCV is 7 weeks, which is distinctly different from that of HAV (3–4 weeks) or HBV (12 weeks). HCV infections more often progress to chronic liver disease than do infections with the other viruses. Fortunately, serologic tests for HCV now exist. Because of their use in screening donated blood, the incidence of transfusion-related hepatitis from HCV has dropped precipitously. It continues to decline and is currently lower than that from HBV (about 1 case per 300,000 vs. 1 case per 60,000 units transfused).

Serologic tests have been the mainstay in the diagnosis of viral hepatitis. Serum immunoglobulin M (IgM) antibody to the HAV capsid or HAV RNA in stool documents an acute infection with HAV; recovery is associated with IgG anti-HAV. The diagnosis of HBV infection is made by identifying either HBsAg or antibody (IgM) to core antigen (HBV core), hepatitis Be antigen (HBeAg), antibody to HBeAg (anti-HBe), antibody to HBsAg (anti-HBs), or HBV DNA measured by polymerase chain reaction (PCR). IgM and total antibody to HDV document an infection with HDV, which requires a coexisting HBV infection. Anti-HCV or the presence of HCV RNA detects HCV. Assay for viral genome helps identify hepatitis G virus (HGV).

Autoantibodies often occur in both HBV and HCV infections, especially anti-smooth-muscle antibodies and antinuclear antibodies. The latter are associated with an HLA phenotype of AI,B8,DR3, which may be a marker for susceptibility to fulminant viral hepatitis. Anti-asialoglycoprotein receptor antibodies often appear in HAV infections, as well as in autoimmune hepatitis, but they are almost undetectable in HCV infections. HAV may trigger autoimmune mechanisms (partially primed by HCV) in susceptible patients, leading to massive hepatocellular necrosis.

Serologic tests used to diagnose viral hepatitis have their limitations; they are neither 100% sensitive nor 100% specific. Tests that screen for HBsAg are negative during the incubation period of HBV infections. Similarly, HDV infections generally suppress HBV replication; hence, patients with chronic liver disease caused by HBV, may have HDV but no detectable HbsAg in their blood. However, the identification of hepatitis B viral DNA in the blood of such patients indicates that the HbsAg assay may yield false-negative results in patients infected with HDV.¹⁴⁰ Acute HAV infections can cause previously detectable HBV DNA or HCV RNA to become undetectable until recovery from the HAV infection. Moreover, new hepatotoxic viruses continue to arise and may cause significant disease that eludes detection by present assays.

Fatty Liver Diseases

The most prevalent of the fatty liver diseases are alcoholic liver disease and nonalcoholic steatosis. These are the most common causes of cryptogenic cirrhosis. Morbid obesity or diabetes is present in about 70% of patients who develop cryptogenic cirrhosis. Increased fat appears to stress the hepatocyte and render it more susceptible to necrosis and apoptosis from other causes.

Nonalcoholic Steatohepatitis

Nonalcoholic steatohepatitis (NASH) is the most common cause of elevated liver blood tests in healthy blood donors. Up to 20% of these patients may have unsuspected fibrosis or cirrhosis. In this population, liver disease was the third most common cause of death, with a liver-related mortality of 11%.

Ethanol-Related Liver Diseases

Chronic alcoholism produces a wide spectrum of liver diseases, including steatosis (fatty liver), alcoholic hepatitis, and cirrhosis. Chronic alcoholism is notoriously difficult to detect by a brief patient history and physical examination. Laboratory values can be misleading, and the correlation between clinical presentation and hepatic histopathology is poor because compensatory mechanisms often mask extensive liver disease.¹⁴¹ Alcohol abusers by definition consume more than 5 g of alcohol per day (35 drinks per day). Recent studies indicate alcohol abusers have a 2- to 3-fold increase in perioperative morbidity (Fig. 39-13).¹⁴² The most frequent complications are bleeding, infections, and cardiopulmonary insufficiency. The pathogenic mechanisms include immune incompetence, subclinical cardiac insufficiency, hemostatic imbalance, and perhaps an exaggerated stress response to surgery or alcohol abstinence.

Figure 39-13. Prospective studies of postoperative morbidity in alcohol abusers and control subjects. * $p < 0.05$ vs. control subjects. (Reprinted with permission from Tonnesen H, Kehlet H: Preoperative alcoholism and postoperative morbidity. Br J Surg 86:869, 1999.)

Hereditary Hemochromatosis

More than one million Americans absorb and store too much iron in their bodies. This condition, called hemochromatosis, is the most common inherited metabolic disease. Approximately 85–90% of patients with hemochromatosis are homozygous for a C282Y mutation on the short arm of chromosome 6. The highest prevalence is in people of western European, specifically Celtic, descent. Patients are usually diagnosed with the disease when they are between 40 to 60 years old; they complain of vague symptoms, including fatigue, abdominal pain, joint pain, and exhibit slightly elevated liver enzymes and bronze discoloration of the skin.

The pathophysiology of hereditary hemochromatosis (HHC) involves an up-regulation of iron absorption from the duodenal mucosa. Decreased mucosal ferritin concentrations are associated with increased transferrin receptor levels. The mucosa behaves as if the patient were iron-deficient, leading to deposition of increased quantities of iron in a variety of tissues including the liver, skin, heart, pancreas, and joints.

Hereditary hemochromatosis is associated with a 150- to 200-fold increase in the risk of developing hepatocellular carcinoma. Liver cancer occurs in about 30% of the advanced cases, leading to the need for transplantation. However, survival rates after liver transplantation are much lower in hemochromatosis patients than in patients who undergo this procedure because of other liver diseases. This may relate to the devastating impact of untreated hemochromatosis on organs, such as the heart and pancreas.

Most of the clinical manifestations respond to phlebotomy. Once cirrhosis develops, however, phlebotomy will not reduce the risk of liver cancer. If HHC seems likely, it is important to obtain a liver biopsy and a quantitative iron determination because identification and treatment in the precirrhotic stage results in a normal long-term survival. The treatment of choice for these patients is quantitative phlebotomy performed on a weekly basis. Patients may have a total body iron content of 20–60 g. Since a unit of packed red blood cells contains 250 mg of iron, removal of excess iron stores may require 2–4 years. Thereafter, life-long phlebotomy treatments every 2–4 months will prevent accumulation of iron.

CIRRHOSIS: A PARADIGM FOR END-STAGE PARENCHYMAL LIVER DISEASE

For simplicity, this section discusses the pathophysiology of parenchymal liver disease with the example of hepatic cirrhosis as it relates to the practice of anesthesia. The most common clinical features of cirrhosis are an enlarged spleen and liver, ascites, mild to moderate jaundice, weakness, large esophageal varices, spider nevi, anorexia, nausea, vomiting, encephalopathy, and, sometimes, abdominal pain. Advanced parenchymal hepatic disease alters the function of nearly every organ and body system.

Cardiovascular Abnormalities

A hallmark of liver cirrhosis and portal hypertension is a hyperdynamic cardiovascular system, characterized by high cardiac output, low peripheral vascular resistance, and normal filling pressures, heart rate, and arterial pressure (Table 39-4). The earliest changes include arterial dilation and a decrease in peripheral vascular resistance. Stroke volume and cardiac index increases, which may even occur in patients with cardiomyopathy. The total blood volume tends to increase, but its maldistribution often leads to central hypovolemia and splanchnic hypervolemia. Peripheral blood flow markedly exceeds the metabolic oxygen requirements. Therefore, oxygen tension and saturation in the peripheral and mixed venous blood typically increase, and the arteriovenous difference in oxygen content narrows. The clinical and pathophysiologic syndrome is reminiscent of a peripheral arteriovenous fistula. This is not surprising, considering the extensive arteriovenous collateralization that occurs in many organs and tissues, including the splanchnic organs, lungs, skin, muscles, and probably others. The mechanism by which these collaterals develop is complex and not completely understood. Experimentally induced portal stenosis in rats increases arteriovenous shunting and blood flow in preportal tissues; 40% of this effect may be attributable to an increase in plasma glucagon.¹⁴³ The remaining 60% may be due to substances such as nitric oxide, ferritin, and vasoactive intestinal polypeptide (VIP), which can induce peripheral vasodilation, decrease vascular resistance, and increase arteriovenous shunting.

| |
|--|
| Decreased vascular resistance (peripheral vasodilation, increased arteriovenous shunting) |
| Increased cardiac output |
| Maintained arterial blood pressure, filling pressures, and heart rate (deterioration is late) |
| Blood volume maintained or increased, but redistributed (splanchnic hypervolemia, central hypovolemia) |
| Possible cardiomyopathy |
| Increased O ₂ content in mixed venous blood; decreased difference in the O ₂ contents of arterial and venous blood |
| Diminished responsiveness to catecholamines |
| Increased blood flow in splanchnic (extrahepatic), pulmonary, muscular, and cutaneous tissues |
| Decreased total hepatic blood flow |
| Maintained hepatic arterial blood flow |
| Decreased portal venous blood flow |
| Maintained or decreased renal blood flow |

Table 39-4. CARDIOVASCULAR FUNCTION IN HEPATIC CIRRHOSIS

Cirrhosis reduces the responsiveness of the cardiovascular system to sympathetic discharge, as well as to endogenous and exogenous cardiovascular stimulants. These distorted responses probably relate to circulating vasodilating factors, but could also result from an impairment of baroreceptor reflexes. The mechanism of the decreased responsiveness to cardiovascular stimulation is not completely clear. Glucagon, whose concentration invariably increases in cirrhotic patients with portal hypertension, reduces the vascular responsiveness to infused catecholamines and other vasopressors in experimental settings.¹⁴⁴

Does Nitric Oxide (NO) Mediate the Hyperdynamic Circulatory Changes?

Recent evidence indicates that nitric oxide (NO) may be an important mediator of the hyperdynamic changes, as well as the disorders of sodium and water excretion, that occur in cirrhosis and portal hypertension. NO-induced cyclic guanosine monophosphate (cGMP) production correlates with the degree of peripheral arterial dilation in experimental models of chronic portal hypertension (partial portal vein ligation and CCl₄-induced cirrhosis in rats). The CCl₄ model is characterized by significant decreases both in MAP (20 mm Hg) and in systemic vascular resistance (by 45%) and a marked increase (44%) in cardiac index (Fig. 39-14). Treatment with inhibitors of NO synthase returns these parameters to baseline values, as well as restoring the responsiveness of blood vessels to vasoconstrictor therapy. Moreover, inhibition of NO synthase restores plasma concentrations of aldosterone and arginine vasopressin to normal values, and corrects abnormalities of sodium and water excretion in experimental models of cirrhosis and portal hypertension (Fig. 39-15). Preliminary evidence in humans suggests that NO may mediate the hyperdynamic circulatory state that occurs clinically. Data from normal subjects and patients with cirrhosis reveal a positive correlation between the exhaled concentration of NO and cardiac index (Fig. 39-16). Based on such observations, it may be possible to develop a new class of therapeutic agents to treat the major causes of morbidity and mortality in cirrhosis.

Figure 39-14. Effects of 7-day administration of L-NAME (*N*[G]-nitro-L-arginine methyl ester) on cyclic guanosine monophosphate (cGMP), mean arterial pressure, systemic vascular resistance, and cardiac index in cirrhotic rats with ascites. Rats were either untreated (solid bars) or treated (stippled bars) with L-NAME (0.5 mg · kg⁻¹ · day⁻¹). A group of normal untreated rats (open bars) served as controls. For each measurement, values in untreated cirrhotic rats with ascites differed significantly from those in the treatment and control groups ($p < 0.01$; $n = 8$ per group). Values for systemic vascular resistance and cardiac index are per 100 g of body

weight. Values shown are means \pm SE. (Reprinted with permission from Niederberger, M, Martin, PY, Gines, P *et al*: Normalization of nitric oxide production corrects arterial vasodilation and hyperdynamic circulation in cirrhotic rats. *Gastroenterology* 109:1624, 1995.)

Figure 39-15. Effects of the inhibition of nitric oxide synthase with L-NAME (*N*[G]-nitro-L-arginine methyl ester) on mean urinary sodium excretion, plasma aldosterone concentrations, water excretion, and plasma vasopressin concentrations in rats with cirrhosis. (Reprinted with permission from Martin PY, Ohara M, Gines P *et al*: Nitric oxide synthase [NOS] inhibition for one week improves renal sodium and water excretion in cirrhotic rats with ascites [published erratum appears in *J Clin Invest* 102(3), 1998, inside back cover]. *J Clin Invest* 101:235, 1998.)

Figure 39-16. Relationship between nitric oxide in exhaled air and the cardiac index in 25 patients who had either normal hepatic function or cirrhosis with varying degrees hepatic dysfunction. (Severity of liver dysfunction increases progressively from Child class A to class C.) A positive correlation exists between nitric oxide output (expressed in nanoliters per minute per square meter of body surface area) and cardiac index (expressed in liters per minute per square meter). $r = 0.62$ and $p < 0.001$. (Reprinted with permission from Matsumoto, A, Ogura, K, Hirata, Y *et al*: Increased nitric oxide production in the exhaled air of patients with decompensated cirrhosis. *Ann Intern Med* 123:110, 1995.)

Pulmonary Dysfunction

Patients with cirrhosis and portal hypertension will have some degree of pulmonary dysfunction; the severity is usually greatest in patients with the most advanced liver disease.¹⁴⁵ Hypoxemia commonly occurs for a variety of reasons (Table 39-5). Vasodilatory substances (e.g., nitric oxide, glucagon, adenosine, or prostacyclin) may account for the impaired hypoxic pulmonary vasoconstriction associated with liver disease.¹⁴⁶ Erythrocyte concentrations of 2,3-diphosphoglycerate may increase, reducing the affinity of hemoglobin for oxygen and shifting the oxyhemoglobin dissociation curve to the right. Major intrapulmonary arteriovenous shunting of blood is present in some patients with advanced liver disease; these shunts are of great clinical concern and a characteristic feature of the hepatopulmonary syndrome. The development of severe ascites and pleural effusions leads to atelectasis, marked restrictions of lung volumes and capacities (including FRC and closing capacity) and causes major V/Q mismatching and severe hypoxemia.

| |
|--|
| Rightward shift of the oxyhemoglobin dissociation curve (increased 2,3 = DPG) |
| Ventilation-perfusion abnormalities (impaired hypoxic pulmonary vasoconstriction) |
| Hypoventilation secondary to ascites |
| Decreases in pulmonary diffusing capacity secondary to increased extracellular fluid |
| Right-to-left pulmonary shunts caused by: |
| Spider angiomas in the lungs |
| Portopulmonary venous communications |
| Humoral factors (e.g., vasodilators, nitric oxide, glucagon) |

Table 39-5. HYPOXEMIA IN HEPATIC CIRRHOSIS

Hepatic Hydrothorax

Hepatic hydrothorax occurs in 4–10% of cirrhotic patients. This disorder is characterized by pleural effusions in the absence of cardiopulmonary disease.¹⁴⁷ Most often, ascitic fluid fluxes from the peritoneal cavity into the pleural space through diaphragmatic defects. Initial treatment of hepatic hydrothorax consists of sodium restriction, diuretics, and thoracentesis; transjugular intrahepatic portosystemic stent shunts (TIPS) may be required in refractory cases. Because most of these patients have end-stage liver disease, liver transplantation becomes the preferred treatment if the above options fail.¹⁴⁷

Pulmonary Pathophysiology in Patients with End-Stage Liver Disease

In a group of patients ($n = 362$) awaiting their first liver transplantation, 20% had mean pulmonary artery pressures that exceeded 25 mm Hg.¹⁴⁸ Only 4% of patients had pulmonary hypertension (defined as mean pulmonary artery pressure ≥ 25 mm Hg and pulmonary vascular resistance >120 dyn \cdot s \cdot cm⁻⁵). Seven percent of patients had obstructive airways disease, 18% had restrictive disease, and 46% had low diffusion capacity on pulmonary function tests.

Ascites, Renal Dysfunction, and the Hepatorenal Syndrome

Portal hypertension alone does not impair renal circulation or cause obvious renal dysfunction. However, the combination of portal hypertension and cirrhosis leads to a spectrum of renal abnormalities. Derangements of sodium, potassium, and water metabolism and excretion occur commonly, as well as disorders of renal acidification. Glomerulopathy, acute renal failure, or hepatorenal syndrome often complicates severe liver disease.

Ascites and Edema

Nearly 50% of cirrhotic patients develop ascites within 10 years of being diagnosed with cirrhosis.¹⁴⁹ Ascites markedly worsens the prognosis of cirrhotic patients. Those with mild ascites retain sodium, but the problem usually corrects with diuretics. More severe forms, however, may be refractory to diuretic therapy (refractory ascites) and degenerate into hepatorenal failure. Of patients who have ascites, 18% develop hepatorenal syndrome at 1 year and 39% at 5 years.¹⁵⁰

The most important treatments for patients with ascites are dietary sodium restriction and diuretic therapy, particularly spironolactone and furosemide. However, the overaggressive use of diuretics to increase urine output and decrease ascites often results in potentially serious complications, including hypovolemia, hyponatremia, hypokalemia, azotemia, and encephalopathy. Without proper fluid management, diuretics can severely diminish a patient's effective plasma volume, leading to azotemia or to the hepatorenal syndrome.

Pathogenesis of Ascites

The pathogenesis of ascites in cirrhosis is complex and not completely understood¹⁴⁹ (Fig. 39-17). Cardiovascular abnormalities (discussed previously) associated with advanced liver disease cause major alterations of renal function. The kidneys avidly retain sodium, which leads to the accumulation of extracellular fluid and the development of ascites and edema. It is thought that the sodium retention results from either a decrease in "effective" blood volume (traditional or arterial underfilling hypothesis¹⁵¹),¹⁵² or from a renal tubular disorder (Fig. 39-17).

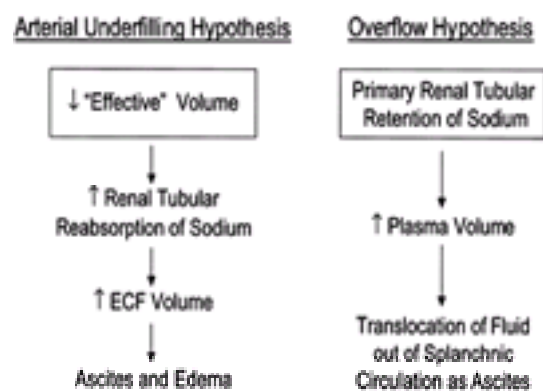

Figure 39-17. The presumed sequences of events that result in ascites formation according to the arterial underfilling hypothesis and the overflow hypothesis. The proposed primary disorders are shown in the boxes. According to the underfilling hypothesis, cirrhosis induces abnormal Starling forces in the portal venous circulation that cause an unfavorable distribution of the circulating blood volume (decreased effective blood volume). The diminished "effective" volume constitutes an afferent signal to the renal tubules to augment salt and water reabsorption. The attempt to replenish the diminished effective volume results in an expansion of the total blood volume to values far in excess of normal, with resultant ascites and edema formation. The overflow hypothesis holds that the primary disorder is retention of excessive sodium by the kidneys. In the setting of abnormal Starling forces in the portal venous bed, the expanded plasma volume is sequestered preferentially in the peritoneal sac. ECF = extracellular fluid. (Reprinted with permission from Epstein M: Renal functional abnormalities in cirrhosis: Pathophysiology and management. In Zakim D, Boyer TD [eds]: Hepatology: A Textbook of Liver Disease, p 448. Philadelphia, WB Saunders, 1982.)

Schrier and Abraham¹⁵¹ suggest that the concept of arterial underfilling provides the basis for a unifying hypothesis that explains the regulation of body-fluid volume in health and disease. The hypothesis states that "the integrity of the arterial circulation, as determined by cardiac output and peripheral arterial resistance, is the primary determinant of renal sodium and water excretion."¹⁵¹ In other words, the body activates neurohumoral reflexes to retain sodium and water whenever it senses a decrease in the volume of the arterial system, whether the decrease results from a lowering of cardiac output or from an increased degree of arterial dilation. In cirrhotic patients, the effective (circulating) plasma volume decreases owing to the combined effects of arteriolar dilation (discussed earlier) and an imbalance of Starling forces in the hepatic sinusoids and splanchnic capillaries. This leads to excessive formation of lymph, which engorges the lymphatic system and transudes through Glisson's capsule, to accumulate in the peritoneal cavity as ascites. The total plasma volume remains normal or may even increase, but the effective plasma volume decreases. The neurohumoral response to the "ineffective" plasma volume triggers the kidney to retain sodium and water. Thus, the underfilling hypothesis explains renal sodium retention as a secondary rather than a primary phenomenon.

In contrast, the overflow hypothesis posits that abnormal sodium retention *per se* is the primary pathogenetic factor that increases plasma volume in cirrhotic patients. Accordingly, expansion of plasma volume causes portal hypertension (via increased hydrostatic pressure). This, in conjunction with a decrease in the colloid osmotic pressure of plasma, leads to ascites formation. Thus, the overflow hypothesis contends that renal sodium retention and plasma volume expansion, rather than plasma volume reduction are responsible for ascites formation.

Conceptually, these two hypotheses are not mutually exclusive; each may play a role in various stages of cirrhosis. Conceivably, in the early stages of cirrhosis, a primary defect in sodium excretion plays the more critical role, whereas with more advanced disease, a reduction in circulating plasma volume is more essential.¹⁵²

Pathogenesis of Renal Dysfunction

A decrease in renal cortical blood flow is one of the earliest manifestations of impaired renal function in cirrhotic patients. Renal blood flow decreases because renal vascular resistance increases. This occurs despite a lowering of total peripheral vascular resistance and an elevation of cardiac output. Thus, the kidneys suffer from hypoperfusion while other tissues (preportal organs, skin, lungs, and muscles) tend to be hyperperfused. The increase in renal vascular resistance is greater in afferent than in efferent arterioles. Various neurohumoral substances as well as intrarenal factors mediate the increases in renal vascular resistance (Fig. 39-18).

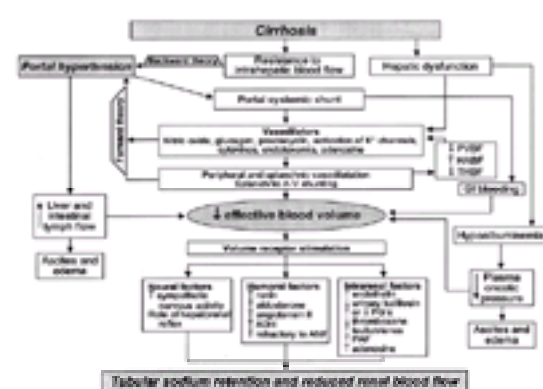

Figure 39-18. This schematic representation depicts the cirrhosis-induced development of portal hypertension, according to the forward theory and backward theory. Circulatory changes associated with cirrhosis and portal hypertension ultimately decrease the effective blood volume. This decrease stimulates volume receptors, which activate the neural, humoral, and intrarenal pathways that cause renal dysfunction (tubular sodium retention and decreased renal blood flow) in patients with hepatic cirrhosis. PVBF = portal vein blood flow; HABF = hepatic artery blood flow; THBF = total hepatic blood flow; A-V = arteriovenous; PG = prostaglandins; ADH = antidiuretic hormone; ANF = atrial natriuretic factor; PAF = platelet-activating factor.

Volume receptors detect decreases in effective plasma volume and activate the sympathetic nervous system. This causes the kidney to release renin, which leads to an increased production of angiotensin II (vasoconstrictor) and aldosterone. Both aldosterone and increased sympathetic nervous system outflow enhance tubular resorption of sodium. Norepinephrine concentrations are inversely related to renal blood flow, suggesting that the sympathetic nervous system plays an important role in sodium retention. Both norepinephrine and angiotensin II, through their vasoconstrictive actions, cause a redistribution of intrarenal blood flow, which further decreases sodium elimination. The kallikrein-kinin system also participates in modulating sodium retention. The concentration of endothelin, which is the most potent naturally occurring vasoconstrictor, is elevated in cirrhotic patients with ascites and probably contributes to the renal dysfunction. Renal prostaglandin synthesis appears crucial to the preservation of renal function in patients with advanced liver disease because inhibitors of prostaglandin synthesis (*e.g.*, NSAIDs) markedly

decrease renal plasma flow and glomerular filtration rate and can precipitate acute renal insufficiency. Cirrhotic patients without ascites do not seem to be susceptible to this untoward effect of NSAIDs. Thus, in cirrhotic patients with ascites, vasodilatory actions of prostaglandins synthesized in the kidney play an essential role in maintaining renal blood flow.

Hepatorenal Syndrome

The hepatorenal syndrome occurs primarily in hospitalized patients who have cirrhosis, portal hypertension, and moderate to severe ascites. The syndrome is typically associated with therapeutic interventions (or events) that can critically decrease plasma volume, including paracentesis, vigorous diuretic therapy, and gastrointestinal bleeding. Patients with hepatorenal syndrome continue to produce urine, although the rate of urine formation is somewhat decreased. Quite remarkably, this urine, even when concentrated, contains almost no sodium, similar to the urine of hypovolemic patients. Serum creatinine and blood urea nitrogen increase continuously as the syndrome progresses. When hepatorenal failure occurs, the kidneys are histologically intact and the renal damage is reversible; such kidneys, when transplanted, can function normally. Nonetheless, most patients with hepatorenal syndrome die. It is therefore imperative to prevent this syndrome by judicious management of diuretic therapy and volume status.

The pathogenesis of hepatorenal syndrome is complex and involves intense renal vasoconstriction and marked decreases in renal blood flow. The syndrome involves alterations of key vasoregulatory pathways, including the renin–angiotensin system, sympathetic nervous system, kallikrein–kinin system, prostaglandins synthesis, as well as the production and removal of endotoxin from blood. Endothelin-1 can produce intense renal vasoconstriction, which correlates with the severity of the renal dysfunction. Renal prostaglandins usually compensate for the intense vasoconstriction that occurs in patients with advanced liver disease. In hepatorenal syndrome, this compensatory mechanism fails to maintain renal perfusion. Concentrations of atrial natriuretic factor, a powerful vasodilator, increase in cirrhotic patients, but the kidney is somewhat refractory to its vasodilatory effects.

Patients with hepatorenal syndrome usually have a decreased mean arterial pressure, which adds to the difficulty of successfully treating them. These patients have a rightward shift of their autoregulatory curve (renal blood flow and renal perfusion pressure); hence, small reductions in arterial pressure produce profound decreases in renal blood flow.

Acute Renal Failure and Acute Tubular Necrosis

Cirrhotic patients are also at risk for developing acute renal failure (ARF) and acute tubular necrosis (ATN), especially following infection or episodes of arterial hypotension. ATN appears to occur more often after operative interventions to relieve obstructive jaundice than following similar operations on nonjaundiced patients. Renal tubular injury may occur because patients with hepatic parenchymal disease and obstructive jaundice do not effectively mobilize blood from the splanchnic (including hepatic) vasculature to increase the central blood volume. Thus, even moderate hemorrhage may produce severe hypotension and cause ATN. In addition, conjugated bilirubin appears to be toxic to renal tubules and may contribute to the development of ATN in jaundiced patients.

The differential diagnosis of acute azotemia, shown in [Table 39-6](#), indicates that the urinary characteristics of prerenal azotemia and hepatorenal syndrome are remarkably similar, but are clearly distinct from the urinary profile of ATN. Nonetheless, hepatorenal syndrome and ATN require similar therapeutic strategies. In both disorders, it is critically important to identify the underlying causes of renal insufficiency and to ensure an adequate circulating blood volume. To do this mandates prompt detection and treatment of bleeding and cautious use of diuretics.

| | Prerenal Azotemia | Hepatorenal Syndrome | Acute Renal Failure (Acute Tubular Necrosis) |
|----------------------------------|--|--|--|
| Urinary sodium concentration | <10 mEq L ⁻¹ | <10 mEq L ⁻¹ | >30 mEq L ⁻¹ |
| Urine-to-plasma creatinine ratio | >30:1 | >30:1 | <20:1 |
| Urinary osmolality | Exceeds plasma osmolality by at least 100 mOsm | Exceeds plasma osmolality by at least 100 mOsm | Equal to plasma osmolality |
| Urinary sediment | Normal | Unremarkable | Cells, cellular debris |

Table 39-6. DIFFERENTIAL DIAGNOSIS OF ACUTE AZOTEMIA IN PATIENTS WITH LIVER DISEASE: IMPORTANT DIFFERENTIAL URINARY FINDINGS

Hepatic Circulatory Dysfunction

The pathogenesis of hepatic cirrhosis and portal hypertension is extremely complex and not well understood (see [Fig. 39-18](#)). Elevation of portal pressure stems from one or a combination of three factors: preportal blood flow, resistance to intrahepatic flow, and resistance to flow through the portacaval collaterals.

The classic “backward theory” posits that proliferation of fibrotic tissue, which gives rise to hepatic cirrhosis, increases the resistance to portal flow, thereby causing portal hypertension. However, many clinical and experimental observations do not fit the backward theory. For example, in experimental animals, restriction of transhepatic portal flow does not always produce portal hypertension comparable to that encountered clinically, nor does it produce bleeding from esophageal varices. In addition, when acute portal hypertension is produced by specifically narrowing the portal vein, splanchnic venous oxygen saturation decreases substantially, mesenteric arterial venous oxygen content difference increases, mesenteric vascular resistance increases, and mesenteric arterial flow decreases. Such changes are in diametric opposition to those observed in cirrhotic patients with portal hypertension.

To explain the clinical and physiologic features that are not well explained by the backward theory, a “forward theory” has been proposed.¹⁵³ This theory posits that certain mediators (nitric oxide, glucagon, prostacyclin, adenosine, and other compounds) cause vasodilation and formation of arteriovenous fistulae in the intestine and the spleen, thereby producing a hyperdynamic state with increased splanchnic blood flow and cardiac output. Portal blood flow to the liver decreases substantially, whereas hepatic arterial flow remains unchanged or increases. Thus, while total blood flow to the liver decreases, the hepatic oxygen supply is preserved. The decrease in total hepatic flow has pharmacokinetic implications: compounds, exogenous as well as endogenous, with high hepatic clearances are eliminated more slowly than in healthy people.

Hematologic and Coagulation Disorders

Anemia is common in cirrhotic patients for a variety of reasons. A dilutional anemia results from an increase in plasma volume, and is often exacerbated by erythrocyte loss from gastrointestinal bleeding. Malnutrition may lead to megaloblastic anemia because of deficiencies of vitamin B₁₂ and other vitamins, especially in alcoholics. There is an increased rate of hemolysis; the hemolytic activity is proportional to the size of the spleen but not to the degree of portal hypertension, and relates to reticulocytosis. Leukopenia and thrombocytopenia may also arise owing to hypersplenism or ethanol-induced depression of the bone marrow.

Most patients with liver cirrhosis have mild abnormalities of coagulation. Factor VII, owing to its relatively short half-life, decreases earlier and to lower levels than the other clotting factors produced by the liver. This is followed by a decrease in Factors V, X, and II (prothrombin); Factor I (fibrinogen) synthesis deteriorates last. The liver does not synthesize Factor VIII, which occasionally increases in cirrhotic patients. Usually, the concentration of fibrin degradation products is not increased, although severe disseminated intravascular coagulation develops in some settings, such as after LeVeen shunt surgery. When hepatic failure is severe, clotting factors synthesis decreases substantially, resulting in prolongation of the prothrombin (PT or INR) and partial thromboplastin times. Changes in the prothrombin time (PT or INR) usually provide an accurate reflection of the extent of liver dysfunction.

Endocrine Disorders

Cirrhotic patients often have abnormal glucose utilization. The mechanism of this phenomenon is rather complex and includes increased fatty acid concentrations in plasma, which antagonize the effects of insulin on glucose uptake by skeletal muscles. In addition, plasma concentrations of growth hormone and glucagon are often increased, and undoubtedly contribute to the glucose intolerance and other derangements of intermediary metabolism that occur in patients with hepatic dysfunction.

Abnormal metabolism of sex hormones causes gonadal dysfunction in both men and women. Men undergo feminization, often developing gynecomastia along with a decrease in the size of their testes and prostate gland. Testicular dystrophy is often apparent microscopically. The frequency of impotence increases and sperm counts typically decrease in those who still produce and ejaculate semen. In women with liver dysfunction, oligomenorrhea or amenorrhea commonly occurs.

Hepatic Encephalopathy

Hepatic encephalopathy is a complex neuropsychiatric syndrome with clinical manifestations ranging from subtle abnormalities, detectable only by psychometric testing, to confusion, obtundation, and deep coma. Some degree of encephalopathy occurs in 50–70% of patients with cirrhosis. Many of the encephalopathic changes are reversible with medical therapy. Even the most progressive, debilitating abnormalities, such as dementia, spastic paresis, cerebellar degeneration, and extrapyramidal movement disorders, may gradually improve after successful orthotopic liver transplantation. The encephalopathy may result from inadequate hepatocyte function, reduced hepatic blood flow, or diversion of portal flow through extrahepatic collateral vessels (*i.e.*, portacaval blood flow). These vessels include the portacaval collaterals that commonly develop in cirrhotic patients with portal hypertension (*e.g.*, esophageal, rectal) as well as surgically created portacaval shunts.

Patients with advanced hepatocellular dysfunction often have elevated ammonia levels in arterial blood, especially when significant portosystemic shunting is present. Ammonia levels, however, correlate poorly with the grade of hepatic encephalopathy and therefore are of little clinical value either for establishing a diagnosis of hepatic encephalopathy or for assessing prognosis. Of greater value are the physical examination and bedside psychometric tests (number-connection, trail-making tasks), which provide inexpensive, useful information about the progression and severity of the encephalopathy. The pathogenesis of hepatic encephalopathy is complex (Fig. 39-19). While ammonia seems to play the central role (inset; Fig. 39-19) a wide variety of pathologic changes probably contribute to the genesis of the encephalopathy. Putative mechanisms include neurotoxic effects of gut-derived molecules (*e.g.*, short-chain fatty acids, mercaptans, phenols, manganese), impairment of cerebral energy metabolism, disruption of the blood–brain barrier, and neuropathic changes that intensify neuroinhibition (*e.g.*, synthesis of endogenous ligands that activate central g-aminobutyric acid–benzodiazepine receptors) or diminish neuroexcitation (*e.g.*, production of false neurotransmitters). For example, encephalopathic patients appear to form abnormal biogenic amines in the central nervous system that are released by neural stimulation along with, or instead of, normal neurotransmitters. Structurally, these amines are similar to norepinephrine or dopamine, but they are much less active in eliciting a response from the effector (*i.e.*, false neurotransmitters).

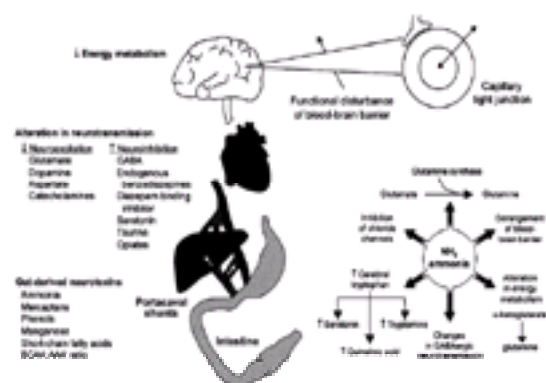

Figure 39-19. Schematic representation of pathogenesis of hepatic encephalopathy: *Inset:* proposed mechanisms of neurotoxicity of ammonia. AAA = aromatic amino acid; BCAA = branched-chain amino acid; GABA = g-aminobutyric acid. (Reprinted with permission from Jalan R, Hayes PC: Hepatic encephalopathy and ascites. *Lancet* 350:1309, 1997.)

Despite recent insights into the etiology of hepatic encephalopathy, the ammonia hypothesis still provides the rationale for most therapies used to stabilize or reverse the encephalopathy. The diet should restrict the intake of nitrogen-containing food (protein) to minimize the synthesis of ammonia. Lactulose, which promotes ammonia excretion from the body by trapping it in the acidified fecal stream (ammonium), makes ammonia unavailable for absorption. It is especially important to prevent gastrointestinal bleeding, control infection (neomycin is usually the drug of choice), correct acid–base and electrolyte imbalances, and to titrate diuretic drugs and the fluid load. L-Dopa may facilitate renal excretion of ammonia. In addition, dopamine agonists and L-dopa may produce beneficial effects by promoting displacement of false neurotransmitters in the central nervous system.

It appears clear that encephalopathic changes are associated with clinically important alterations in pharmacodynamic and pharmacokinetics of various medications. For example, cerebral uptake of benzodiazepines increases substantially, which may reflect an increase in the density or affinity of benzodiazepine receptors or a leaky blood–brain barrier. Drugs administered to patients with advanced hepatic disease require careful titration against effect. The pathogenesis and management of hepatic encephalopathy are described in detail elsewhere.^{149,152,154}

Effects on Responses to Pharmacologic Agents

Pharmacokinetic Alterations

Data concerning the pharmacokinetics of midazolam in patients with advanced liver disease are conflicting. One study¹⁵⁵ demonstrated a significant decrease in clearance and elimination half-life, whereas another study¹⁵⁶ demonstrated only slightly impaired disposition in cirrhotic patients. The pharmacokinetics of single doses of sufentanil¹⁵⁷ and propofol¹⁵⁸ were found to be similar in cirrhotic patients and those with normal hepatic function, although some differences in elimination time were observed. Such findings imply that administering infusions or multiple doses of certain intravenous drugs can result in prolonged pharmacologic effects because of impaired hepatic elimination in patients with advanced hepatic disease. The differences in the results of these studies are probably a consequence of certain differences in the binding proteins, as well as accumulation of endogenous binding inhibitors such as bilirubin. This might explain a smaller degree of midazolam protein binding in cirrhotic individuals, with a subsequent increase in the free fraction of the drug and enhancement of the pharmacologic effect in cirrhotic patients.

For thiopental, total plasma clearance and total apparent volume of distribution at the steady state are unchanged in cirrhotic patients. Therefore, the elimination half-life is not prolonged.¹⁵⁹ Thiopental has a low extraction ratio, so its clearance is independent of hepatic blood flow. Nonetheless, decreases in plasma protein binding, which are often unpredictable, may cause excessive pharmacologic responses to standard doses of the various agents used to induce anesthesia.

The plasma clearance of fentanyl is significantly lower in cirrhotic patients than in control subjects. The total apparent volume of distribution does not change, but the elimination half-life increases owing to decreased plasma clearance. With alfentanil, the free fraction also increases, and this agent exerts prolonged and pronounced effects in cirrhotic patients with advanced liver disease.¹⁶⁰

The data regarding morphine pharmacokinetics in cirrhotic patients are contradictory. For example, Patwardhan *et al*¹⁶¹ reported that the pharmacokinetics of morphine in cirrhotic patients and healthy people are similar. They suggested that “reported intolerance to the central effects of morphine cannot be explained by impaired drug elimination and increased availability of morphine to cerebral receptors.”¹⁶¹ Other investigators, however, reported that the clearances of free morphine and its metabolites are decreased and their half-lives prolonged in cirrhotic patients compared to healthy control subjects.¹⁶²

Pharmacodynamic Alterations

Although hepatic disease often produces substantial pharmacokinetic changes, it also can lead to important pharmacodynamic alterations. Patients with cirrhosis, particularly those with hepatic encephalopathy, are much more sensitive to sedatives (*e.g.*, opioids and benzodiazepines) than are healthy people. For example, at equal plasma concentrations of diazepam, more pronounced encephalographic alterations occur in those with severe hepatic disease than in healthy people.¹⁶³ By contrast, pharmacologic responses to some medications decrease in patients with cirrhosis and portal hypertension as a result of the pathophysiologic changes associated with the disease. Increases in plasma concentrations of certain vasodilatory substance antagonist responses to catecholamines and other vasoconstrictors. Patients, as well as animals, with portal hypertension have elevations of plasma glucagon,¹⁴³ which substantially reduces the responses of a variety of blood vessels to catecholamines.¹⁴⁴ Thus, while patients with advanced liver disease often require reduced doses of central nervous system depressants (morphine, chlorpromazine, and benzodiazepines), they require increased doses of catecholamine or addition of a nonadrenergic vasoconstrictor (vasopressin) when such therapy is needed to support blood pressure.

Rational Drug Therapy

Rational drug selection mandates an understanding of the effects of hepatic disease on pharmacokinetics and pharmacodynamics, but it does not preclude the use of medications whose pharmacology is significantly altered by hepatic disease. Indeed, a drug's effects may be rendered less predictable by hepatic disease, but the drug may still be clinically preferable to an alternative agent whose pharmacology is unaffected by hepatic disease. As an illustration, cirrhotic patients require higher initial doses of *d*-tubocurarine than do healthy patients to achieve a similar degree of muscle relaxation.¹⁶⁴ This effect seems to be related purely to pharmacokinetic factors: cirrhotic patients have a larger volume of distribution for *d*-tubocurarine, primarily related to an increased α -globulin fraction (greater binding of *d*-tubocurarine and a smaller free fraction). On the other hand, the presence of end-stage liver disease plus cholestasis (obstructive jaundice) results in an impairment of clearance and a potential for prolonged effects of all drugs excreted in bile, including muscle relaxants. To some clinicians, these observations might suggest the advisability of using gallamine or, particularly, atracurium, since these relaxants are not excreted with the bile.¹⁶⁵ However, pharmacokinetic data should not dictate therapeutic decisions, because pharmacodynamic factors, such as the undesirable effects of alternative medications, may be of greater clinical relevance. For example, severe liver disease may decrease vecuronium clearance and prolong its half-life, but it has no significant effect on gallamine clearance. This does not mean that vecuronium is contraindicated in cirrhotic patients. In fact, a cirrhotic patient with coronary artery disease may have a better outcome with cautious titration of vecuronium than with gallamine, which induces tachycardia. The lesson is clear. Owing to the pharmacodynamic and pharmacokinetic alterations that accompany hepatic disease, responses of cirrhotic patients to drugs are often unpredictable. Minimizing the adverse consequences of this unpredictability requires judicious drug selection and, perhaps more importantly, careful titration of the drug to the desirable effect.

CHOLESTATIC DISEASE

Cardiovascular Dysfunction

The presence of bile salts in circulating blood (cholemia) can impair myocardial contractility.¹⁶⁶ Cholemia also blunts the response to norepinephrine, angiotensin II, and isoproterenol,¹⁶⁷ probably by interfering with their binding to membrane receptors. Less severe hemodynamic perturbations occur in patients with biliary obstruction than in those with cirrhosis. However, the pattern of the pathophysiologic change is remarkably similar: peripheral vascular resistance decreases, cardiac output increases, portal venous pressure increases, and portal venous blood flow decreases.

Patients with hepatic disease, either parenchymal or cholestatic, have a reduced sensitivity to vasopressor drugs. The exact reasons for the decreased sensitivity is unclear. However, data from *in vitro* and *in vivo* experiments indicate that bile acids contribute to the vasodilation and hypotension that often occur in patients with biliary obstruction.¹⁶⁶ Conceivably, a decreased responsiveness to vasoactive substances (including catecholamines) is responsible for the interesting and clinically important observation that patients with biliary obstruction are often intolerant of even small blood losses. A moderate loss (10%) of blood volume in normal animals does not substantially decrease mean arterial pressure, but a 10% loss of blood volume in animals with experimentally induced biliary obstruction causes severe (~50%) arterial hypotension. Intact animals respond to such blood loss with an approximately 15% decrease in blood volumes in both the pulmonary and splanchnic vascular beds. Animals with biliary obstruction have only a 7% decrease of their pulmonary blood volume and no change in splanchnic blood volume.¹⁶⁷ If we can extrapolate these results to humans, patients with biliary obstruction would have an impaired hemodynamic response to blood loss. An impairment of the ability to translocate blood from pulmonary and splanchnic blood reservoirs to the systemic circulation would render patients highly susceptible to arterial hypotension from bleeding. Furthermore, the results would indicate the urgency of expeditiously replacing perioperative volume losses in this patient population. The anesthesiologist should be aware that biliary decompression may be accompanied by severe cardiovascular collapse.¹⁶⁸

Coagulation Disorders

Patients with biliary obstruction are prone to certain coagulation disorders. During brief episodes of biliary obstruction, coagulopathy can result from a deficiency of coagulation factors whose activation depends on the presence of vitamin K. Absorption of vitamin K depends on the excretion of bile into the gastrointestinal tract. Long-lasting biliary obstruction can cause liver injury, with subsequent deterioration in the hepatic synthesis of proteins, including coagulation factors. Usually, the coagulation disorders are moderate, and parenteral vitamin K corrects the problem. If this treatment is not fully effective, one should suspect that the disease is not purely cholestatic, and that hepatic parenchymal injury exists. Should such patients need urgent surgery, the coagulopathy will require immediate treatment with fresh frozen plasma. The failure of parenteral vitamin K to correct a prolonged prothrombin time typically indicates the presence of severe hepatic parenchymal dysfunction and portends a poor prognosis.

CLINICAL APPROACH TO PATIENTS WITH ASYMPTOMATIC BIOCHEMICAL ABNORMALITIES OR OVERT LIVER DISEASE

A careful history and physical examination will usually suffice to detect patients with significant hepatic dysfunction. Unless liver disease is suspected, it is probably best not to order a panel of liver blood tests. This is because routine testing may yield false-positive results, engendering patient anxiety and prompting the performance of expensive, unnecessary, and potentially injurious invasive tests.

Perioperative physicians are presented with a dilemma when patients without clinically apparent hepatic disease have recently had liver blood tests with one or more abnormal results. The prudent course in patients with asymptomatic biochemical abnormalities may be to delay surgery and repeat the test(s) later (Fig. 39-20). This conservative approach helps to ensure that a patient is not in the early stages of a disease process that may abruptly worsen.

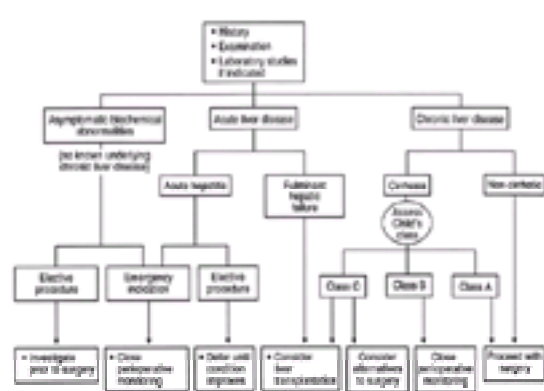

Figure 39-20. Preoperative approach to patient with known or suspected liver disease. (Modified with permission from Patel T: Surgery in the patient with liver disease. Mayo Clin Proc 74:593, 1999.)

Assessing perioperative risks for patients with liver disease is an inexact science. Their risk of perioperative morbidity and mortality appears to depend on three major factors: (1) type of operation, (2) nature and severity of the underlying hepatic disease, and (3) extent of the hepatic dysfunction. Most of the data on perioperative risk derive from retrospective studies or clinical reports of cirrhotic patients undergoing abdominal surgeries rather than from large, prospective studies on the subject. Nonetheless, these data persuasively suggest that patients with severe hepatic dysfunction have a high risk for morbidity and mortality from major operative procedures. In addition, acute hepatitis (viral, alcoholic, ischemic, or drug-related) is associated with increase perioperative risk and mortality. These patients deserve supportive therapy; an improvement in their overall condition will diminish their perioperative risk. Therefore, in the presence of acute hepatic disease, elective surgery should be postponed (Fig. 39-20).

ANESTHESIA FOR PATIENTS WITH MODERATE-TO-SEVERE LIVER DISEASE (HEPATITIS, CIRRHOSIS)

Significant liver disease greatly increases the risk of postoperative hepatic complications, especially after emergency surgery.¹⁶⁹ These risks are greater for abdominal operations than for peripheral or superficial procedures. The severity of the hepatic dysfunction, as assessed by the Child-Pugh classification (Table 39-7), correlates with the incidence of both perioperative complications (liver failure, bleeding, infection, sepsis, renal failure, pulmonary failure, and ascites)^{170,171} and mortality.¹

| Presentation | Points ^a | | |
|---|---------------------|-----------------|--------------|
| | 1 | 2 | 3 |
| Albumin (g·dl ⁻¹) | >3.5 | 2.8-3.5 | <2.8 |
| Prothrombin time | | | |
| Seconds prolonged | <4 | 4-6 | >6 |
| International normalized ratio | <1.7 | 1.7-2.3 | >2.3 |
| Bilirubin (mg·dl ⁻¹) ^b | <2 | 2-3 | >3 |
| Ascites | Absent | Slight-moderate | Tense |
| Encephalopathy | None | Grade I-II | Grade III-IV |

^aClass A = 5-6 points; B = 7-9 points; C = 10-15 points.

^bCholestatic diseases (e.g., primary biliary cirrhosis) produce bilirubin elevations that are disproportionate to the hepatic dysfunction. Thus, the following adjustments should be made: assign 1 point for a bilirubin level of 4 mg·dl⁻¹; 2 points for bilirubin concentrations between 4 and 10 mg·dl⁻¹; and 3 points for bilirubin > 10 mg·dl⁻¹.

Table 39-7. MODIFIED CHILD-PUGH SCORE

Preoperative Evaluation

During the preoperative visit, the anesthesiologist should note current medications (including pharmaceutical and herbal preparations). The history should include mention of previous jaundice, blood product transfusions, gastrointestinal bleeding, prior surgeries and the anesthetic management techniques used. In addition to the routine examination of organs and systems, the physical examination should detail the patient's appearance, and document the degree of ascites and encephalopathy. The physical evaluation of a patient with chronic liver disease is particularly valuable, as the patient may feel unwell or look ill before there is evidence of hepatic dysfunction by liver blood tests.

Blood tests should include determinations of hemoglobin and hematocrit; platelet count; serum bilirubin; serum electrolytes; creatinine and blood urea nitrogen; arterial blood gases; serum proteins; prothrombin time; and several enzymes, including aminotransferases, alkaline phosphatase, lactate dehydrogenase, and hydroxybutyrate dehydrogenase (lactate dehydrogenase isoenzyme being more specific for liver function).

Preoperative Preparation

In nonemergent situations, surgical preparation of a patient with severe hepatic disease should focus on correcting clinical or laboratory abnormalities identified in the preoperative evaluation. A failure to correct coagulation abnormalities can predispose to major complications including hemorrhage, encephalopathy, or renal failure (hepatorenal syndrome). Significant coagulation abnormalities must be corrected before performance of spinal or epidural anesthesia to prevent the development of epidural hematomas. A patient with obstructive jaundice, who has a prolonged PT or an increased INR, can receive a trial of vitamin K (10 mg im 3 times a day for a few days) to correct the problem. If this therapy is unsuccessful, or if there is insufficient time for vitamin K to be effective, administration of fresh frozen plasma is indicated. Platelet transfusions should be considered for patients with evidence of platelet dysfunction or thrombocytopenia (<100,000 mm⁻³). Each unit transfused into an average adult will increase the platelet count in blood by about 10,000 mm⁻³.

The patient's fluid and electrolyte status should be optimized before elective surgery (to minimize the risk of hepatic, splanchnic, and renal ischemia). Urine output is generally considered adequate if it is at least 1 ml · kg⁻¹ · hr⁻¹. If a patient has been aggressively diuresed, he or she may require proper fluid therapy to correct volume deficits and electrolyte abnormalities. A central venous catheter may suffice to guide fluid administration to patients with relatively normal myocardial and pulmonary function. For those with severe cardiorespiratory or renal dysfunction, however, pulmonary artery catheterization may be required. To tailor intravenous fluid therapy to meet the specific needs of each patient requires obtaining blood samples at appropriate intervals. Using this laboratory information, the appropriate fluids can be selected to normalize volume deficits, electrolyte imbalances (especially sodium, potassium, and ionized calcium), as well as abnormalities of blood glucose and hemoglobin. In patients with excessive intravascular fluid, diuretic therapy may include furosemide, mannitol, or both, and a low dose of dopamine (2-4 ml · kg⁻¹ · min⁻¹), owing to its antialdosterone effect and ability to produce renal vasodilation. Perioperative administration of spironolactone may also be a diuretic of choice because of its strong antialdosterone activity.

Medications needed to control the myriad complications of severe liver disease should be continued throughout the perioperative period. Preoperative sedatives, when indicated, should be used in lower doses because of the marked derangements in pharmacokinetics and pharmacodynamics associated with advanced liver disease. These patients may have a full stomach, even if they have not taken food or fluid for several hours, because of hiatal hernia, massive ascites, and decreased gastric and intestinal motility. Therefore, premedication may include an H₂ histamine receptor blocker (e.g., ranitidine), metoclopramide, as well as sodium citrate.

Monitoring

In addition to using the routine array of monitors required by the ASA, the need for invasive monitoring will be dictated by the severity of the liver disease and type of surgery. For severely ill patients or major operative procedures, cannulation of an artery is important for direct blood pressure monitoring, as well as for periodic determinations of blood gases, electrolytes, hematocrit, and other laboratory data as needed during surgery. Because patients with advanced liver disease require fluids to be titrated carefully, insertion of a pulmonary artery catheter, or at least a central venous catheter, is often necessary. It is always important to monitor the urine output of patients with advanced liver disease when they undergo operations lasting longer than an hour. Surgical procedures associated with extensive blood loss (e.g., liver transplantation) require monitoring of the blood coagulation status, including periodic determinations of prothrombin time, partial thromboplastin time, and platelet count. Thromboelastography may be helpful.¹⁷² A transcutaneous nerve stimulator facilitates the titration of muscle relaxants, especially when treating cirrhotic patients in whom the effects of muscle relaxants are often unpredictable.

Selection of Anesthetic Technique

Regional anesthesia is generally the preferred anesthetic technique in patients without coagulation abnormalities who are undergoing peripheral surgery. However, it would be difficult to justify using regional anesthesia or analgesia for patients with overt coagulopathies who undergo major operations. Local anesthesia with sedation is usually the best approach for relatively minor procedures, such as sclerotherapy. A short-acting benzodiazepine, such as midazolam combined with remifentanyl, or a low dose of fentanyl, will usually provide sedation, anxiolysis, and analgesia. As mentioned previously, patients with advanced hepatic disease have extensive pharmacodynamic and pharmacokinetic abnormalities, so each medication should be titrated carefully to achieve the desired effect.

Induction of General Anesthesia

Rapid-sequence induction (or awake intubation of the trachea) is indicated in patients perceived to be at risk for aspiration pneumonitis (full stomach). All widely used intravenous induction agents have been administered to patients with advanced hepatic disease. For patients who do not require rapid-sequence induction, careful titration of the anesthetic will minimize hemodynamic lability while achieving the desired anesthetic effect. Succinylcholine is a reasonable choice to facilitate endotracheal intubation. Although severe liver dysfunction can markedly decrease cholinesterase activity and may prolong the effect of succinylcholine somewhat, this rarely causes a clinical problem. When using nondepolarizing neuromuscular blocking agents to induce anesthesia, consider that the initial dose to achieve total relaxation may be higher than in healthy patients. This increased dose requirement results primarily from pharmacokinetic alterations and pertains to relaxants such as atracurium,¹⁷³ d-tubocurarine, and pancuronium,¹⁷⁴ but not to vecuronium.¹⁷⁵

Maintenance of Anesthesia

Intraoperative liver injury can develop from oxygen deprivation, the stress response, drug toxicity, blood transfusion, and infection. An impairment of hepatic oxygen supply can occur at any step in the process of delivering oxygen to the liver. Hypoxic hypoxia may result from inadequate FIO₂ or hypoventilation. Anemic hypoxia may develop when the oxygen-carrying capacity of the blood (hematocrit) is inadequate. Circulatory hypoxia may result from systemic (hypovolemia, arterial hypotension, reduction in cardiac output) or regional (decrease in hepatic blood and oxygen supply) hemodynamic disorders. Delivery of blood and oxygen to the liver may decrease owing to systemic circulatory disturbances, surgical manipulation of the liver or adjacent structures, or from endogenous vasoconstrictors (e.g., renin-angiotensin, catecholamines, and antidiuretic hormone). Anesthetics or other medications that impair electron transport could also induce histotoxic hypoxia, but this mechanism does not appear to be clinically important.

In addition to assuring adequate oxygen supply, one must always consider the oxygen supply-demand relations in the liver. Experimental data indicate that severe surgical stress during fentanyl (moderate dose) anesthesia can produce a somewhat higher hepatic oxygen supply and uptake than an identical stress during isoflurane

anesthesia; this results in similar values of hepatic oxygen supply–uptake ratio with the two anesthetics.⁸³ Taking this into consideration, the guiding principle is to maintain adequate pulmonary ventilation and cardiovascular function, including cardiac output, blood volume, and perfusion pressures. One should strive to prevent arterial hypotension by adequate blood and volume replacement and avoidance of relative overdoses of anesthetics or other blood pressure–lowering drugs. Vasodilation, a reduced perfusion pressure, and a decrease in blood velocity will inevitably increase oxygen extraction in all tissues, including those in the preportal area. A decreased blood velocity and an increased oxygen extraction will cause a decrease in venous oxygen content—in this case, decreased oxygen content in the portal venous blood. A reduction in portal blood oxygen content or flow usually leads to a compensatory increase in hepatic arterial flow. Thus, hepatic injury after moderate arterial hypotension is a relatively rare event. However, in the presence of severe liver dysfunction, the ability of autoregulatory mechanisms to increase hepatic arterial blood flow may be diminished or abolished.¹⁷⁶ Therefore, with severe hepatic disease, the hepatic arterial blood flow may not increase when portal blood flow or oxygen content decreases. This might lead to hepatic oxygen deprivation. Thus, the lesson is clear: take all precautions to avoid arterial hypotension as well as low cardiac output states.

When performing general anesthesia, it seems prudent to avoid halothane, and possibly enflurane, because they cause the most prominent decreases in hepatic blood and oxygen supply and are associated with the highest incidences of postoperative hepatic dysfunction. Isoflurane and probably sevoflurane appear to be the anesthetics of choice for inhalational anesthesia. Nitrous oxide does not appear to be associated with major hepatic complications in patients with advanced liver disease despite its abilities to produce sympathomimetic effects and to limit the maximum oxygen content of arterial blood. Opioids are reasonable to include in the anesthetics of patients with hepatic disease. Despite certain pharmacokinetic concerns (decreased clearance and prolonged half-life), fentanyl is probably the opioid of choice. Interestingly, fentanyl neither decreases the hepatic oxygen or blood supply nor prevents an increase in hepatic oxygen requirements when used in moderate doses. Therefore, the oxygen supply–demand relation in the liver is no better with a fentanyl-based anesthetic than during anesthesia with isoflurane.⁸³ It seems that anesthetic management using inhaled agents (especially isoflurane or sevoflurane) alone or in combination with small doses of fentanyl would be the method of choice, provided that adequate pulmonary ventilation, cardiac output, and arterial pressures are maintained. Many other agents also have favorable risk–benefit profiles for patients with advanced hepatic disease.

Because substantial alterations in pharmacokinetics occur in patients with advanced hepatic disease, dose requirements for a variety of medications can be unpredictable. For example, the hepatic clearance of lidocaine may be increased by more than 300%, and benzodiazepines by more than 100%. Drugs that bind to albumin (e.g., thiopental) usually have a decreased volume of distribution, so a lower initial dose will be required. The volume of distribution of other agents, such as muscle relaxants, may increase substantially for various reasons, including an increase in g-globulin concentration or the presence of edema. This appears to account for the so-called resistance to such agents and explains why the initial dose requirements of these medications are increased in cirrhotic patients. However, subsequent dose requirements may be decreased, and drug effects prolonged, owing to decreases in hepatic blood flow, impaired hepatic clearance, and possible renal dysfunction (e.g., *d*-tubocurarine or pancuronium). Advanced hepatic disease does not appear to significantly affect the pharmacokinetics of vecuronium, although some dose-dependent pharmacokinetic alterations may occur.¹⁷⁵ This may be the result of a limited hepatic uptake capacity, which is usually exceeded at doses greater than 0.15 mg · kg⁻¹. At lower doses, hepatic dysfunction does not affect the pharmacokinetics or duration of action of vecuronium.¹⁷⁵

Severe hepatic dysfunction *per se* does not contraindicate the use of any specific muscle relaxant. Atracurium has a theoretical advantage because its elimination occurs mainly by Hofmann decomposition, making its clearance relatively independent of renal or hepatic function. Thus, both the elimination half-life and clearance of atracurium are similar in healthy subjects and cirrhotic patients with impaired renal function. However, volumes of distribution are larger and, accordingly, the distribution half-life is shorter in patients with severe hepatorenal dysfunction compared with normal individuals.¹⁷³ The only situation that appears to prolong the elimination half-life of atracurium is marked metabolic acidosis, which may decrease the rate of Hofmann decomposition.¹⁷³ Rapacuronium, which has a more rapid onset and shorter duration of action than other currently used nondepolarizing agents, may have advantages in patients with cirrhosis. A recent study of cirrhotic patients (Child-Pugh score of 7; see Table 39-7) showed that the onset and recovery rate from a single bolus dose (1.5 mg · kg⁻¹) of rapacuronium is similar in cirrhotic patients and in patients with normal hepatic function.¹⁷⁷ The presence of cirrhosis did not affect the elimination half-life or plasma clearance of rapacuronium.

The pharmacokinetics of many muscle relaxants in conditions of cholestasis and obstructive jaundice may be altered: prolonged duration of action has been demonstrated.¹⁷⁸ However, when postoperative ventilation of the lungs is planned, vecuronium, atracurium, and pancuronium can be used successfully. Titration of any relaxant according to transcutaneous nerve stimulation monitoring is beneficial.

Although pharmacokinetic studies in patients with hepatic cirrhosis provide interesting results that are helpful in understanding the pathogenic aspects of chronic liver disease, the results do not have significant value for predicting the safety of a drug. The degree of hepatic dysfunction affects the degree of pharmacokinetic disorder; therefore, the best way to avoid complications when administering medications is to titrate to effect.

Renal function must be maintained by administering proper fluid therapy (volume and content), including diuretics, as needed. It can be extremely difficult to maintain the proper fluid balance without monitoring filling pressures. Therefore, insertion of a pulmonary artery catheter, or at least a central venous catheter, is often indicated. The contents of infused solutions should be initially selected and subsequently adjusted based upon periodic determinations of blood electrolyte concentrations. For example, when the serum sodium concentration is normal or elevated, a solution with a little or no sodium is indicated (5% glucose in water). A decrease in serum sodium below 130–135 mEq · l⁻¹ would favor the use of a sodium-containing solution such as Normosol. Furosemide and mannitol are often effective diuretics in these patients. Infusion of a low dose of dopamine (2–4 mg · kg⁻¹ · min⁻¹) can also be beneficial owing to its many pharmacologic actions, including enhancement of renal perfusion and antagonism of the aldosterone effect.

The parameters of controlled ventilation should be carefully selected to avoid an unnecessary increase in intrathoracic pressure which may impede venous return, thereby decreasing cardiac output. Hypocarbica should probably be avoided because it can aggravate hepatic encephalopathy. As mentioned previously, opioids may induce spasm of the sphincter of Oddi (see Fig. 39-12) in nearly 3% of opioid-treated patients.¹⁰⁷ This spasm can be relieved by many agents, including antimuscarinic drugs such as atropine. The clinical disadvantage of this treatment is the accompanying tachycardia. Naloxone relaxes the sphincter of Oddi, but it also antagonizes the analgesic effects of the opioid, increasing the requirements for supplemental anesthetics. The potential of naloxone to produce cardiovascular complications should also be kept in mind. Glucagon effectively relaxes biliary smooth muscle; however, it might not be the drug of choice because it can cause many untoward effects, including hyperglycemia and a hyperdynamic cardiovascular state. Finally, nitroglycerin is effective in relieving opioid-induced spasm of the sphincter of Oddi. Volatile anesthetics similarly attenuate contractile responses of the sphincter to opioids.

Because coagulopathy can develop during surgery, perioperative monitoring of the coagulation state is important. Treatment may include administration of platelets, fresh frozen plasma, cryoprecipitate, and sometimes e-aminocaproic acid. Interestingly, coagulopathies that develop during liver transplantation are occasionally caused by heparin, which had been sequestered in, and subsequently washed from, the graft. Protamine sulfate effectively reverses this effect of heparin. Although patients with advanced liver disease are at risk for fibrinolysis and disseminated intravascular coagulation, a note of caution is in order: overly aggressive treatment of a coagulopathy, especially in patients on anti-fibrinolytic therapy, may lead to a hypercoagulable state, thrombosis, and pulmonary embolism.

POSTOPERATIVE LIVER DYSFUNCTION: AN OVERVIEW

Postoperative liver dysfunction is common, but rarely severe. While it is usually asymptomatic, it may progress to overt liver failure on rare occasions.

Mild, transient increases in serum concentrations of hepatic enzymes are often detectable within hours of surgery but do not usually persist for more than 2 days. Such subclinical hepatocellular injury occurs in as many as 20% of patients who receive enflurane anesthesia and in nearly 50% of those receiving halothane.^{122,179} Jaundice rarely occurs in healthy patients following minor operations but appears in up to 20% of patients after major surgical procedures.¹⁷⁹ Jaundice is typically the earliest sign of serious hepatic or hepatobiliary dysfunction and therefore requires prompt medical attention. Marked increases of serum aminotransferase activities are an ominous finding, reflecting extensive hepatocellular necrosis.

Severe Postoperative Liver Dysfunction

Some cases of severe postoperative liver dysfunction are apparent hours after surgery (e.g., with hypoxic injury), whereas other cases are delayed in onset for days to weeks (e.g., with anesthesia-induced hepatitis). With severe postoperative liver dysfunction, residual liver function may fall below a critical threshold, leading to the development of hepatic encephalopathy. If encephalopathy occurs within 2 weeks of the onset of jaundice or within 8 weeks of the initial manifestation of hepatic disease, the disorder is defined as fulminant hepatic failure. Fulminant hepatic failure has a variety of causes.¹⁸⁰ The mortality rate from fulminant hepatic failure correlates with the severity of encephalopathy. The shorter the interval between the appearance of jaundice and presentation of encephalopathy, the worse the prognosis.

Treatment of Fulminant Hepatic Failure

Successful treatment of patients with fulminant hepatic failure requires the clinician to make prompt and accurate predictions about the outcome of the disease. Proper recognition of reversible disease obviates unnecessary orthotopic liver transplantation (OLT). Irreversible cases of fulminant hepatic failure require immediate

identification. Otherwise, the severe complications of fulminant hepatic failure that develop may render patients unacceptable candidates for OLT.

CAUSES OF POSTOPERATIVE LIVER DYSFUNCTION UNRELATED TO PERIOPERATIVE FACTORS

Asymptomatic Diseases

Although postoperative liver dysfunction can clearly result from anesthetic or surgical interventions, it is often unrelated to perioperative factors. For example, it can arise from pre-existing liver disease that has escaped preoperative detection. According to a study by Schemel¹⁸¹ the prevalence of acute, asymptomatic liver disease in a healthy-appearing surgical population may approach 0.25%. During a 1-year period, Schemel and co-workers performed multiple laboratory screening tests in 7620 patients (ASA Physical Status I) scheduled for elective surgical procedures. Eleven of these patients (approximately 1 per 700) were found to have abnormal increases of AST, ALT, and LDH, and the proposed surgeries were canceled. All 11 proved to have overt hepatic disorders (infectious mononucleosis, viral hepatitis, cirrhosis, or alcoholic hepatitis), and three later became clinically jaundiced (overall incidence of jaundice of 1:2540). Had any of these three patients actually received a halogenated anesthetic, with the subsequent development of overt hepatic disease between the 6th and 14th postoperative days, their diseases may well have been diagnosed erroneously as anesthesia-induced hepatitis. None of the 7609 patients who underwent anesthesia and surgery exhibited laboratory evidence of pre-existing hepatic disease, and none developed unexplained postsurgical jaundice. Another clinical study¹⁸² has documented a prevalence of unsuspected preoperative hepatic dysfunction similar to that reported by Schemel. Thus, it appears that approximately 1 out of every 2500 healthy patients who undergo surgery and anesthesia may have clinically significant postoperative liver dysfunction that is totally unrelated to surgery or anesthesia.

Unrecognized Pre-existing Hepatic Injury Caused by Drugs or Medications

Because a pre-existing disease is more likely than an anesthetic agent to cause severe postoperative liver dysfunction, the preoperative evaluation should address the important risk factors for liver disease. These include use of potentially hepatotoxic medications or illicit drugs (cocaine), alcoholism, prior episodes of jaundice or history of viral hepatitis, congenital disorders (e.g., Gilbert's disease), and systemic diseases or conditions associated with hepatic pathology (e.g., pre-eclampsia). Exposure to environmental and occupational hepatotoxins should also be considered as possible causes of liver disease of unknown origin.¹⁸³ Hepatotoxins can produce a broad spectrum of liver disorders, including abnormal liver blood tests in asymptomatic patients, steatosis, acute or chronic hepatitis, fulminant hepatic necrosis, cirrhosis, veno-occlusive disease, and hepatic neoplasia.

Use of prescription and over-the-counter medications is ubiquitous. Polypharmacy is the rule rather than the exception, especially in elderly and debilitated patients who undergo major operations. Thus, the capacity of pharmacologic agents to injure the liver is an important perioperative concern. Some 500–1000 therapeutic agents have been implicated in a broad spectrum of liver diseases.¹⁸⁴ These diseases may be classified in accordance with whether the drug produces primarily direct cell toxicity (necrosis), cholestasis (cessation of bile flow), or steatosis (fatty liver). Most forms of drug-induced liver disease are benign and of little consequence (estrogen-induced cholestasis), producing only transient alterations of liver blood tests. Severe drug toxicities, which are typically dose-related (acetaminophen) or idiosyncratic (halothane), are responsible for 15–30% of the cases of fulminant hepatic failure and 20–50% of the cases of chronic hepatitis (nonviral). Moreover, when drug reactions produce hepatocellular necrosis, the estimated case fatality approaches 50%.

Drugs known to produce hepatocellular injury and centrilobular necrosis include acetaminophen, isoniazid, and methyl dopa. Other cytotoxic drugs include oxyphenisatin, rifampin, papaverine, phenytoin,¹⁸⁵ indomethacin, monoamine oxidase inhibitors, and amitriptyline.¹⁸⁶ The use of dantrolene for treatment of muscle spastic disorders has been associated with the development of hepatic failure in patients receiving the drug for more than 60 days. Cholestatic reactions often result from drugs such as chlorpromazine, phenylbutazone, and androgenic and anabolic steroids. In at least one case, erythromycin (ethylsuccinate form) has caused hepatic failure that had initially been attributed to halothane administration.

A drug's potential to cause hepatotoxicity is influenced by various pharmacologic (other drugs) or pathophysiologic (hepatitis) factors. For example, the combination of trimethoprim sulfamethoxazole is nearly five times more frequently associated with hepatotoxicity than sulfamethoxazole alone. By inducing hepatic microsomal drug-metabolizing systems, some drugs can markedly increase the injurious potential of others by altering their metabolism to favor the production of toxic metabolites. For example, phenobarbital increases the hepatotoxicity of various drugs including chemotherapeutic agents (methotrexate) and antibiotics (tetracycline).¹⁸⁷

Ethanol is obviously an important hepatotoxin. Although elective surgery is not contraindicated in patients with alcoholic steatosis, the mortality from acute alcoholic hepatitis, even without surgery, is significant. Animal studies indicate that alcohol ingestion increases the likelihood that centrilobular necrosis will develop after halothane anesthesia, which may relate to the ability of ethanol to increase hepatic hypoxia. Therefore, if alcoholic hepatitis is suspected, further examination of liver function is warranted before performing an elective operation.

Congenital Disorders

The most common cause of jaundice in the United States is a benign metabolic disorder known as Gilbert's syndrome (familial unconjugated hyperbilirubinemia). In this syndrome, bilirubin uptake by the liver is impaired and the activity of bilirubin glucuronyl transferase is decreased. Patients often do not manifest their disease until the second decade of life. Stress, fasting, fever, and infection can exacerbate this condition. Diagnosis is suggested by clinical (jaundice without dark urine) and laboratory (unconjugated hyperbilirubinemia) abnormalities.

A less common metabolic disorder, the Crigler-Najjar syndrome (type II), is also associated with unconjugated hyperbilirubinemia; surgical and anesthetic-related problems are apparently minimal. However, surgery can exacerbate the Dubin-Johnson syndrome.

Pregnancy-Related Disorders

Well known disorders of pregnancy that cause fulminant hepatic failure during the third trimester or in the immediate postpartum period include acute fatty liver of pregnancy (AFLP) and the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count). In addition, parturients are unusually susceptible to morbidity and mortality from hepatitis E infection.¹⁸⁸ It is unclear how the natural courses of these diseases are affected by the analgesic or anesthetic techniques used for vaginal or abdominal deliveries.

Acute Fatty Liver of Pregnancy

A rare disease that occurs in the late stages of pregnancy, AFLP probably represents an abnormality of lipid metabolism. Jaundice, encephalopathy, hypoglycemia, and pre-eclampsia are common, but hypertension is rare (incidence of 1 in 13,000 births) with advanced liver failure. Liver biopsy shows infiltration of centrilobular hepatocytes with microvesicular fat, producing a histopathologic picture that is strikingly similar to that seen in disorders called hepatic microvesicular steatosis (including Reye's syndrome and injury produced by valproic acid or tetracycline). Serum aminotransferases typically do not exceed $1000 \text{ IU} \cdot \text{l}^{-1}$ because hepatocellular necrosis is not a major feature of this disease. When AFLP is diagnosed, delivery of the fetus is expedited, usually by induction of labor or, occasionally, cesarean section. Some patients continue to decline clinically after delivery, but most begin to recover by the third day postpartum. On rare occasions, liver transplantation has been necessary. Recurrence of AFLP with future pregnancy is uncommon.

Pre-eclampsia and HELLP

Defined by Louis Weinstein in 1982, the HELLP syndrome (Hemolysis Elevated Liver enzymes Low Platelets) is much more common and generally occurs earlier in pregnancy than AFLP. This syndrome, which appears to represent a severe manifestation of pre-eclampsia, affects about 10% of all pre-eclamptic women. In some cases, pregnancy-induced hypertension (in the absence of pre-eclampsia) adversely affects hepatic function. This presumably results from marginal hepatic perfusion, owing to profound peripheral vasoconstriction accompanied by hypovolemia and starvation.¹⁸⁹

On liver biopsy, pre-eclampsia has three characteristic histopathologic features: diffuse fibrin deposition along the sinusoids; periportal and portal tract hemorrhage; and ischemic necrosis, which is usually focal but occasionally confluent. Because hepatocellular necrosis is present in all patients with HELLP, serum aminotransferases are almost invariably increased; mean values of AST and ALT are 434 and $239 \text{ IU} \cdot \text{l}^{-1}$, respectively. At times, the degree to which laboratory abnormalities reflect hepatic dysfunction is difficult to assess. For example, hyperbilirubinemia, which occurs in approximately 40% of cases of HELLP, may be caused by a combination of hemolysis and liver dysfunction.

Hepatic hemorrhage or rupture probably results from confluent hepatocellular necrosis from pre-eclampsia. Abdominal computed tomography scans in women with few symptoms other than right upper quadrant abdominal pain suggest that hepatic hemorrhage may occur in up to 2% of women with pre-eclampsia. The most important factors in ensuring maternal survival following hepatic rupture are prompt identification of this disorder before irreversible shock occurs, vigorous hemodynamic support,

and emergency laparotomy if Glisson's capsule has ruptured.

CONCLUSION: PREVENTION AND TREATMENT OF POSTOPERATIVE LIVER DYSFUNCTION

Identifying patients at high risk for developing liver dysfunction or for having an exacerbation of pre-existing liver disease is of utmost importance for minimizing the morbidity and mortality in such patients. Thus, a careful preoperative evaluation is required to detect pre-existing liver disease and to identify important risk factors for anesthesia-induced hepatic injury. Perioperative physicians who are armed with an understanding of the interactions among liver disease, surgical procedures, and anesthetic interventions can formulate and orchestrate therapeutic plans to optimize patient outcome.

When liver abnormalities are recognized preoperatively, it is prudent to defer elective procedures until the course of the disease can be determined. For operations that cannot be deferred, clinically significant pathophysiologic changes associated with the liver disease (e.g., coagulopathy, fluid and electrolytes abnormalities) should be corrected as soon as practical.

Which anesthetic technique best preserves the function of the liver? The choice of anesthesia is usually an insignificant issue for peripheral or minor surgery (operations that do not affect splanchnic blood flow), even in patients with severe liver disease. Regional anesthetic techniques, when appropriate (e.g., absence of coagulopathy), are often preferred because they often minimize the cardiovascular and pulmonary perturbations associated with anesthesia. The selection of pharmacologic anesthetic agents may have important implications, especially in patients undergoing major operations. A rational approach to general anesthesia would include the use of agents that preserve cardiac output and do not adversely affect the oxygen supply–demand relationships of the liver (e.g., isoflurane, sevoflurane, fentanyl, remifentanyl). Throughout the perioperative period, medications must be carefully titrated to achieve the desired pharmacologic effects while minimizing untoward effects; this can be challenging because pharmacokinetics and pharmacodynamics of many drugs are often unpredictable in patients with hepatobiliary dysfunction.

A primary goal during the maintenance of anesthesia is to ensure the adequacy of hepatic and renal perfusion, especially in patients with severe liver disease who undergo major abdominal operations. Although well tolerated in the absence of liver disease, hepatic hypoperfusion in patients recovering from infectious hepatitis or chronic alcoholics can have devastating consequences. These patients may be highly susceptible to hepatic ischemia because of critically compromised liver blood flow, impaired pressure-flow autoregulation, and a dysfunctional hepatic arterial buffer response. In such cases, invasive monitoring of the circulation is indicated, so that acute hypovolemia can be rapidly detected and expeditiously treated.

Although anesthesia-induced hepatitis rarely occurs, we must remain aware of the association between this disorder and the use of halogenated vapors. Halothane hepatitis produces high rates of morbidity and mortality, and survival of the most severely affected may necessitate liver transplantation. The disease affects primarily middle-aged people, particularly obese females. A history of fever or unexplained jaundice after a previous halothane anesthetic is a contraindication to another halothane anesthetic. A history of anesthesia-induced hepatitis may also be a reason to avoid general anesthesia with any inhaled vapor. This admonition, however, is predicated on remote possibilities: that immune crossover could occur with various halogenated vapors, or that the anesthesia apparatus could harbor residual amounts of the offending anesthetic, allowing trace amounts to enter the patient and trigger an allergic response. In the final analysis, avoiding the use of halothane is perhaps the single most effective way to decrease the frequency of anesthesia-induced hepatitis.

When postoperative hepatic injury occurs, the mainstay of therapy is supportive. A thorough search is required to identify any reversible cause of the injury. The hepatotoxic potentials of all medications merit consideration. Discontinue any medication that is suspect. Search for all sources of sepsis, as the presence of sepsis mandates rapid, aggressive therapy. Consider extrahepatic biliary obstruction in the differential diagnosis because this may require prompt surgical intervention. In some cases, identifying the pathogen or documenting the type of hepatic injury requires a percutaneous liver biopsy. Judicious use of biochemical tests and imaging studies, which can help delineate hepatocellular from cholestatic dysfunction, usually shortens the list of diagnostic possibilities and provides useful prognostic information.

Orthopaedic anesthesia is a logical outgrowth of the subspecialization that has taken place in the field of anesthesiology. Several factors bind this diverse patient group together. Although patients vary in age from very young to very old, the surgical procedures involving bone, muscle, and related soft tissues require similar monitoring and anesthetic techniques. For example, many orthopaedic surgical procedures lend themselves to the use of regional anesthesia. Regional anesthetic techniques allow intraoperative surgical anesthesia as well as postoperative pain relief, and create a further subspecialty within orthopaedic anesthesia. Another seemingly trivial but vitally important part of orthopaedic anesthesia is patient positioning. Unusual patient positioning is a common feature in orthopaedic cases. Experience and specific knowledge are required to produce optimal surgical conditions and avoid potential injuries. Orthopaedic procedures are frequently associated with major blood loss and its related risks. The orthopaedic anesthesia care provider must be experienced in techniques that decrease these risks, must be able to use intraoperative hypotension and blood salvage techniques, and must be able to manage transfusion-related complications. The orthopaedic surgical patient is also at risk for deep venous thrombosis and pulmonary embolus. Knowledge of the current pharmacologic and mechanical methods of thromboprophylaxis is required to prevent the occurrence of these thromboembolic complications. Likewise, potential interactions between anticoagulants and anesthetic drugs or regional anesthetic techniques must be thoroughly understood to reduce the risk of perioperative bleeding.

Knowledge of specific orthopaedic surgical techniques, including duration, extent, predicted blood loss, and associated complications, is invaluable to the anesthesia care provider working in a team to provide the best possible patient care. Orthopaedic surgical patients usually require early mobilization and rehabilitation, both of which can be expedited by appropriate selection of anesthetic techniques and management of postoperative analgesia. In this chapter, we discuss the various aspects of orthopaedic anesthesia, emphasizing the anesthetic techniques and patient management issues unique to this practice.

PREOPERATIVE ASSESSMENT

The anesthesiologist's preoperative assessment is crucial to the formulation and execution of the anesthetic plan. The patient must be evaluated for pre-existing medical problems, previous anesthetic complications, potential airway difficulties, and considerations relating to intraoperative positioning. This evaluation, coupled with an appreciation of the surgeon's needs, is used to formulate the anesthetic plan.

Pre-existing medical conditions may have a profound impact on anesthetic choice and perioperative management. Optimal patient management balances the pathophysiology of concurrent medical conditions, the cause and significance of physiologic changes to regional block or general anesthesia, and the results of outcome studies. *Advancing age* is often accompanied by decreases in physiologic function that can progress to significant illness. *Hypertension* is the most prevalent medical problem seen in elderly patients undergoing orthopaedic surgery. Hypertensive patients experience wider fluctuations in intraoperative blood pressure than normotensive patients. Noxious stimuli lead to exaggerated hypertensive responses. Conversely, because hypertensive patients tend to be intravascularly depleted, once general or neuraxial anesthesia is induced, hypotension may occur. Intraoperative blood loss exacerbates this response. In general, hypertensive patients should continue their antihypertensive medications during the perioperative period.

Patients with *coronary artery disease* pose unique problems to the anesthesiologist. For the patient who has experienced a myocardial infarction, elective surgery should typically be delayed by 6 months to avoid significant cardiac morbidity and mortality. Patients with unstable angina require a cardiac evaluation before elective surgery to determine the extent of disease and plan appropriate interventions. However, it is often difficult to assess exercise tolerance or a recent progression of cardiac symptoms because of the limitations in mobility induced by the underlying orthopaedic condition. Antianginal medications should be continued during the perioperative period. During surgery, patients may require intravenous nitrates to improve coronary blood flow and β blocking agents to control heart rate.

Many patients undergoing orthopaedic surgery have *rheumatoid arthritis*. Systemic manifestations of this disease include pulmonary, cardiac, and musculoskeletal involvement. Particularly significant to the anesthesiologist is involvement of the cervical spine, temporomandibular joint, and larynx. Rheumatoid involvement of the cervical spine may result in limited neck range of motion, which interferes with airway management. Atlantoaxial instability, with subluxation of the odontoid process, can lead to spinal cord injury during neck extension. Patients with rheumatoid arthritis are often on chronic steroid therapy and require perioperative steroid replacement.

Management of orthopaedic *trauma* patients involves unique preoperative considerations. Trauma patients requiring emergency surgical intervention are assumed to have full stomachs because of delayed gastric emptying secondary to the traumatic event, and because of opioid administration. Patients who have sustained cervical spine trauma require careful and controlled airway management to avoid further injury. Associated injuries and blood loss may further complicate management of otherwise routine orthopaedic surgery in the trauma patient.

The *past medical history*, including the *past anesthetic history* of the patient and his or her family, should be reviewed. A history of coagulation disorders associated with easy bruising or bleeding in the patient or family may make regional anesthesia inadvisable. Other familial traits, such as sickle cell disease or porphyria, affect surgical and anesthetic management. Some hereditary diseases, such as plasma cholinesterase deficiency or malignant hyperthermia, may not be diagnosed until the patient or a member of his or her family is anesthetized.

Preoperative evaluation should include a focused *physical examination*. Patients should be assessed for limitation in mouth opening or neck extension, adequacy of thyromental distance (measured from the lower border of the mandible to the thyroid notch), and state of dentition. The heart and lungs should be auscultated. In addition, the site of proposed injection for regional anesthesia should be assessed for evidence of infection and anatomic abnormalities or limitations. At this time, the

patient should also be evaluated for any potential positioning difficulties related to arthritic involvement of other joints or body habitus.

CHOICE OF ANESTHETIC TECHNIQUE

Orthopaedic surgery can often be completed under either regional or general anesthesia. The risks and benefits of each are discussed in the following sections. Any patient who has an absolute contraindication to regional anesthesia (patient refusal, infection at the site of needle placement, systemic anticoagulation) is a candidate for general anesthesia. General anesthesia provides the patient with amnesia, analgesia, and muscle relaxation.

Many orthopaedic surgical procedures, because of their localized peripheral site, lend themselves to regional anesthetic techniques. Neural structures may be blocked at the peripheral nerve, plexus, or neuraxial level. A regional anesthetic provides the patient with surgical analgesia and muscle relaxation; intravenous sedatives can be used to provide mild sedation and amnesia during the operative procedure. The regional technique and local anesthetic solution used depend on a variety of factors, including duration of surgery, length of desired postoperative analgesia, and indication for postoperative sympathectomy.

Regional anesthetics offer several advantages over general anesthetics in patients undergoing orthopaedic procedures, including improved postoperative analgesia, decreased incidence of nausea and vomiting, less respiratory and cardiac depression, improved perfusion *via* sympathetic block, reduced blood loss, and decreased risk of thromboembolism. It is important to explain these benefits and encourage regional anesthesia where appropriate.

SURGERY TO THE UPPER EXTREMITIES

Orthopaedic surgical procedures to the upper extremity are well suited to regional anesthetic techniques. Surgery to the elbow, forearm, and hand may be accomplished with regional blockade alone, whereas surgery to the shoulder and upper arm can be performed under regional blockade alone or a combination of regional and general anesthesia. In addition to intraoperative anesthesia, brachial plexus and peripheral nerve blocks may be used in the treatment and prevention of reflex sympathetic dystrophy. Continuous catheter techniques provide postoperative analgesia and allow early limb mobilization. However, although the benefits of regional anesthesia in this patient population are well established, orthopaedic surgical procedures often involve peripheral nerves with pre-existing deficits, such as ulnar nerve transposition and carpal tunnel release. In addition, the operative site may be adjacent to neural structures, as with total shoulder arthroplasty or fractures of the proximal humerus. Improper surgical positioning and the use of a tourniquet or constrictive casts or dressings may also result in perioperative neurologic ischemia. The use of regional techniques in the patient at increased risk for perioperative nerve injury remains controversial. Therefore, the patient should be examined before surgery to document pre-existing neurologic deficits. Meticulous regional anesthetic technique with appropriate use of local anesthetic solutions and vasoconstrictors, careful patient positioning, and serial postoperative neurologic examinations reduce the incidence of neurologic dysfunction.

Local anesthetic selection should be based on the duration and degree of sensory or motor block required. Although prolonged blockade of the lower extremities interfere with ambulation and therefore delay outpatient discharge, persistent upper extremity block is not a contraindication to hospital dismissal. However, during the postoperative visit, the patient should be informed of the anticipated duration of analgesia and instructed to protect the blocked extremity until block resolution.

Surgery to the Shoulder and Upper Arm

Reconstructive shoulder surgery, including total shoulder arthroplasty and rotator cuff repair, presents unique management and positioning considerations to the anesthesiologist. These surgical procedures are typically performed with the patient in the "beach chair" position. The patient is flexed at the hips and knees and placed in a 10–20-degree reverse Trendelenburg position to promote venous return. The patient is shifted laterally to the edge of the operating table to allow unrestricted surgical access to the upper extremity. The patient's head, neck, and hips must be secured to prevent additional lateral movement. The head and neck must remain firmly supported by the operating table and secured in a neutral position; excessive rotation or flexion of the head away from the operative side results in stretch injury to the brachial plexus. Care also must be taken to avoid pressure on the eyes and ears. All airway connections should be tightened and possibly reinforced with tape because after surgical draping, access to the patient's face and airway is limited. Hypotension can be minimized by gradual assumption of the beach chair position and by delaying head elevation until the time of surgical incision. A tourniquet cannot be used during proximal upper extremity surgical procedures, and significant blood loss may occur. Therefore, arterial cannulation may be helpful for direct blood pressure measurement and monitoring of intraoperative hemoglobin concentrations during total shoulder arthroplasty and reduction of humeral fractures. In theory, venous air embolism (VAE) may occur during surgical procedures to the shoulder because the operative site is higher than the heart. However, this complication has not been reported in the literature. Patients with a documented right-to-left shunt may be monitored with a precordial Doppler to allow prompt diagnosis and treatment of VAE.

Surgery to the shoulder and humerus may be performed under regional or general anesthesia.¹ With careful positioning and appropriate sedation, interscalene or supraclavicular blockade alone can provide excellent surgical anesthesia. However, general anesthesia or a combination of regional and general anesthesia is often chosen because of limited access to the patient's airway during these surgical procedures. Interscalene brachial plexus block may be performed before surgical incision or after postoperative upper extremity neurologic function has been determined. Although preoperative interscalene block reduces the intraoperative requirement of volatile anesthetic and opioids, and in theory provides pre-emptive analgesia, postoperative evaluation of neurologic function will not be possible until block resolution.

Nerve injury often occurs in association with upper extremity trauma. Radial nerve palsy is identified in up to 18% of patients with humeral shaft fractures, whereas injury to the axillary nerve and brachial plexus is associated with proximal humerus fractures. In addition, 4% of patients undergoing total shoulder arthroplasty have a documented postoperative neurologic deficit, including 3% of patients with injury to the brachial plexus. The level of injury is at the level of the nerve trunks, which is the level at which an interscalene block is performed, making it impossible to determine the etiology of the nerve injury (surgical vs. anesthetic). Most of these nerve injuries represent a neurapraxia; 90% resolve in 3–4 months.² However, the significant incidence of neurologic deficits demonstrates the importance of clinical examination before regional anesthetic techniques in these patients. Interscalene block should be performed with caution in patients with a pre-existing brachial plexopathy because of the risk of perioperative exacerbation of neurologic deficits. The ipsilateral diaphragmatic paresis and 25% loss of pulmonary function produced by interscalene block also contraindicates this block in patients with severe pulmonary disease.³ The reduction in pulmonary function is present for the duration of the interscalene block and is present even with concentrations of bupivacaine as low as 0.125%.

Surgery to the Elbow

Surgical procedures to the distal humerus, elbow, and forearm are commonly performed under regional anesthetic techniques. Infraclavicular and supraclavicular approaches to the brachial plexus are the most reliable and provide consistent anesthesia to the four major nerves of the brachial plexus: median, ulnar, radial, and musculocutaneous. However, the small but definite risk of pneumothorax associated with supraclavicular and infraclavicular blocks makes this approach unsuitable for outpatient procedures. Typically, the pneumothorax occurs 6–12 hours after hospital discharge; therefore, a postoperative chest radiograph is not helpful. Although chest tube placement is advised for pneumothorax greater than 20% of lung volume, the lung may also be re-expanded with a small Teflon catheter under fluoroscopic guidance, eliminating the need for hospital admission. The axillary approach to the brachial plexus eliminates the risk of pneumothorax and reliably provides adequate anesthesia for surgery near the elbow.⁴ Injection of greater volumes of local anesthetic solution into the axillary sheath or supplemental musculocutaneous nerve block at the level of the axilla, in the coracobrachialis muscle, increases the probability of successful block of the brachial plexus and the surgical field.

Surgery to the Wrist and Hand

Surgery to the distal forearm, wrist, and hand may be performed under general or regional anesthesia. Brachial plexus block provides comprehensive and consistent regional anesthesia for the distal upper extremity.⁵ Although the brachial plexus may be successfully blocked at several sites, the interscalene approach is seldom used for wrist and hand procedures because incomplete anesthesia of the ulnar nerve is produced in 15–30% of patients. In addition, although the supraclavicular approach results in blockade of all four major nerves, the risk of pneumothorax reduces its suitability for outpatient procedures. Therefore, the axillary approach is most commonly used for surgical procedures to the forearm, wrist, and hand.

Minor hand procedures such as carpal tunnel release, reduction of phalanx fractures, and superficial wound débridements may require only local infiltration or peripheral blockade at the mid-humeral, elbow, or wrist level. Inflation of an upper arm tourniquet in these patients causes significant discomfort in 45–60 minutes, and limits the duration of the surgical procedure. Intravenous regional anesthesia (Bier block) using a double tourniquet permits more extensive surgery and longer tourniquet times. However, the Bier block has several disadvantages, including the potential for high blood levels of local anesthetic solutions, a maximum anesthetic duration of 90–120 minutes, and rapid termination of anesthesia (and analgesia) on tourniquet deflation.

Continuous Brachial Plexus Anesthesia

Indwelling brachial plexus catheters allow prolonged upper extremity anesthesia and postoperative analgesia. A continuous infusion of local anesthetic solution, such as bupivacaine 0.125%, prevents vasospasm and increases circulation after limb replantation or vascular repair. More concentrated solutions of bupivacaine result in complete sensory block and allow early joint mobilization after painful surgical procedures to the elbow. Brachial plexus catheters may be inserted using interscalene,

infraclavicular, and axillary approaches. However, the axillary approach is most common. The catheter is inserted 5–10 cm through a medium-gauge needle after elicitation of a paresthesia (or motor response if the nerve stimulator technique is used), and 45–50 ml of local anesthetic is injected. Although *analgesia* is produced in all nerve distributions, the block may not provide satisfactory surgical *anesthesia*, even with administration of more potent local anesthetic solutions. Therefore, for surgical procedures, the continuous brachial plexus block is often supplemented with a general anesthetic. After surgery, the catheters may be left indwelling for 4–7 days without adverse effects.

SURGERY TO THE LOWER EXTREMITIES

Although orthopaedic procedures to the lower extremity may be performed under both general and regional anesthesia, the ability to provide superior postoperative analgesia, rapid postoperative rehabilitation, and reduced cost of medical care may result from thoughtfully implemented regional anesthetic and analgesic techniques.

Multiple studies demonstrate significantly reduced intraoperative blood loss during total hip arthroplasty (THA) completed under central neuraxial blockade compared with general anesthesia.⁹ The reasons for this reduction are unproved but may be influenced by the decrease in mean arterial pressure, blood flow redistribution to larger-caliber vessels, and locally reduced venous pressure. Decreased postoperative blood loss can be demonstrated when the epidural local anesthetic is continued for analgesia.

Postoperative pulmonary thromboembolism (PTE) from deep venous thrombosis (DVT) is an important cause of morbidity and mortality in orthopaedic surgical patients. A variety of authors have identified decreased incidence of DVT and PTE in patients whose surgery was conducted under regional anesthesia.^{7,8,9} However, these patients did not receive anticoagulants. The potential benefit of regional anesthesia in reducing thromboembolic complications is discussed later in this chapter.

Surgery to the Hip

In 1990, more than 120,000 total hip replacements were performed in North America. Patients undergoing surgical procedures to the hip for arthritic conditions typically are elderly and often have pre-existing medical conditions that may affect perioperative outcome. In addition, because hospital costs appear to be directly related to the length of hospital stay, anesthetic techniques associated with improved recovery and reduced complications may decrease the total hospital costs among these patients.

Positioning

The lateral decubitus position is frequently used to facilitate surgical exposure for THA, whereas the fracture table is often used for repair of femur fractures. In transferring the patient from the supine to lateral decubitus position, care must be taken to maintain the head and shoulders in a neutral position. Ideally, a separate person is responsible for moving the legs, the torso, the shoulders, and the head. The patient is supported while the position is secured with hip rests or other mechanical devices. The dependent arm is abducted and placed on a padded arm rest; a rolled towel or wrapped intravenous fluid bag is placed in the axilla to avoid compression of the brachial plexus and vascular structures. The upper arm is placed on a padded over-arm board.

Positioning on the fracture table (Fig. 40-1) also requires adequate personnel to move the patient, with one person assigned to apply traction to the fractured limb. The fracture table affords two advantages: maintenance of traction on the fractured extremity, allowing manipulation for closed reduction and fixation; and access to the fracture site for radiography in several planes. The patient must be carefully monitored for hemodynamic changes during positioning, whether under regional or general anesthesia. Care must be taken to pad the perineal post before positioning the patient's pelvis. Usually the arm ipsilateral to the fractured hip is placed on an arm board or in a sling to keep it from obstructing the fluoroscopic view.

Figure 40-1. The fracture table. The patient must be moved carefully with continuous traction on the fractured limb. The ipsilateral arm is positioned on an arm board or sling without stretching the brachial plexus. (Courtesy of Midmark Corporation, Versailles, OH.)

Anesthetic Technique

Regional anesthetic techniques are well suited to procedures involving the hip. Central neuraxial blockade, including spinal and epidural blockade, is commonly used. Regional anesthesia may be instituted with the patient sitting or in the lateral decubitus position. Both hypobaric and isobaric spinal anesthetic solutions are effective. After establishment of spinal anesthesia, a dense sensory and motor block progresses quickly. Adequate intravenous hydration before placing the spinal block protects against a precipitous drop in blood pressure that can occur secondary to sympathetic blockade and peripheral vasodilation. In any patient, there is a risk of postdural puncture headache, but this risk diminishes with increasing age and decreasing needle gauge. Epidural blockade also provides excellent surgical anesthesia. Placement of a catheter allows the anesthesiologist to provide prolonged anesthesia as well as postoperative analgesia.

Regional anesthetic techniques reduce blood loss in patients undergoing hip surgery. Deliberate hypotension can also be used with general anesthesia as a means of reducing surgical blood loss and has been recommended when the benefits can be expected to outweigh the risks. In a comparative study, average blood loss during induced nitroprusside hypotension with nitrous oxide–halothane anesthesia for hip arthroplasty was 1.3l, whereas neuroleptanalgesia or nitrous oxide–halothane without hypotension yielded blood losses of 2.6 and 2 l, respectively.¹⁰ Diltiazem, nitroprusside with and without captopril, b blockers, and nitroglycerin have also been used to induce hypotension.

Surgery to the Knee

The most common surgical procedures to the knee are arthroscopy, anterior cruciate ligament repair, and total knee arthroplasty. Oral opioids and other adjuvant analgesics relieve postoperative pain after ambulatory knee surgery. However, open knee procedures are extremely painful. Therefore, continuous regional anesthetic techniques are helpful in facilitating rehabilitation and maintaining adequate joint range of motion.

Regional anesthetic techniques that can be used for surgical procedures about the knee include neuraxial as well as peripheral leg blocks. Spinal anesthesia can be accomplished with hyperbaric or isobaric solutions, although the latter are favored by most orthopaedic anesthesiologists. Injection of hyperbaric solutions often results in a higher level of sensory and motor blockade than needed for the surgical procedure, with subsequent earlier offset of anesthesia. Epidural blockade offers the advantage of a continuous catheter technique that can be continued into the postoperative period. These procedures are often associated with significant postoperative pain, particularly when continuous-motion machines are applied to the affected joint. The patient undergoing amputation of a lower limb often benefits from the use of regional anesthesia, although adequate sedation is imperative.

Peripheral nerve blocks of the lower extremity are not as popular as upper extremity blocks. Whereas the brachial plexus is a compact and conveniently located grouping of nerves that may be blocked at a single injection site, there is no anatomic correlate in the lower extremity. To provide surgical anesthesia of the lower extremity using peripheral nerve blocks, each major nerve is blocked individually at separate locations. These blocks do offer the advantage of limiting sympathetomy to the extremity blocked. Also, depending on the local anesthetic agent used, significant postoperative analgesia can be provided.

Surgical anesthesia for operative procedures on the knee in which a tourniquet will be used requires blockade of all four nerves (femoral, lateral femoral cutaneous, obturator, and sciatic nerves) innervating the leg. Although it is possible to perform major knee surgery under peripheral nerve blocks, more often a femoral

three-in-one or lumbar plexus (psoas) block is combined with a spinal or general anesthetic. This is less difficult technically, reduces the amount of local anesthetic (and associated systemic toxicity), and provides postoperative analgesia for 12–24 hours. Continuous lumbar plexus and sciatic techniques allow for prolonged postoperative analgesia.

Minor knee procedures with limited tourniquet inflation times, such as knee arthroscopy, may be performed solely under femoral or lumbar plexus block. Thus peripheral lower extremity blocks provide adequate surgical anesthesia and also allow for rapid recovery and early hospital dismissal for ambulatory patients.

The supine position optimizes surgical exposure during knee arthroscopy or arthroplasty, lower extremity amputations, and procedures to the tibia and fibula. Care must be taken to cushion the extremities and bony prominences.

Surgery to the Ankle and Foot

Innervation of the foot is provided by the femoral nerve (*via* the saphenous nerve) and by the sciatic nerve (*via* the posterior tibial, sural, and deep and superficial peroneal nerves). Therefore, central neuraxial blockade and peripheral nerve blocks at the upper leg, knee, or ankle are appropriate regional anesthetic techniques for foot surgery. The selection of the regional technique is based on the surgical site, use of a calf or thigh tourniquet, degree of weight bearing/ambulation, and the need for postoperative analgesia. For example, inflation of a thigh tourniquet for longer than 15–20 minutes necessitates a general or neuraxial anesthetic, regardless of surgical site. Common surgical procedures and considerations regarding the choice of regional technique are discussed in [Table 40-1](#).¹¹

| Surgical Procedure | Regional Technique | Comments |
|--------------------|---|---|
| Finger* | Median, ulnar, popliteal blockade | Sural nerve block not necessary for surgery |
| Amputation | Ankle, popliteal blockade | Popliteal blockade is the technique of choice in the presence of infection or swelling |
| Midfoot* | Popliteal, ankle blockade | |
| Medial* | Spinal, epidural, or general anesthesia | Operation typically requires good muscle relaxation for manipulation; thigh tourniquet |
| Medial* | Spinal, epidural, or popliteal blockade | Spinal or epidural anesthesia whenever thigh tourniquet is required |
| Acute fracture | Spinal, epidural, or popliteal blockade | Epidural block requires blockade of L5-S1 |
| Tight orthosis | Spinal or epidural | Neuraxial technique preferred for bone graft harvesting; popliteal blockade for postoperative analgesia |

* Femoral or saphenous block required if the incision extends to the medial aspect of the foot or ankle.

Table 40-1. ANESTHETIC TECHNIQUES FOR COMMON FOOT AND ANKLE OPERATIONS

The distal surgical site and the ability to block the pain pathways at multiple sites give regional anesthesia an advantage over general anesthesia for surgery to the ankle and foot. Peripheral blockade avoids the cardiovascular and respiratory side effects and the urinary retention associated with neuraxial and general anesthesia. Often patients undergoing lower extremity peripheral techniques may be discharged directly from the operating room to the outpatient nursing station, reducing recovery time and charges. The use of long-acting local anesthetics and the addition of epinephrine or clonidine allow prolongation of postoperative analgesia. However, additional onset time is required with bupivacaine and ropivacaine. Mepivacaine and lidocaine may be more appropriate in the ambulatory setting, where fast-onset and reliable surgical anesthesia are essential. The main disadvantage of peripheral blocks is the technical expertise required for consistent success; neuraxial techniques are a suitable alternative. The additional time that is often required for induction of regional anesthesia, as opposed to general anesthesia, can also be problematic in an era promoting increased surgical through-put and health care cost reduction.

Postoperative Analgesia

Systemic opioids remain a popular postoperative regimen for major orthopaedic surgery because they are relatively simple to administer, safe, and cost effective. Delivery of opioids using patient-controlled analgesia (PCA) devices results in improved analgesia, decreased total opioid consumption, and increased patient and nurse satisfaction. However, the pain after total joint replacement, particularly total knee arthroplasty, is severe. Adequate analgesia achieved with systemic opioids is frequently associated with side effects, including sedation, nausea, and pruritus. Anti-inflammatory medications and acetaminophen are valuable adjuvants to systemic opioids. The addition of non-opioid analgesics reduces opioid use, improves analgesia, and decreases opioid-related side effects.

Studies have demonstrated that epidural analgesia or peripheral nerve blocks provide better pain relief and faster postoperative rehabilitation than intravenous PCA with morphine after total joint replacement. For example, after total knee arthroplasty, patients receiving epidural analgesia or continuous femoral three-in-one block reported lower pain scores, better knee flexion, faster ambulation, and shorter hospital stays compared with patients who received intravenous PCA morphine.^{12,13} In addition, the patients with continuous femoral three-in-one blocks had the fewest side effects. These studies support the movement toward peripheral nerve blocks as a valuable technique for providing postoperative analgesia after major joint replacement. However, additional studies are needed further to define their use, duration, and application.

MICROVASCULAR SURGERY

Microvascular surgery includes both replantation, the reattachment of a completely severed body part, and revascularization, the re-establishment of blood flow through a severed body part. Most replantation surgery involves the upper extremity. Anesthetic management in microvascular surgery includes maintenance of blood flow through microvascular anastomoses, positioning considerations associated with a long surgical procedure during which the patient must lie completely still, and replacement of blood and fluid losses, which may be extensive.

Maintenance of blood flow through microvascular anastomoses is paramount to limb or graft viability. Blood flow may be improved by increasing the perfusion pressure, preventing hypothermia, and using vasodilators and sympathetic blockade. Microvascular perfusion pressure depends on both adequate intravascular volume and oncotic pressure. Blood loss during microvascular surgery is typically continual and insidious. Unrecognized bleeding and migration of intravascular fluid into the third space reduce microvascular perfusion pressure, and must be corrected. However, overzealous use of crystalloid results in generalized edema, including the replanted body part, whereas excessive transfusion of blood products increases blood viscosity and therefore decreases flow. Evidence suggests that use of phenylephrine to support blood pressure does not jeopardize blood flow to the tissue being replanted.¹⁴ Rheologically, the oxygen-carrying capacity of blood is optimized with a hematocrit of 30%. Normovolemic hemodilution may be used to improve tissue blood flow and decrease transfusion requirements in patients without significant cardiovascular, cerebrovascular, and renal disease.¹⁵ Preoperative autologous blood donation and intraoperative use of a cell saver also significantly reduce the number of transfused homologous units. Arterial cannulation allows frequent assessment of hemoglobin levels and acid–base status, as well as direct blood pressure measurement.

Body temperature is also a determinant of blood flow. Hypothermia not only results in peripheral vasoconstriction, but causes sympathetic activation, shivering, increased oxygen demand, a leftward shift of the oxygen–hemoglobin dissociation curve, and altered coagulation. Therefore, hypothermia must be prevented in microvascular surgical patients. The operating room temperature should be increased to 21°C, intravenous solutions should be warmed,¹⁶ and the patient covered with a forced-air warming blanket.

The use of vasodilators has also been studied in the treatment of perioperative vasospasm. Local anesthetics and papaverine, applied *topically*, may be used to provide relaxation of vascular smooth muscle in the intraoperative setting.¹⁷ All of the volatile anesthetics are potent vasodilators, and can increase tissue blood flow 200–300%, even at typical expired anesthetic concentrations. Direct-acting vasodilating agents, such as sodium nitroprusside, trimethaphan, and hydralazine, produce vasodilation but do not prevent vasospasm due to direct surgical stimulation. Nitroprusside has been shown to reduce perfusion in a microvascular free flap.¹⁴ In addition, the volatile anesthetics and intravenous agents also may result in hypotension and decreased microvascular perfusion pressure. Regional anesthetic techniques provide sympathectomy and vasodilation to the proximal (innervated) segment of an extremity, but have no effect on vasospasm in the replanted (denervated) tissue. Currently, antithrombotics (heparin), fibrinolytics (streptokinase, urokinase, low–molecular-weight dextran), and smooth muscle relaxants (papaverine, local anesthetics) are used to preserve blood flow in microvascular anastomoses.

Microvascular surgery may be performed under regional or general anesthesia. Regional anesthesia has several advantages over general anesthesia. The sympathectomy associated with local anesthetic blockade results in vasodilation and increased blood flow. A “single-shot” regional anesthetic technique may be of insufficient duration for many microvascular procedures. However, placement of an indwelling catheter (intrathecal, epidural, or axillary) provides extended intraoperative anesthesia and continuous postoperative analgesia. General anesthesia is more reliable, ensures airway access, and reduces the possibility of patient

movement during critical surgical events. A combination of general and continuous regional anesthesia allows prolonged intraoperative anesthesia and postoperative analgesia, reduces the amount of inhalational agent, and increases the patient's acceptance of lengthy surgical procedures. However, regardless of anesthetic technique, conditions that stimulate vasospasm or vasoconstriction, such as pain, hypotension, and hypovolemia, must be avoided. Whether administration of a vasopressor with vasoconstrictive qualities, or addition of epinephrine to local anesthetic solutions may decrease anastomotic blood flow is controversial.¹⁴

PEDIATRIC ORTHOPAEDIC SURGERY

Pediatric patients present with a variety of orthopaedic conditions, including congenital deformities, traumatic injuries, infections, and malignancies. Anesthetic management of the pediatric orthopaedic patient involves not only the usual pediatric patient considerations, such as airway management, fluid replacement, and maintenance of body temperature, but the unique concerns associated with orthopaedic surgery. Coexisting neuromuscular conditions, such as arthrogryposis or myelomeningocele, may predispose pediatric orthopaedic patients to latex allergy and malignant hyperthermia. In addition, patient positioning and the use of regional techniques for intraoperative anesthesia and postoperative analgesia must be considered.

Regional techniques are readily adaptable to the pediatric orthopaedic patient. Often, regional anesthetic procedures are technically easier to perform on children because the relative lack of subcutaneous tissue facilitates identification of bony and vascular landmarks as well as spread of local anesthetic solutions. The advantages of regional anesthesia in children are similar to those in adults and include earlier ambulation and hospital discharge, decreased incidence of nausea and vomiting, and prolonged postoperative analgesia. However, pediatric patients often are not considered candidates for regional techniques. The preoperative visit is essential in building a patient–parent–physician relationship and establishing an anesthetic plan. The use of preoperative and preblock sedation (oral and intranasal midazolam, intramuscular ketamine, and rectal methohexital) decreases anxiety and increases acceptance of regional anesthesia in the pediatric patient.

Orthopaedic procedures may be performed under regional, general, or a combination of anesthetic techniques. The patient's age, operative site and positioning, and surgical duration are important factors in selection of an anesthetic. Children older than 7 years of age may tolerate a primary regional anesthetic technique, whereas younger children may benefit from a general or combination regional/general anesthesia. Neural blockade may be initiated after induction of general anesthesia and before surgical incision, to provide possible pre-emptive analgesia, or on completion of the surgical procedure to extend the duration of postoperative analgesia.

Surgical procedures to the lower extremity may be safely and successfully performed under caudal, epidural, and spinal anesthesia.¹⁸ However, the anatomic differences between the pediatric and adult spine and spinal cord must be appreciated.¹⁹ In addition, femoral, lateral femoral cutaneous, and sciatic nerve blocks allow prolonged anesthesia and analgesia to the blocked extremity, but often require additional intraoperative supplementation with intravenous or inhalational agents.²⁰

Upper extremity procedures may be performed with any of the anesthetic techniques previously described for adults. The superficial location of the brachial plexus, decreased neural diameter, and rapid diffusion of local anesthetics contribute to the high success rate, which approaches 100%, even with a variety of techniques.²¹ Blockade of the brachial plexus is usually accomplished with perivascular, sheath, or nerve stimulator techniques in children younger than 7 years of age because elicitation of paresthesias is regarded as uncomfortable (and therefore unacceptable) by the younger pediatric patients. Intravenous regional (Bier) block is particularly useful in the pediatric population for limited procedures such as closed reduction of forearm fractures. The use of local anesthetic eutectic creams minimizes patient discomfort during intravenous catheter placement. Once intravenous access has been established, and the patient sedated, placement of a second venous cannula in the operative extremity is well tolerated. The small size of the upper arm often precludes the use of a double tourniquet in pediatric patients, limiting the duration of the surgical procedure to 45–60 minutes.

SURGERY TO THE SPINE

Spinal Cord Injuries

Spinal injury occurs at a rate of 11,000 cases per year. Approximately one half of these are at the cervical level. The examination of a person with a suspected spinal cord injury begins with a prompt neurologic examination and a rapid assessment for possible injury to other systems. Cervical injuries are frequently associated with head injury, thoracic fractures with pulmonary and cardiovascular injury, and lumbar fractures with abdominal and long bone injuries. The patient should be examined immediately for signs of respiratory insufficiency, airway obstruction, rib fractures, and chest wall or facial trauma.

Serial neurologic examination is necessary to assess function of the spinal cord above the level of the fracture. The fifth cervical segment is perhaps the most important in providing clinical evidence of cervical spinal injury. This segment controls motor function of the deltoid, biceps, brachialis, and brachioradialis muscles. If these muscles are flaccid, the fifth cervical nerve is involved and there will be partial diaphragmatic paralysis. A complete lesion at the fourth cervical segment is not compatible with survival unless artificial respiration is initiated.

Tracheal Intubation

Airway management is critical in patients with cervical spinal cord injury. The most common cause of death with acute cervical spinal cord injury is respiratory failure. All patients with severe trauma or head injuries should be assumed to have an unstable cervical fracture until proven otherwise radiographically. During transport, the patient should be moved on a spine board with the neck immobilized to prevent further injury. Fiberoptic intubation of an awake patient may be necessary. Blind nasotracheal intubation can be used when there is no evidence of facial or basal skull fractures. In a truly emergent situation, oral intubation with direct laryngoscopy is the usual approach. The trachea should be intubated with minimum flexion or extension of the neck.

Surgical Management

Surgical treatment of spinal cord injuries is based on the presence or absence of neurologic function and the radiographic evaluation of vertebral displacement and instability. Patients with unstable spines who are not quadriplegic or paraplegic may become so during positioning for surgery. The period of greatest risk is associated with turning the patient prone. Safe positioning for posterior cervical and thoracolumbar procedures may be performed by using a Foster frame, Jackson table, or other rotating bed. When appropriate, line placement, intubation, and positioning can be performed while the patient is awake with general anesthesia induced only after voluntary upper and lower extremity movement is confirmed. Cervical spine fractures are most often surgically treated by anterior open reduction and fusion. The surgical incision approximates the anterior border of the sternocleidomastoid muscle, and is therefore near critical anatomic structures. Lateral retraction of the carotid artery may endanger blood flow to the brain, particularly in the elderly patient.²² Retraction of the esophagus and trachea medially may cause pharyngeal laceration, laryngeal edema, and recurrent laryngeal nerve paralysis. Cerebrospinal fluid leaks and trauma to the vertebral artery have also been reported. Thoracolumbar dislocations are typically posterior.

Maintaining Spinal Cord Integrity

Spinal shock occurs acutely and results in complete cessation of spinal cord functions below the level of the lesion. This results in flaccid paralysis, loss of visceral and somatic sensation, and paralytic ileus. Vasopressor reflexes are also lost. Spinal shock may persist from a few days to 3 months.

All patients with spinal cord trauma should be considered to have compromised spinal cords, and an important component of anesthetic management is the preservation of spinal cord blood flow. Blood pressure and intravascular volume should be maintained within normal levels to ensure adequate spinal cord perfusion pressure. Sustained hypotension may worsen neurologic deficits. Hyperventilation should be avoided because hypocarbia decreases spinal cord blood flow. Neurophysiologic monitoring, such as the use of somatosensory evoked potentials (SSEPs), motor evoked potentials (MEPs), or electromyography, assists in prompt diagnosis of neurologic changes and early intervention in situations of potential neurologic ischemia. The wake-up test may also be used to confirm neurologic dysfunction in the presence of changes in MEP or SSEP waveforms.

Respiratory Considerations

Ventilatory impairment increases with the higher level of spinal injury. A high cervical lesion that includes the diaphragmatic segments (C4–5) results in respiratory failure, and death occurs unless artificial pulmonary ventilation is used. Lesions between C5 and T7 cause significant alterations in respiratory function owing to the loss of abdominal and intercostal support. The indrawing of flaccid thoracic muscles during inspiration produces paradoxical respirations, resulting in a vital capacity reduction of 60%. Inability to cough and effectively clear secretions results in atelectasis and infection.

Cardiovascular Considerations

During spinal shock, there is loss of sympathetic vascular tone below the injury. If the cardioaccelerator fibers (T1–4) are damaged, bradycardia results. Therefore,

hemorrhagic shock may not produce a compensatory tachycardia in these patients; the rate may remain at 40–60 beats · min⁻¹. Monitoring of central venous or pulmonary artery pressures may be necessary as an aid to fluid management in a patient with a high cervical lesion. Autonomic instability should be treated with vasoconstrictors, vasodilators, and positive chronotropic drugs as needed.

Succinylcholine-Induced Hyperkalemia

In patients with motor deficits from spinal cord injuries, hyperkalemia may develop after administration of succinylcholine. The amount of potassium released depends on the degree of paralysis. It is usually safe to administer succinylcholine for the first 48 hours. After that time, there is a proliferation of acetylcholine receptors in muscle and they become supersensitive to depolarizing muscle relaxants.²³ The increases in serum potassium are maximal between 4 weeks and 5 months after spinal injury. Serum potassium levels may increase from normal to as high as 14 mEq · l⁻¹, causing ventricular fibrillation or cardiac arrest. Therefore, succinylcholine should be avoided in all spinal cord-injured patients after 48 hours. There are no contraindications to the nondepolarizing agents.

Temperature Control

Disruption of the sympathetic pathways carrying temperature sensation and subsequent loss of vasoconstriction below the level of injury cause spinal cord-injured patients to be poikilothermic. Maintenance of normal temperature can be achieved by applying exogenous heat to the skin, increasing ambient air temperature, warming intravenous fluids, and humidifying gases.

Autonomic Hyper-reflexia

After recovery from spinal shock, 85% of patients exhibit autonomic hyper-reflexia when there has been complete cord transection above T5. The syndrome can also occur with injuries at lower levels and is characterized by severe paroxysmal hypertension with bradycardia, arrhythmias, and cutaneous vasoconstriction below and vasodilation above the level of the injury. The episode is typically precipitated by distention of a viscus (bladder or rectum), but can be induced by any noxious stimulus. The lack of supraspinal inhibition allows the sympathetic outflow below the lesion to react to the stimulus unopposed. If untreated, the hypertensive crisis may progress to seizures, intracranial hemorrhage, or myocardial infarction. If autonomic hyper-reflexia occurs, it should be treated by removal of the stimulus, deepening anesthesia, and administration of direct-acting vasodilators.

Scoliosis

Scoliosis is a deformity of the spine resulting in lateral curvature and rotation of the vertebrae as well as deformity of the rib cage (Fig. 40-2). The incidence of scoliosis predominantly reflects the incidence of idiopathic scoliosis, which represents 75–90% of cases. The remaining 10–25% of cases are associated with neuromuscular diseases, congenital abnormalities including congenital heart disease, trauma, and mesenchymal disorders. A diagnosis of scoliosis in a patient should therefore include a family history and physical examination with particular attention to the respiratory, cardiac, and neuromuscular systems.

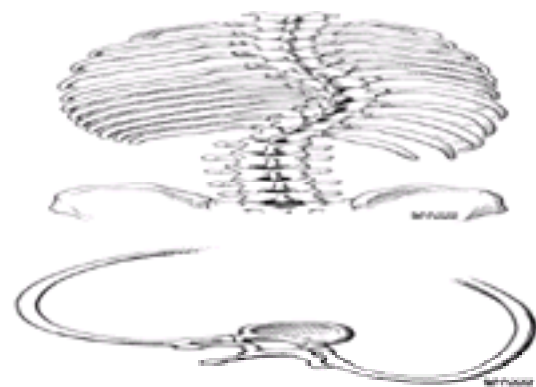

Figure 40-2. Deformity of the vertebrae and rib cage in scoliosis. Primary curvature occurs most frequently in the thoracic and lumbar regions. The vertebral bodies are wedge shaped and the posterior angles of the ribs are shallow on the side of concavity. On the convex side, the rib angles are more acute. (Reprinted with permission from Horlocker TT, Cucchiara RF, Ebersold MJ: Vertebral column and spinal cord surgery. In Cucchiara RF, Michenfelder JD [eds]: Clinical Neuroanesthesia, p325. New York, Churchill Livingstone, 1990.)

Respiratory Function

Scoliosis has profound effects on the respiratory and cardiovascular systems (Fig. 40-3). In patients with untreated scoliosis, respiratory failure and death usually occur by 45 years of age. Vital capacity appears to be a reliable prognostic indicator of perioperative respiratory reserve. Postoperative ventilation will most likely be required for patients with a vital capacity less than 40% of predicted. Although the long-term effect of scoliosis repair is to halt the decline in respiratory function, pulmonary function acutely deteriorates for 7–10 days after surgery.

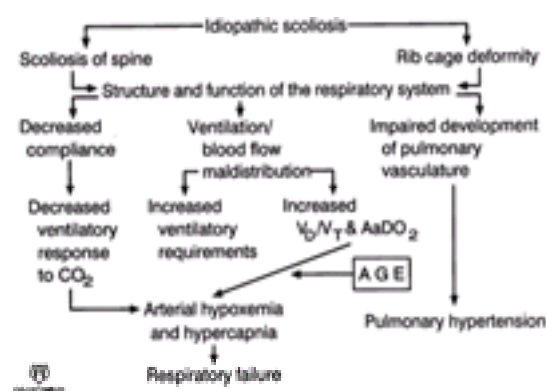

Figure 40-3. The factors in idiopathic scoliosis that contribute to respiratory function abnormalities and failure. (Reprinted with permission from Kafer ER: Respiratory and cardiovascular functions in scoliosis. Bull Eur Physiopathol Respir 13:299, 1977.)

The primary abnormality in gas exchange is ventilation–perfusion maldistribution, which contributes to hypoxemia. However, hypercapnia develops with increasing age as compensatory mechanisms fail. Prolonged hypoxia, hypercapnia, and pulmonary vascular constriction may result in irreversible pulmonary vascular changes and pulmonary hypertension. In general, the prognosis of scoliosis associated with neuromuscular disease is worse than that of idiopathic scoliosis. These patients frequently need postoperative ventilatory support.

Cardiovascular Function

Cardiovascular function is also affected in patients with scoliosis. At autopsy, these patients exhibit right ventricular hypertrophy and hypertensive pulmonary vascular changes. Prolonged alveolar hypoxia due to hypoventilation and ventilation–perfusion mismatch eventually causes irreversible vasoconstriction and pulmonary hypertension. Scoliosis is also associated with congenital heart conditions, including mitral valve prolapse, coarctation, and cyanotic heart disease, suggesting a common embryonic insult or collagen defect.

Preoperative Assessment

The primary aim of preoperative evaluation of patients with scoliosis is to detect the presence and extent of cardiac or pulmonary compromise. Respiratory reserve is assessed by exercise tolerance, vital capacity, and arterial blood gases. Cardiac studies are performed as indicated to optimize preoperative cardiovascular status. A brief neurologic examination is also performed at the time of the preoperative evaluation to document pre-existing neurologic deficits. Finally, cervical mobility and upper airway anatomy are assessed to discover any potential airway or positioning difficulties and the need for fiberoptic intubation. Patients should also be encouraged to participate in preoperative autologous blood donation. Usually 4 or more units of blood can be collected in the month before surgery.

Anesthetic Management

Anesthetic considerations in orthopaedic surgery for scoliosis include management of a patient in the prone position, hypothermia secondary to a long procedure with an extensive exposed area, and replacement of blood and fluid losses, which may be extensive.²⁴ Recently, attention has been focused on the maintenance of spinal cord integrity, the prevention and treatment of VAE, and reduction of blood loss through hypotensive anesthetic techniques.

Adequate monitoring and venous access are essential in management of patients undergoing spinal fusion and instrumentation. The radial artery is cannulated for direct blood pressure measurement and assessment of blood gases. A central venous catheter is helpful in evaluating blood and fluid management and can be used to aspirate air should VAE occur. Patients with evidence of pulmonary hypertension or severe coexistent cardiovascular or pulmonary disease may require a pulmonary artery catheter.

After anesthetic induction and establishment of vascular access are completed, the patient is positioned for surgery. The prone position is used for the posterior approach. Pressure points should be carefully padded. An orthopaedic frame, such as the Jackson table or Wilson frame, can be used to free the chest and abdomen. In correct prone positioning for thoracolumbar spine surgery, the head is turned, the neck is slightly flexed, and the arms are anteriorly flexed and abducted to reduce tension on the brachial plexus (Fig. 40-4). If only one arm is abducted, the head should be laterally rotated toward the ipsilateral arm to prevent stretch injury to the brachial plexus. Because rotation of the neck in patients with cervical spondylosis may alter cerebrovertebral circulation and compromise the spinal cord, patients should be evaluated for neck pain or neurologic symptoms with neck rotation before surgery. The chest and iliac crest are supported by chest rolls or other supports to leave the abdomen free. Breasts should be positioned medially to avoid traumatic injury. The dependent ear and eye should be checked frequently during surgery to avoid injury and ischemia. Pressure on the globe can result in retinal damage, especially in patients with glaucoma. Unilateral and bilateral blindness have been reported after spinal surgery, and have been attributed to multiple causes, including anemia, hypotension, and improper positioning.^{25,26} Eyes should be taped closed to avoid corneal abrasion, which occurs in the dependent eye with a frequency of 0.17%. Necrosis of the dependent ear cartilage may occur if the pinna is doubled back on itself.

Figure 40-4. Prone position. The head is turned with the dependent ear and eye protected from pressure. Chest rolls are in place, the arms are brought forward without hyperextension, and the knees are flexed. (Reprinted with permission from Horlocker TT, Cucchiara RF, Ebersold MJ: Vertebral column and spinal cord surgery. In Cucchiara RF, Michenfelder JD [eds]: Clinical Neuroanesthesia, p 325. New York, Churchill Livingstone, 1990.)

A nitrous oxide–narcotic–relaxant technique supplemented as necessary by volatile anesthetics is most commonly used for maintenance of anesthesia. The use of low concentrations of inhalational anesthetics helps maintain normotension, reduces total narcotic requirements, and still allows satisfactory interpretation of SSEPs. Narcotics may be administered by either bolus or continuous infusion. However, continuous infusion may reduce total narcotic requirement by over 50% and results in a smoother and more rapidly achievable wake-up test.²⁷

Blood Loss

Most of the blood loss in spinal instrumentation and fusion occurs with decortication and is proportional to the number of vertebral levels decorticated. Blood loss and transfusion requirements may be reduced through proper positioning and the use of intraoperative blood salvage, induced hypotension, and intraoperative hemodilution, although reported results are inconsistent.^{28,29,30,31}

Patient positioning should minimize epidural venous engorgement by freeing the abdomen. Preoperative donation of autologous blood or infusion of a large volume of crystalloid before surgical incision to reduce the hematocrit to 25–28% decreases blood viscosity and enhances organ blood flow. Normovolemic hemodilution combined with induced hypotension and autotransfusion can decrease or eliminate the need for homologous transfusion.³⁰

Moderate induced hypotension (reduction of systolic pressure 20 mm Hg from baseline or lowering mean arterial pressure to 65 mm Hg in the normotensive patient) has been shown to decrease blood loss, reduce transfusion requirements by 50%, and shorten operating times.³⁰ However, induced hypotension is not without risk and has been reported to cause cord ischemia and neurologic deficit, including blindness.^{25,32} Factors associated with increased risk of spinal cord injury include preoperative hypertension, hypocapnia, intraoperative mean arterial pressure less than 60 mm Hg, rapid decrease in blood pressure, and anemia.

The various agents used to induce hypotension in scoliosis surgery include trimethaphan, nitroglycerin, sodium nitroprusside, volatile anesthetics, calcium channel blockers, and α_1 and α_2 antagonists.³³ The volatile agents provide anesthesia as well as hypotension. However, all volatile anesthetics produce a dose-dependent deterioration of evoked potential waveforms. Therefore, a combination of intravenous hypotensive agents and volatile anesthetics is frequently used.

Venous Air Embolus

Several catastrophic events may occur during spine surgery. The large amount of exposed bone and the elevated location of the surgical incision relative to the heart predispose to VAE. The actual incidence of VAE in scoliosis surgery is unknown; however, six cases have been reported in the literature, four of which were fatal.^{34,35,36,37} The presenting sign in all cases was unexplained hypotension and an increase in the end-tidal nitrogen concentration. The anesthesiologist, therefore, should be aware of the possibilities of VAE because prompt diagnosis and treatment increase patient survival. Should VAE be suspected, the wound should be irrigated with saline, nitrous oxide discontinued, and vasopressors administered. Massive embolism may necessitate turning the patient supine and initiating cardiopulmonary resuscitation.

Another rare complication during spine surgery is trauma to the aorta, vena cava, or iliac vessels. Unexplained hypotension or signs of hypovolemia without obvious blood loss should alert the anesthesiologist to this possibility.

Anterior–Posterior Spinal Surgery

Combined anterior and posterior spinal procedures yield higher union rates and greater correction in patients undergoing scoliosis correction. It remains unclear whether these two major procedures should be performed on the same day or whether the posterior fusion should be delayed to allow the patient to recover from the anterior (first) procedure. Furthermore, the actual timing of the second procedure remains controversial. Although the degree of correction and the arthrodesis rates are similar for one- or two-stage procedures, the morbidity and number of complications, such as increased blood loss and transfusion requirements, decreased nutritional parameters, and longer hospital stays, may be increased for staged procedures.³⁸ However, these results are not consistent.³⁹ Because the risk of significant complications is present with either same-day or staged anterior–posterior fusion, prospective studies are needed to clarify this issue.

Degenerative Vertebral Column Disease

Spinal stenosis, spondylosis, and spondylolisthesis are all forms of degenerative vertebral column disease. It is not unusual for more than one of these degenerative changes in the spine to occur concomitantly, leading to a more rapid progression of neurologic symptoms and the need for surgical intervention.

Positioning

Cervical laminectomy is performed in the prone, lateral, or sitting position, whereas thoracolumbar laminectomy is usually performed prone. Considerations for positioning a prone patient have been previously discussed. Patients undergoing cervical laminectomy should be assessed before surgery for cervical range of motion and the presence of neurologic symptoms during flexion, extension, or rotation. Awake fiberoptic intubation may be necessary in patients with severely limited cervical movement.

The use of the sitting position for cervical laminectomy has become increasingly popular. Blood flows away from the site of operation, producing a clear operative field and better surgical exposure. In this position, the patient sits with head, arms, and chest supported. The patient must be carefully positioned and dependent areas padded to prevent compression injuries to nerves and skin. Extreme cervical flexion may obstruct the airway. Hypotension can be minimized by gradual attainment of the sitting position.

A disadvantage of the sitting position is the increased occurrence of VAE. Although the incidence of VAE in sitting posterior fossa cases is 40%, the incidence is only 5–25% in sitting cervical spine procedures. This decreased incidence may alter the need for a central venous pressure catheter. The use of capnography, mass spectrometry, and precordial Doppler should be routine for such cases because they are noninvasive yet effective in detecting VAE. VAE can occur in all positions associated with laminectomies because the wound is above the cardiac level. Incidences of VAE (defined by aspiration of air through a central venous catheter) in patients undergoing neurosurgical procedures in the sitting, supine, prone, and lateral positions are 25, 18, 10, and 8%, respectively.⁴⁰

Anesthetic Management

Both general and regional anesthesia can be safely administered for lower thoracic and lumbar surgery. Some anesthesiologists and surgeons prefer the use of spinal anesthesia; typically, a hypobaric solution is used. Advocates of regional anesthesia maintain that this type of anesthesia reduces blood loss and improves operating conditions by shrinking epidural veins. If a regional technique is used, a local anesthetic of sufficient duration must be selected. Should surgery last longer than the regional block, conversion to general anesthesia is difficult. Most spine surgery, however, is performed under general endotracheal anesthesia. General anesthesia is preferred for essentially all thoracic and cervical procedures because of the high spinal level that would be required with a regional technique. In addition, general anesthesia ensures airway access, is associated with greater patient acceptance, and can be used for lengthy operations. Succinylcholine should be avoided if there are progressive neurologic deficits because of the possible hyperkalemic response.

Spinal Cord Monitoring

Paraplegia is one of the most feared complications of spinal surgery. The incidence of neurologic injuries associated with scoliosis correction is 1.2%, with partial or complete paraplegia occurring in one half of cases. When patients awaken paraplegic, neurologic recovery is unlikely, although immediate removal of instrumentation improves the prognosis. It is therefore essential that any intraoperative compromise of spinal cord function be detected as early as possible and reversed immediately. The two methods developed to accomplish this are the wake-up test and neurophysiologic monitoring.

The *wake-up test*, first described by Vauzelle *et al*,⁴¹ consists of the intraoperative awakening of patients after completion of spinal instrumentation. Surgical anesthesia is typically provided with a balanced technique of nitrous oxide, a volatile drug, and opioids, although use of opioids and a short-acting volatile anesthetic (such as sevoflurane) alone is also possible. The opioids are important to provide analgesia while the patient is awake and to permit the patient to tolerate the endotracheal tube. During the 30–45 minutes before intraoperative wake-up, the volatile anesthetic is discontinued and the patient is allowed gradually to awaken. Muscle relaxants should be allowed to wear off, or be reversed. Awakening is accomplished by withdrawing the nitrous oxide. The patient is addressed by name and asked to move both hands, and after a positive response, both feet. Patients usually respond within 5 minutes. If there is satisfactory movement of the hands, but not the feet, the distraction on the rod is released one notch, and the wake-up test repeated. Increasing the blood pressure and blood volume may be attempted to increase spinal cord perfusion. Although recall of the event occurs in only 0–20% of patients and is rarely viewed as unpleasant,²⁷ it is important to describe what will transpire to the patient before surgery so that anxiety will be minimized should the patient be fully aware.

The wake-up test is associated with few false-negative results. That is, it is extremely rare for a patient who was neurologically intact when awakened during surgery to have a neurologic deficit on completion of the procedure. However, certain hazards of the wake-up test do exist and include recall, pain, air embolism, dislocation of spinal instrumentation, and accidental tracheal extubation or removal of intravenous and arterial lines. In addition, the wake-up test requires patient cooperation and may be difficult to perform on young children or mentally deficient patients.

An adjunct or alternative to the wake-up test is neurophysiologic monitoring. Neurophysiologic monitoring, including SSEPs, MEPs, and electromyography, is also discussed in [Chapter 25](#). Although the use of MEPs remains limited, SSEP monitoring is widely accepted. However, somatosensory stimulation follows the dorsal column pathways of proprioception and vibration, pathways supplied by the posterior spinal artery. The motor pathway, which is supplied by the anterior spinal artery, is not monitored. MEPs, on the other hand, monitor motor pathways but are technically more difficult to use. Muscle relaxants cannot be used in patients having MEP monitoring. It is of critical importance to note that postoperative paraplegia has occurred in at least one patient with preserved intraoperative SSEPs.⁴²

A number of variables are known to alter SSEP waveforms.^{43,44} In addition to neural injury, SSEPs are altered by hypercarbia, hypoxia, hypotension, and hypothermia. All the volatile anesthetics produce a dose-related decrease in the amplitude and an increase in the latency of SSEPs.

Acute alterations in SSEP amplitude or latency signify spinal cord compromise and may be the result of direct trauma, ischemia, compression, or hematoma. Should changes occur, it is recommended that surgery be discontinued, blood pressure be returned to normal or 20% above normal, and volatile agents decreased or discontinued. Arterial blood gases may be drawn to rule out a metabolic derangement. If the waveform does not return to normal, the surgeon should release distraction on the cord. A wake-up test is often performed at this time definitely to exclude neurologic deficits.

Postoperative Care

Most patients undergoing posterior spinal fusion can be extubated immediately after the operation if the procedure was relatively uneventful and preoperative vital capacity values were acceptable. Residual opioid or muscle relaxant may lead to hypoventilation or apnea, especially in patients with an associated neuromuscular disease. Some patients who have experienced considerable blood loss and who have received large amounts of intravenous fluids, particularly if they were prone, may have severe facial edema that renders immediate tracheal extubation unwise. Aggressive postoperative pulmonary care, including incentive spirometry, is necessary to avoid atelectasis and pneumonia. Continued hemorrhage in the postoperative period is another concern. Careful monitoring of systemic and central venous pressures, urine output, and wound drainage is essential. Neurologic status must also be monitored closely for deterioration.

Epidural and Spinal Anesthesia After Major Spine Surgery

Previous spinal surgery has been considered to represent a relative contraindication to the use of regional anesthesia. Many of these patients experience chronic back pain and are reluctant to undergo epidural or spinal anesthesia, fearing exacerbation of their pre-existing back complaints. Several postoperative anatomic changes make needle or catheter placement more difficult and complicated after major spinal surgery. Degenerative changes such as spondylolisthesis occur in the spine below the level of fusion, increasing the potential for spinal cord ischemia and neurologic complications with regional anesthesia.⁴⁵ The ligamentum flavum may be injured during surgery, resulting in adhesions within or obliteration of the epidural space. Spread of epidural local anesthetic may be affected by adhesions, producing an incomplete or “patchy” block. Obliteration of the epidural space may increase the incidence of dural puncture and make subsequent epidural blood patch placement impossible. Finally, needle placement in an area of the spine that has undergone bone grafting and fusion may not be possible with either midline or lateral approaches; needle insertion can be accomplished only at unfused segments.

Several retrospective studies have demonstrated that epidural anesthesia may be successfully performed in patients with previous spinal surgery; however, successful catheter placement was possible on the first attempt in only 50% of patients, even with an experienced anesthesiologist. In addition, although adequate epidural anesthesia was eventually produced in 40–95% of patients, there appeared to be a higher incidence of traumatic needle placement, inadvertent dural puncture, and unsuccessful epidural needle or catheter placement, especially if spinal fusion extended to L5–S1.^{46,47,48}

Spinal anesthesia may produce a more reliable block and cause less trauma than epidural anesthesia, although this has not been studied. However, it is reasonable to believe that although needle placement may be more difficult or traumatic in these patients, the spread of local anesthetic in the subarachnoid space and quality of block would not be affected. A spinal anesthetic may be more desirable after spinal surgery because the technique does not depend on a subjective loss of resistance, but instead has a definite end point—the presence of cerebrospinal fluid. In addition, the presence of postoperative spinal stenosis or other degenerative changes in the spine or pre-existing neurologic symptoms may preclude the use of regional anesthesia in these patients.

OTHER CONSIDERATIONS

Anesthesia for Nonsurgical Orthopaedic Procedures

Many orthopaedic procedures requiring anesthesia are carried out in areas other than the operating room. These include cast and dressing changes in pediatric patients, pin removal, hip and shoulder relocation, closed reduction of fractures, and joint manipulations. Although some of the minor procedures require only light sedation, those procedures involving bone and joint manipulation usually require a full anesthetic intervention. It is critically important that patients undergoing these procedures be managed with the same careful attention afforded those scheduled for a standard operating room. The orthopaedic surgeon is usually eager to proceed with these surgically straightforward procedures, often without the same preoperative consideration given to a patient undergoing a more extensive surgery.

Regional anesthesia, usually with a short-acting local anesthetic, can be a good choice for these procedures, especially when the patient wishes to leave the hospital on the same day with minimal residual anesthetic effects.

Regional Anesthesia in the Outpatient

The use of regional anesthesia in the outpatient population is associated with several theoretic benefits for the patient. Studies have demonstrated decreased nausea and vomiting, less drowsiness, improved pain control, and shorter stays in the outpatient unit.^{5,20,21} However, management of the outpatient regional anesthetic presents a number of unique problems as well. In many cases, residual blockade at the time of discharge is not desirable. This is particularly true when central neural blockade is used. In such cases, a local anesthetic should be chosen to provide a short duration of blockade, and the patient should be fully recovered by the time of discharge. Full recovery implies return of all motor and sensory function along with evidence that the sympathetic blockade has also dissipated. This can best be evaluated by performing orthostatic blood pressure checks, as well as a nursing assessment of the patient's ability to stand upright and ambulate without assistance. It is also prudent to require that the patient be able to urinate before discharge to prevent overdistention of the bladder, and to demonstrate return of autonomic and somatic nerve function.

Return of full neurologic function may be less important immediately after peripheral nerve blocks. Persisting neural blockade provides excellent pain relief and increased blood flow to the surgical site, both of which may be desirable side effects. However, the risk of accidental nerve trauma in a blocked extremity is theoretically higher outside of the hospital environment. The patient should be informed of the risks and instructed in appropriate care of the extremity. Patients who are unable or unwilling to comply with recommended medical care may not be good candidates for regional anesthesia techniques, and should be fully recovered before discharge.

In all cases, a follow-up telephone call on the first postoperative day should include questions concerning residual areas of neural blockade or altered neural function, such as paresthesias. Any patient concerns regarding the anesthetic or surgery should also be discussed. In the case of outpatient spinal anesthesia or accidental dural puncture during epidural anesthesia, the patient should be informed of the risk of postspinal headache and given a contact person in the anesthesia department to call if problems arise. Postdural puncture headache should be managed conservatively for 24–72 hours with bed rest and rehydration. If it persists, epidural blood patch may be considered.

Tourniquets

Peripheral orthopaedic procedures involving removal of tumors, muscle, and bone may be quite bloody. Tourniquets are often used to minimize blood loss. The cuff should be applied over limited padding or none at all. Padding can cause irritation owing to wrinkling or folds, or by absorbing iodophor. During skin preparation, the cuff and padding may be protected with a plastic drape placed just distal to the cuff. The cuff should be large enough comfortably to circle the limb to ensure circumferentially uniform pressure. The point of overlap should be placed 180 degrees from the neurovascular bundle because there is some area of decreased compression at the overlap point. The width of the inflated cuff should be more than half the limb diameter. Pressure is usually maintained by compressed gas (air or oxygen) and must be monitored continually while the tourniquet is in use. Before tourniquet inflation, the limb should be elevated for approximately 1 minute and tightly wrapped with an elastic bandage distally to proximally. Limb tourniquets are relatively contraindicated when there is infection or tumor.

Opinions differ as to the pressure required in tourniquets to prevent bleeding. Some gauges are marked with average arm and leg pressures, but varying patient sizes render such averages irrational. Leg tourniquets are often pressurized more than arm tourniquets, on the theory that larger limbs require more pressure than smaller limbs. In general, a cuff pressure 100 mm Hg above a patient's measured systolic pressure is adequate for the thigh, and 50 mm Hg above systolic pressure is adequate for the arm, with the understanding that if hypertensive episodes occur, the cuff pressure should be increased. Bleeding from the surgical site after cuff inflation may rarely be due to inadequate occlusion of the major arterial inflow, which is corrected by cuff reapplication and use of the proper degree of inflation. Oozing is more commonly due to intramedullary blood flow in the long bones, particularly in the skeletally immature, and to small arterial vessels between the two bones of distal extremities. Overinflation of the tourniquet does not resolve these problems.

The duration of safe tourniquet inflation is unknown. Recommendations range from 30 minutes to 4 hours. Five minutes of intermittent perfusion between 1- and 2-hour inflations, followed by repeated exsanguination through elevation and compression, may allow more extended use.⁴⁹ Local hypothermia has been shown to protect muscle from ischemia,^{50,51} and decreased muscle activity after neural block may also be protective.

Damage to underlying vessels, nerves, and skeletal muscles has been reported.⁵² Injury is a function of both inflation pressure and duration of inflation.^{53,54} Direct pressure from the cuff is more damaging than the ischemia distally.^{53,55} Arterial spasm, venous thrombosis, and nerve injury are all demonstrable after several hours, depending on the technique used to search for injury. Clinical examination, electromyography, and effluent blood analysis all show completely reversible changes for inflations of 1 to 2 hours, which is the basis for the recommendation of this period as the safe duration for tourniquet use.⁵⁶

Transient systemic metabolic acidosis and increased arterial carbon dioxide levels have been demonstrated after tourniquet deflation, and do not cause deleterious effects in healthy patients.^{57,58} Measurable changes include a 10–15% increase in heart rate, a 5–10% increase in serum potassium, and a rise of 1–8 mm Hg in carbon dioxide tension in blood. Prolonged inflation or the simultaneous release of two tourniquets may produce clinically significant acidosis, particularly in patients with an underlying acidosis due to other causes. Tourniquet release has also been associated with cerebral embolic phenomena.⁵⁹

When a pneumatic tourniquet is used with regional anesthetic techniques, some patients complain of dull, aching pain or become restless, even though seemingly adequate analgesia exists for the operation itself. Patient discomfort usually appears approximately 45 minutes after the tourniquet is inflated and becomes more intense with time. No satisfactory explanation for its genesis has been found. Current explanations involve pain transmission through both A delta and C fibers, and its modulation in the dorsal horn synapses. The C (slow pain) fibers recover faster as the block wanes. Analogous phenomena may be observed at the same time point during general anesthesia. Evidence of lightening anesthesia (increase in blood pressure and pulse rate) may appear even though the same concentrations of anesthetic are being delivered.^{60,61} The definitive treatment for tourniquet pain is release of the tourniquet. Relief of pain is prompt and complete. During surgery, however, opioids and hypnotics are usually effective.

Fat Embolus Syndrome

Fat embolus syndrome (FES) is associated with multiple traumatic injuries and surgery involving long bone fractures.⁶² Risk factors include male sex, age (20–30 years), hypovolemic shock, intramedullary instrumentation, rheumatoid arthritis, THA using the technique of cementing femoral stems designed for press-fit application, and bilateral total knee surgery. The incidence of FES in isolated long bone fractures is 3–4%, and the mortality rate associated with this condition is significant, ranging from 10 to 20%.

Clinical and laboratory signs of FES have been classified by Gurd⁶³ as major or minor (Table 40-2), with a diagnosis requiring at least one major and four minor criteria as well as the exclusion of other post-traumatic causes of hypoxemia. Major signs of the syndrome include the presence of axillary or subconjunctival petechiae, significant hypoxemia, central nervous system depression in excess of that expected due to the level of hypoxemia, and pulmonary edema. Classified as minor signs are tachycardia, hyperthermia, retinal fat emboli on funduscopic examination, urinary fat globules, an unexplained decrease in hematocrit or platelets, an increased erythrocyte sedimentation rate, and fat globules in the sputum. Symptoms usually occur 12–40 hours after the injury and can range from mild dyspnea to frank coma.

Decreased arterial oxygen tension is the most consistent abnormal laboratory value.⁶² Fulminant episodes can occur within hours of the traumatic injury, causing severe hypoxemia, respiratory failure, and severe neurologic impairment. Disseminated intravascular coagulation can also occur in conjunction with FES. Not all trauma patients who have demonstrated evidence of fat emboli fit the criteria for diagnosis of FES. Two theories are hypothesized to explain the mechanism of this syndrome: the mechanical theory and the biochemical theory. The mechanical theory proposes that long bone trauma results in release of fat droplets that enter the vascular system through torn veins. These droplets are transported to the pulmonary vascular bed where they act as microemboli. The biochemical theory can be divided into two mechanisms, toxic and obstructive. The toxic mechanism proposes that free fatty acids released at the time of trauma directly affect pneumocytes in the lung and cause adult respiratory distress syndrome. This effect would be enhanced by the trauma-induced release of catecholamines, which would result in further mobilization of free fatty acids. The obstructive theory hypothesizes that an unspecified chemical event at the site of the fracture releases mediators that affect lipid solubility, resulting in coalescence of lipids and consequent embolization. Some or all of these theories may play a role in development of FES. Other predisposing or aggravating factors such as shock, hypovolemia, sepsis, or disseminated intravascular coagulation may be required to trigger the conversion of fat emboli to FES.

| MAJOR |
|---|
| Axillary/subconjunctival petechiae |
| Hypoxemia (Pao ₂ < 60 mm Hg; Pao ₂ < 0.4) |
| Central nervous system depression (disproportionate to hypoxemia) |
| Pulmonary edema |
| MINOR |
| Tachycardia (>110 beats·min ⁻¹) |
| Hyperthermia |
| Retinal fat emboli |
| Urinary fat globules |
| Decreased platelets/hematocrit (unexplained) |
| Increased erythrocyte sedimentation rate |
| Fat globules in sputum |

Diagnosis of fat embolus syndrome requires at least one sign from the major and four signs from the minor criteria categories.
 From Gurd AR: Fat embolism: An aid to diagnosis. J Bone Joint Surg Br 52:752, 1970, with permission.

Table 40-2. CRITERIA FOR DIAGNOSIS OF FAT EMBOLUS SYNDROME

Appropriate treatment of FES requires early recognition of the syndrome, reversal of possible aggravating factors such as hypovolemia, early surgical stabilization of fracture sites, and aggressive respiratory support. Corticosteroid therapy is controversial, but may be beneficial. Other pharmacologic interventions, including heparin and dextran, have not been shown to be effective in treating FES.

Deep Venous Thrombosis and Pulmonary Embolus

Orthopaedic surgical procedures are associated with a variety of complications due to embolic phenomena. Reported emboli occurring during and after surgery include fat, cement, air, and thrombus. These may be caused by multiple factors such as positioning, fracture of long bones, injection of cement under pressure, and predisposing medical conditions. VAE can occur in orthopaedic surgical patients undergoing spine surgery in the prone position and shoulder surgery in the sitting position, and is discussed earlier in this chapter.

Incidence of Thromboembolic Complications

Venous thromboembolism is a major cause of death after surgery or trauma to the lower extremities. Without prophylaxis, venous thrombosis develops in 40–80% of orthopaedic patients, and 1–24% show clinical or laboratory evidence of pulmonary embolism. Fatal pulmonary embolism occurs in 0.2–13% of patients⁶⁴ (Table 40-3). The incidence of fatal pulmonary embolism is highest in patients who have undergone surgery for hip fracture. Although fatal pulmonary embolism may be the most common preventable cause of hospital death, many physicians fail to use prophylaxis appropriately because of concern about bleeding complications from anticoagulation. Effective thromboprophylaxis requires knowledge of clinical risk factors in individual patients such as advanced age, prolonged immobility or bed rest, prior history of thromboembolism, cancer, pre-existing hypercoagulable state, and major surgery. In many patients, multiple risk factors may be present, and the risks are cumulative. After identification of the risk of thromboembolism, an assessment may be made regarding the risks and benefits of physical or pharmacologic techniques used to prevent thromboembolic complications.

| Procedure | Deep Venous Thrombosis* | | Pulmonary Embolism | |
|------------------------|-------------------------|--------------|--------------------|-----------|
| | Total (%) | Proximal (%) | Total (%) | Fatal (%) |
| Total hip replacement | 45-57% | 21-30% | 0.7-3.0% | 0.34-0% |
| Total knee replacement | 40-54% | 9-20% | 1.9-7% | 0.2-0.7% |
| Hip fracture surgery | 36-60% | 17-30% | 4.3-24% | 3.6-12.9% |

Table 40-3. VENOUS THROMBOEMBOLISM PREVALENCE AFTER ORTHOPEDIC SURGERY

Thromboembolic Prophylaxis

Patients undergoing major orthopaedic surgery are at increased risk for thromboembolism. Although it is recommended that some form of prophylaxis be used in all patients, the method and duration of prophylaxis remain controversial (Table 40-4). Nonpharmacologic measures include graded elastic compression stockings, intermittent pneumatic compression, and early ambulation.

| ADJUSTED-DOSE UNFRACTIONATED HEPARIN |
|---|
| 700 U heparin q6h with dose adjustments to maintain aPTT at high-normal values |
| LOW-MOLECULAR-WEIGHT HEPARIN AND BIPHEMIDOPY |
| Aspirin 81 mg qd twice daily starting 12-24 h after surgery |
| Dabigatran 150 mg q 12h before surgery and once daily starting 12h after surgery |
| Clotaparin 70 U 1-2 h before surgery and once daily after surgery |
| Enoxaparin 30 mg qd twice daily starting 12-24 h after surgery or 40 mg qd once daily starting 12-24 h after surgery |
| Tinzaparin 4.4 mg qd starting 24 h before surgery and once daily after surgery for 14 days. The dose is then increased to 8.8 mg qd once daily. |
| Tinzaparin 5 U qd 2 h before surgery and once daily after surgery, or 7.5 U qd once daily starting 12-24 h after surgery |
| ADJUSTED-DOSE PHARMACOLYTIC WARFARIN |
| Start daily warfarin dose 1 mg the day of surgery or the day after surgery; adjust dose for INR 2-3 by day 5 |

*Dose expressed as anti-factor Xa units. Use with caution in patients receiving concurrent methicillin/valproic acid. Aspirin, enoxaparin, dabigatran, and tinzaparin are approved by the Food and Drug Administration.
 aPTT = activated partial thromboplastin time; INR = international normalized ratio.

Table 40-4. ANTITHROMBOTIC REGIMENS TO PREVENT THROMBOEMBOLISM IN ORTHOPEDIC SURGICAL PATIENTS

Multiple thromboprophylaxis regimens for patients undergoing total hip replacement have been studied. Although aspirin and subcutaneous unfractionated heparin are more efficacious than placebo, the risk of thromboembolism remains significant, and a higher level of anticoagulation is required. In addition, although adjusted-dose administration of unfractionated heparin (to attain an activated partial thromboplastin time in the upper normal range) is effective, most orthopaedic surgeons consider adjusted-dose heparin prophylaxis impractical. The most popular method of thromboprophylaxis after total hip replacement is oral anticoagulation with warfarin, with the

first dose administered the evening before surgery and a target international normalized ratio (INR) of 2.0–3.0. Low-molecular-weight heparin (LMWH) has also been demonstrated to be equally efficacious and cost effective.⁶⁴

Thromboembolic complications occur after total knee replacement despite aggressive measures. Intermittent pneumatic compression devices may be effective, but must be applied during surgery and worn continuously after surgery except during ambulation. Patient intolerance limits their use, however. Subcutaneous heparin and aspirin are also ineffective. Therefore, the two most common anticoagulant-based methods of thromboprophylaxis after total knee replacement are warfarin and LMWH. Current data suggest that LMWH is slightly more effective than warfarin in this patient population.

The optimal duration of anticoagulation after either total hip or knee replacement is unknown. Although available information implies that a minimum of 7–10 days of prophylaxis is required, significant risk for thromboembolism may persist for 1–2 months after surgery. Discontinuation of LMWH or warfarin therapy on hospital discharge (approximately 5 days after surgery) may be inadequate.

Prophylaxis in patients sustaining a hip fracture remains a challenge. Although these patients are at significant risk of thromboembolism, their overall medical condition may also place them at risk for bleeding complications. In addition, no data are available to assess the efficacy of nonpharmacologic methods such as intermittent pneumatic compression. Although prophylaxis with either LMWH or warfarin therapy is preferable, administration of standard subcutaneous heparin or aspirin may be acceptable in some patients.⁶⁴

Neuraxial Anesthesia and Analgesia in the Orthopaedic Patient Receiving Thromboprophylaxis

Several studies show a decrease in the incidence of both DVT and PTE in patients undergoing hip surgery under epidural^{7,8,9} and spinal^{65,66,67} anesthesia. Similar findings have been reported for knee surgery performed under epidural anesthesia.^{68,69} Proposed mechanisms for this effect include (1) rheologic changes resulting in hyperkinetic lower extremity blood flow, reducing venous stasis and preventing thrombus formation; (2) beneficial circulatory effects from epinephrine added to the local anesthetic solutions; (3) altered coagulation and fibrinolytic responses to surgery under central neural blockade, resulting in a decreased tendency for blood to clot and better fibrinolytic function;⁷⁰ (4) the absence of positive-pressure ventilation and its concomitant effects on circulation; and (5) direct local anesthetic effects such as decreased platelet aggregation. Although the improved lower extremity rheology associated with spinal and epidural anesthesia seems self-evident, other cited mechanisms are difficult to prove. Interpretation of studies that examine these factors must take into consideration variations in surgical techniques, fluid management, patient positioning, and other parameters. Finally, most of the studies examining the value of epidural and spinal anesthesia in preventing DVT and PTE involved patients who were not receiving currently recommended pharmacologic prophylaxis. The role of regional anesthesia needs to be re-evaluated in this population to determine the extent of protection as well as the risk of performing neural blockade in partially anticoagulated patients so that a reasonable risk-benefit ratio can be determined.

Despite the advantages of neuraxial techniques, patients receiving perioperative anticoagulants and antiplatelet medications are often not considered candidates for spinal or epidural anesthesia/analgesia because of the risk of neurologic compromise from expanding spinal hematoma. The actual incidence of neurologic dysfunction resulting from hemorrhagic complications associated with neuraxial blockade is unknown; however, the incidence cited in the literature is estimated to be less than 1 in 150,000 epidural and less than 1 in 220,000 spinal anesthetics.⁷¹ The frequency of spinal hematoma is increased in patients who receive perioperative anticoagulation.⁷² The clinician must be aware of the pharmacologic properties of thromboprophylactic medications to evaluate patients for neuraxial block as well as determine the timing of catheter removal.

Extensive clinical testing and use of LMWH in Europe in the 1990s suggested that there was not an increased risk of spinal hematoma in patients undergoing neuraxial anesthesia while receiving perioperative LMWH thromboprophylaxis.⁷² However, 5 years after the release of LMWH for general use in the United States in May 1993, over 40 cases of spinal hematoma associated with neuraxial anesthesia administered in the presence of perioperative LMWH prophylaxis had been reported to the manufacturer.⁷³ Many of these events occurred when LMWH was administered during or soon after surgery to patients undergoing continuous epidural anesthesia and analgesia. Concomitant antiplatelet therapy was administered in several cases. The apparent difference in incidence in Europe compared with the United States may be a result of a difference in dose and dosage schedule. For example, in Europe the recommended dose of enoxaparin is 40 mg once daily (with LMWH therapy initiated 12 hours before surgery), rather than 30 mg every 12 hours. However, timing of catheter removal may also have an impact. It is likely that the lack of a trough in anticoagulant activity associated with twice-daily dosing resulted in catheter removal during significant anticoagulant activity. The incidence of spinal hematoma in patients undergoing neuraxial block in combination with LMWH has been estimated at 1 in 40,800 spinal anesthetics and 1 in 3100 continuous epidural anesthetics.⁷⁴ Although patients with postoperative initiation of LMWH thromboprophylaxis may safely undergo single-dose and continuous catheter techniques, the first dose of LMWH should be administered no earlier than 24 hours after surgery. In addition, it is recommended that indwelling catheters be removed before initiation of LMWH thromboprophylaxis. The decision to implement LMWH thromboprophylaxis in the presence of an indwelling catheter must be made with care.⁷³ Since anti-factor Xa activity is not predictive of the risk of bleeding, monitoring of the anti-factor Xa level is not recommended. Concomitant administration of medications affecting hemostasis, such as antiplatelet drugs, standard heparin, or dextran, should be avoided in patients receiving LMWH to reduce the risk of surgical or anesthetic-related bleeding complications.

Anesthetic management of patients receiving perioperative anticoagulation with warfarin depends on dosage and timing of initiation of therapy. Patients receiving warfarin therapy during epidural analgesia should have their prothrombin time and INR monitored on a daily basis, and checked before catheter removal if the initial dose of warfarin was more than 36 hours beforehand. There is no definitive recommendation for removal of neuraxial catheters in patients with therapeutic levels of anticoagulation; the trauma associated with catheter removal must be compared with the ongoing trauma produced by an indwelling catheter in an anticoagulated patient, as well as the degree and duration of anticoagulation.⁷⁵

Many orthopaedic patients receive perioperative antiplatelet agents such as aspirin or ibuprofen. Antiplatelet drugs, by themselves, appear to represent no added significant risk for the development of spinal hematoma in patients having epidural or spinal anesthesia. It is not necessary to discontinue antiplatelet medications or assess platelet function before neuraxial anesthesia. However, careful preoperative assessment of the patient to identify alterations of health that might contribute to bleeding is crucial.⁷⁶ The relative risk of other antiplatelet agents such as ticlopidine and clopidogrel remains undetermined.

In summary, the decision to perform spinal or epidural anesthesia/analgesia and the timing of catheter removal in the orthopaedic patient receiving thromboprophylaxis should be made on an individual basis; alternative anesthetic and analgesic techniques exist for patients considered to be at an unacceptable risk. The patient's coagulation status should be optimized at the time of spinal or epidural needle/catheter placement, and the level of anticoagulation must be carefully monitored during the period of epidural catheterization. Patients respond with variable sensitivities to anticoagulant medications. Indwelling catheters should not be removed in the presence of therapeutic anticoagulation because this appears to significantly increase the risk of spinal hematoma.^{72,73} In addition, communication between clinicians involved in the perioperative management of patients receiving anticoagulants for thromboprophylaxis is essential to decrease the risk of serious hemorrhagic complications.

The patient should be closely monitored in the perioperative period for signs of cord ischemia. If spinal hematoma is suspected, the treatment of choice is immediate decompressive laminectomy. Recovery is unlikely if surgery is postponed for more than 10–12 hours; less than 40% of the patients in a series reported by Vandermeulen *et al*⁷² had partial or good recovery of neurologic function.

Methyl Methacrylate

Methyl methacrylate is an acrylic bone cement used during arthroplastic procedures. Insertion of this cement is associated with sudden onset of hypotension in some patients. This hypotension has been attributed to absorption of the volatile monomer of methyl methacrylate, embolization of air and bone marrow during femoral reaming, lysis of blood cells and marrow induced by the exothermic reaction, and conversion of methyl methacrylate to methacrylate acid. Adequate hydration and maximizing inspired oxygen concentration minimize the hypotension and hypoxemia that can accompany cementing of the prosthesis. Because air can be entrained during this procedure, nitrous oxide should be discontinued several minutes before this point.

Intra-articular Injections

Peripheral opioid receptors may be increased in the presence of chronic inflammation. Intra-articular injection of local anesthetics can be used during arthroscopic procedures along with local infiltration to provide surgical anesthesia. These agents can be injected into the articular space before the start of surgery or added to the irrigation solution. Longer-acting local anesthetic agents alone, or combined with opioids or nonsteroidal agents, can provide postoperative pain relief when injected at the end of the procedure.

Intra-articular injections of local anesthetics, opioids, or combinations have become routine for perioperative pain management after arthroscopic knee surgery. A number of reports enthusiastically recommend the use of this technique; however, the results remain conflicting.^{77,78} Comparison of reports is difficult because of variability in underlying anesthetic techniques, different dosages and concentrations of local anesthetic, and lack of control groups. The safety of injecting large

volumes of intra-articular bupivacaine has been ascertained,⁷⁹ and side effects are rare after intra-articular doses of morphine. Because these techniques are simple and low risk and seem to afford pain relief under some conditions, they will likely be continued. Carefully controlled studies are necessary to determine which techniques are efficacious and under what clinical circumstances they should be applied.

THYROID GLAND

The thyroid gland secretes thyroid hormones, thyroxine (T_4) and 3,5,3'-1-tri-iodothyronine (T_3), which are the major regulators of cellular metabolic activity. Thyroid hormones influence a variety of proteolytic reactions by regulating the synthesis and activity of various proteins. They are necessary for proper cardiac, pulmonary, and neurologic function during both health and illness.

Thyroid Metabolism and Function

The production of thyroid hormone is initiated by the active uptake and concentration of iodide in the thyroid gland (Fig. 41-1). Dietary iodine is reduced to iodide in the gastrointestinal (GI) tract. Circulating iodide is taken up by the thyroid gland where it is then bound to tyrosine residues to form various iodotyrosines. After organification, monoiodotyrosine or diiodotyrosine is coupled enzymatically by thyroid peroxidase to form either T_3 or T_4 . These hormones are attached to the thyroglobulin protein and stored as colloid in the gland. The release of T_3 and T_4 from the gland is accomplished through proteolysis from the thyroglobulin and diffusion into the circulation. Thyrotropin (thyroid-stimulating hormone; TSH) is produced in the anterior pituitary gland, and its secretion is regulated by thyrotropin-releasing hormone, produced in the hypothalamus. TSH is responsible for maintaining the uptake of iodide and proteolytic release of thyroid hormone. Excess iodine inhibits the synthesis and secretion of thyroid hormone. Circulating thyroid hormone inhibits thyroid-releasing hormone and TSH secretion in a negative feedback loop. The thyroid gland is solely responsible for the daily secretion of T_4 ($80\text{--}100\ \mu\text{g} \cdot \text{day}^{-1}$). The half-life of T_4 in the circulation is 6–7 days.

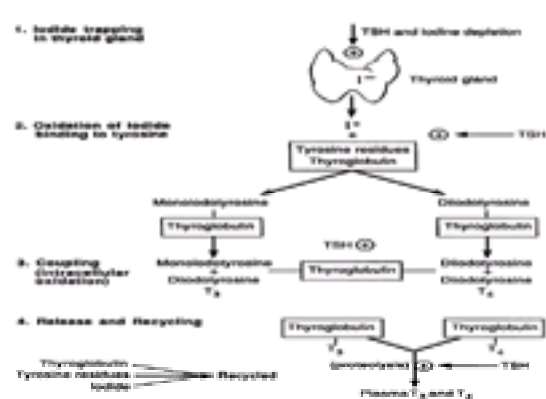

Figure 41-1. Thyroid hormone biosynthesis consists of four stages: (1) organification, (2) binding, (3) coupling, and (4) release. TSH = thyroid-stimulating hormone; T_3 = triiodothyronine; T_4 = thyroxine.

Approximately 80% of T_3 is produced by the extrathyroidal deiodination of T_4 and 20% by direct thyroid secretion. The half-life of T_3 is 24–30 hours. Most of the effects of thyroid hormones are mediated by the more potent and less protein bound T_3 . The degree to which these hormones are protein bound in the circulation is the major factor influencing their activity and degradation. T_4 is metabolized by monodeiodination to either T_3 or reverse T_3 (rT_3). T_3 is biologically active, whereas rT_3 is inactive. The major fraction of circulating hormone is bound to thyroid-binding globulin (TBG), with a smaller fraction bound to albumin and thyroid-binding prealbumin. Less than 0.1% is present as free, unbound hormone. Changes in serum binding protein concentrations have a major effect on total T_3 and T_4 serum concentrations. The plasma normally contains $5\text{--}12\ \mu\text{g} \cdot \text{dl}^{-1}$ of T_4 and $80\text{--}220\ \text{ng} \cdot \text{dl}^{-1}$ of T_3 . Many drugs can affect thyroid function, including amiodarone and dopamine.¹

Although the thyroid hormone is important to many aspects of growth and function, the anesthesiologist is most often concerned with the cardiovascular manifestations of thyroid disease. Thyroid hormones affect tissue responses to sympathetic stimuli and increase the intrinsic contractile state of cardiac muscle. β -adrenergic receptors are increased in number and cardiac α -adrenergic receptors are decreased by thyroid hormone.²

Tests of Thyroid Function

Serum Thyroxine

The serum T_4 assay is the standard screening test for evaluation of thyroid gland function (Table 41-1). The total T_4 is elevated in approximately 90% of patients with

hyperthyroidism, and it is low in 85% of those who are hypothyroid. The concentration of T_4 is measured by radioimmunoassay (RIA). The serum T_4 concentration is influenced by thyroid hormone protein-binding capacity. An increase or decrease in TBG levels or in protein binding may therefore alter the total T_4 but not the concentration of the free T_4 . Because of the effect of TBG on circulating total T_4 , T_4 levels should never be used alone to evaluate thyroid disease. Elevations in the TBG concentration are the most common cause of hyperthyroxinemia in euthyroid patients. Increases in TBG due to acute liver disease, pregnancy, or drugs (oral contraceptives, exogenous estrogens, clofibrate, opioids) may be responsible. Because a total T_4 can be misleadingly high in euthyroidism or normal in hypothyroidism, some measure of free thyroid hormone activity (free T_4) must also be used.

| | T_4 | THBR | T_3 | TSH |
|--|----------|----------|---------------|---------------|
| Hyperthyroidism | Elevated | Elevated | Elevated | Normal or low |
| Primary hypothyroidism | Low | Low | Low or normal | Elevated |
| Secondary hypothyroidism | Low | Low | Low | Low |
| Sick euthyroid syndrome (decreased peripheral conversion of T_4 to T_3) | Normal | Normal | Low | Normal |
| Pregnancy | Elevated | Low | Normal | Normal |

T_4 = total serum thyroxine; T_3 = serum triiodothyronine; TSH = thyroid-stimulating hormone; THBR = thyroid hormone binding rate.

Table 41-1. TESTS OF THYROID GLAND FUNCTION

Serum Triiodothyronine

The serum T_3 is also measured by RIA. Serum T_3 levels are often determined to detect disease in patients with clinical evidence of hyperthyroidism in the absence of elevations of T_4 . T_3 may be the only thyroid hormone produced in excess. T_3 concentrations may be depressed by factors that impair the peripheral conversion of T_4 to T_3 (sick euthyroid syndrome). In 50% of hypothyroid patients, the serum T_3 concentration is low; in the remaining 50% it is normal.

Tests for Assessing Thyroid Hormone Binding

It is necessary to find some measure of thyroid binding proteins, mostly TBG, to interpret correctly total thyroxine levels. The "T uptake" test measures the ability of the patient's serum to bind exogenously introduced T_4 and reflects the amount of TBG and the extent of T_4 saturation on TBG. The T uptake is inversely related to the degree of unsaturation of TBG. The T uptake can be used to calculate the T_4 -binding capacity, which is directly related to the degree of unsaturation of TBG. The T uptake or T_4 -binding capacity can be used to calculate the estimated free T_4 or free T_4 index, which reflect the free T_4 concentration in the blood independent of binding proteins.

Thyroid-Stimulating Hormone

The RIA for this hormone has proved most useful in detecting patients who are hypothyroid. It is often higher than $20 \mu\text{U} \cdot \text{mL}^{-1}$ in primary hypothyroidism (normal, $8 \mu\text{U} \cdot \text{mL}^{-1}$). In the past, the TSH assay was not sensitive enough to discriminate between the normal levels associated with euthyroid states and the suppressed levels associated with hyperthyroidism, but current assays have made the measurement of TSH a valuable adjunct in the diagnosis of hyperthyroidism. A condition characterized by elevated TSH and normal T_4 may represent subclinical hypothyroidism. A low TSH level in a clinically hypothyroid patient indicates disease at the pituitary or hypothalamic level. The goal of thyroid replacement therapy is to normalize TSH levels.³ Starvation, fever, stress, corticosteroids, and T_3 or T_4 can all depress TSH levels.

Radioactive Iodine Uptake

The thyroid gland has the ability to concentrate large amounts of inorganic iodide. The oral administration of radioactive iodine (^{131}I) can be used to indicate thyroid gland activity. Thyroid uptake is elevated in hyperthyroidism unless the hyperthyroidism is caused by thyroiditis, in which case the uptake is low or absent. Because of overlap in values, it is difficult to distinguish euthyroid from hypothyroid people. Radioactive iodide uptake may be increased by a variety of factors, including dietary iodine deficiency, renal failure, and congestive heart failure. Because uptake is under TSH control, elevated free T_4 levels and corticosteroids decrease radioactive iodide uptake. Functioning ("hot") thyroid tissue is rarely malignant. Nonfunctioning ("cold") tissue may be malignant or benign.

Hyperthyroidism

Hyperthyroidism results from the exposure of tissues to excessive amounts of thyroid hormone (Table 41-2). The most common etiology is the multinodular diffuse goiter of Graves' disease. This typically occurs between the ages of 20 and 40 years and is predominant in women. Most of these patients demonstrate a syndrome characterized by diffuse glandular enlargement, ophthalmopathy, dermopathy, and clubbing of the fingers. A thyroid-stimulating autoantibody may be present. Thyroid adenoma is the second most common cause. Another cause of increased thyroid hormone synthesis is thyroiditis. Subacute thyroiditis frequently follows a respiratory illness and is characterized by a viral-like illness with a firm, painful gland. This type of thyroiditis is frequently treated with anti-inflammatory agents alone. Rarely, subacute thyroiditis may occur in a patient with a normal-sized, painless gland. Hashimoto's thyroiditis is a chronic autoimmune disease that usually produces hypothyroidism but may occasionally produce hyperthyroidism. Hyperthyroidism may also be associated with pregnancy, ^{131}I therapy, thyroid carcinoma, trophoblastic tumors, or TSH-secreting pituitary adenomas. Iatrogenic hyperthyroidism may follow thyroid hormone replacement or may occur after iodide exposure (angiographic contrast) in patients with chronically low iodide intake (Jodbasedow phenomenon). The antiarrhythmic agent amiodarone is iodine rich and is another cause of iodine-induced thyrotoxicosis.⁴

| |
|--|
| Intrinsic Thyroid Disease |
| Hyperfunctioning thyroid adenoma |

TSH = thyroid-stimulating hormone.

Table 41-2. CAUSES OF HYPERTHYROIDISM

The major manifestations of hyperthyroidism are weight loss, diarrhea, skeletal muscle weakness and stiffness, warm, moist skin, heat intolerance, and nervousness. Cardiovascular manifestations include increased left ventricular contractility and ejection fraction, tachycardia, elevated systolic blood pressure, and decreased diastolic blood pressure. Hypercalcemia, thrombocytopenia, and a mild anemia may be present. Elderly patients may present with heart failure owing to papillary muscle dysfunction, atrial fibrillation, or other cardiac dysrhythmias without other systemic signs or symptoms of hyperthyroidism (apathetic hyperthyroidism).

Treatment and Anesthetic Considerations

The most important goal in managing the hyperthyroid patient is to make the patient euthyroid before any surgery, if possible. The drugs propylthiouracil and methimazole are thiourea derivatives that inhibit the synthesis of thyroid hormone.⁵ Propylthiouracil also decreases the peripheral conversion of T_4 to T_3 . Normal thyroid glands usually contain a store of hormone that is large enough to maintain a euthyroid state for several months, even if all synthesis is abolished. Therefore, hyperthyroid patients are unlikely to be regulated to a euthyroid state with antithyroid drugs alone in less than 6–8 weeks. Toxic reactions from these drugs are uncommon but include skin rash, nausea, fever, agranulocytosis, hepatitis, and a lupus-like syndrome.

Inorganic iodide inhibits iodide organification and thyroid hormone release. Iodide is also effective in reducing the size of the hyperplastic gland and has a role in the preparation of the patient for emergency thyroid surgery.

β -Adrenergic antagonists are effective in attenuating the manifestations of excessive sympathetic activity.⁶ For example, propranolol given over 12–24 hours decreases tachycardia, heat intolerance, anxiety, and tremor. β -adrenergic blockade alone does not inhibit hormone synthesis, but it does impair the peripheral conversion of T_4 to T_3 over 1–2 weeks. The combination of propranolol (in doses titrated to effect) plus potassium iodide (two to five drops every 8 hours) is frequently used before surgery to ameliorate cardiovascular symptoms and reduce circulating concentrations of T_4 and T_3 . Preoperative preparation usually requires 7–14 days. β -adrenergic antagonists should not be used routinely in patients with symptoms of congestive heart failure or bronchospasm. Heart failure secondary to poorly controlled paroxysmal atrial fibrillation may improve with slowing of the ventricular rate, but abnormalities of left ventricular function secondary to hyperthyroidism may not be corrected with the use of β antagonists. If a hyperthyroid patient with clinically apparent disease requires emergency surgery, β -adrenergic blockade should be administered to achieve a heart rate less than 90 beats \cdot min⁻¹. Glucocorticoids such as dexamethasone (8–12 mg \cdot day⁻¹) are used in the management of severe thyrotoxicosis because they reduce thyroid hormone secretion and reduce the peripheral conversion of T_4 to T_3 .

Radioactive iodine therapy is an effective treatment for some patients with thyrotoxicosis.⁷ It should not, however, be administered to pregnant patients because it crosses the placenta and may destroy the fetal thyroid. A side effect of RAI therapy is hypothyroidism; 10–60% of cases occur in the first year of therapy, and an additional 2% occur per year thereafter.

A variety of anesthetic techniques and drugs have been used for hyperthyroid patients undergoing surgery. The key to the management of these patients is delaying the stress of surgery until the patient has been brought to a euthyroid state. All antithyroid medications are continued through the morning of surgery. The goal of intraoperative management in the hyperthyroid patient is to achieve a depth of anesthesia that prevents an exaggerated sympathetic response to surgical stimulation while avoiding the administration of medication that stimulates the sympathetic nervous system. It is best to avoid using ketamine even when a patient is clinically euthyroid.⁸ Hypotension that occurs during surgery is best treated with direct-acting vasopressors rather than a medication that provokes the release of catecholamines. The appropriate selection of neuromuscular blocking drug deserves mention. Pancuronium has the ability to increase the heart rate and should be avoided; muscle relaxants that provide greater cardiovascular stability (vecuronium, atracurium) should be used. The incidence of myasthenia gravis is increased in hyperthyroid patients; thus, the initial dose of muscle relaxant should be reduced and a twitch monitor should be used to guide all subsequent administration of neuromuscular blocking agents. Regional anesthesia is an excellent alternative when appropriate; however, epinephrine-containing solutions should be avoided.

Thyroid storm is a life-threatening exacerbation of hyperthyroidism that may occur during or immediately after surgery. Operating on an acutely hyperthyroid patient may provoke thyroid storm, although this is probably not due to mechanical release of hormone.⁹ Thyroid storm may develop in the undiagnosed hyperthyroid patient because of the stress of surgery and nonthyroid illness.¹⁰ Its manifestations include hyperthermia, tachycardia, dysrhythmias, congestive heart failure, agitation, and confusion. It must be distinguished from, or considered with, pheochromocytoma, malignant hyperthermia, and light anesthesia. Although free T_4 levels are often markedly elevated, no laboratory test is diagnostic. Treatment is with large doses of propylthiouracil and supportive measures to control fever and restore intravascular volume. Hemodynamic monitoring (pulmonary artery catheter, arterial catheter) is especially useful in guiding the treatment of patients with significant left ventricular dysfunction (Table 41-3). Again, it is essential to remove or treat the precipitating event.

Administer iv fluids.
Administer sodium iodide, 250 mg po or iv q6h.
Administer propylthiouracil, 200–400 mg po or pNGT q6h.
Administer hydrocortisone, 50–100 mg iv q6h.
Administer propranolol 10–40 mg po q4–6h or esmolol infusion to treat hyperadrenergic signs.
Cooling blankets and acetaminophen and meperidine (25–50 mg) iv q4–6h may be used to prevent shivering.
Using digoxin for heart failure especially in the presence of atrial fibrillation with rapid ventricular response.

iv = intravenous; po = oral; NGT = nasogastric tube.

Table 41-3. MANAGEMENT OF THYROID STORM

Complications of surgery in hyperthyroid patients occur more frequently when preoperative preparation has been inadequate. Airway obstruction is a potential problem in the patient with a large substernal goiter, although rarely a problem with goiters exclusively in the neck. Preoperative computed tomography of the neck provides valuable information about airway anatomy.¹¹

Anesthesia for Thyroid Surgery

Subtotal thyroidectomy as an alternative to prolonged medical therapy is used less frequently today than in the past. It is usually performed under general endotracheal anesthesia, although the use of the laryngeal mask airway is increasing. Use of a laryngeal mask airway allows real-time visualization of vocal cord function because the patient is allowed to breathe spontaneously. The complications after subtotal thyroidectomy include recurrent laryngeal nerve damage, tracheal compression secondary to hematoma or tracheomalacia, and hypoparathyroidism.¹² Hypoparathyroidism secondary to the inadvertent surgical removal of parathyroid glands is most frequently seen after total thyroidectomy. The symptoms of hypocalcemia develop within the first 24–96 hours after surgery.¹³ Laryngeal stridor progressing to laryngospasm may be one of the first indications of hypocalcemic tetany. The intravenous (iv) administration of calcium chloride or calcium gluconate is warranted in this situation. Magnesium levels should also be monitored and corrected if low. Bilateral recurrent laryngeal nerve injury is an extremely rare injury and necessitates reintubation. Unilateral nerve injury is more common and is often transient.¹⁴ Unilateral damage to the recurrent laryngeal nerve is characterized by hoarseness and a paralyzed vocal cord, whereas bilateral injury causes aphonia. It is wise to evaluate vocal cord function before and after surgery by laryngoscopy or by asking the patient to phonate by saying the letter “e”. Routine postoperative visualization of the vocal cords is not warranted.¹⁵ Postoperative extubation of the trachea should be performed under optimal conditions. Intraoperative laryngeal nerve injury or collapse of the tracheal rings from previous weakening may mandate emergency reintubation.

Hypothyroidism

Hypothyroidism is a relatively common disease (0.5–0.8% of the adult population) that results from inadequate circulating levels of T_4 or T_3 , or both.¹⁶ The development of hypothyroidism is often slow and progressive, making the clinical diagnosis difficult, especially in the more subtle cases. Hypofunctioning of the thyroid gland has many causes (Table 41-4). Primary failure of the thyroid gland refers to decreased production of thyroid hormone despite adequate TSH production and accounts for 95% of all cases of thyroid dysfunction. The remainder are caused by either hypothalamic or pituitary disease (secondary hypothyroidism) and are associated with other pituitary deficiencies.

Primary Hypothyroidism
 Autoimmune
 Irradiation to the neck
 Previous ^{131}I therapy
 Surgical removal
 Thyroiditis (Hashimoto's)
 Severe iodine depletion
 Medications (iodines, propylthiouracil, methimazole)
 Hereditary defects in biosynthesis
 Congenital defects in gland development

Secondary or Tertiary Hypothyroidism
 Pituitary
 Hypothalamic

Table 41-4. CAUSES OF HYPOTHYROIDISM

A lack of thyroid hormone produces a variety of signs and symptoms. These early findings are often nonspecific and difficult to recognize. A history of RAI therapy, external neck irradiation, or the presence of a goiter are all helpful in making a diagnosis. There is a generalized reduction in metabolic activity, resulting in lethargy, slow mental functioning, cold intolerance, and slow movements. The cardiovascular manifestations of hypothyroidism reflect the importance of thyroid hormone for myocardial contractility and catecholamine function. These patients exhibit bradycardia and depressed myocardial contractility. The accumulation of a cholesterol-rich pericardial fluid produces low voltage on the electrocardiogram (ECG). Impaired myocardial contractility generally correlates with the severity of hypothyroidism, although myxedema rarely produces congestive heart failure in the absence of coexisting heart disease. Angina pectoris itself is unusual in hypothyroidism and usually appears when thyroid hormone treatment is initiated (catecholamine hypersensitivity). Ventilatory responsiveness to hypoxia and hypercapnia is depressed in hypothyroid patients. This depression is potentiated by sedatives, opioids, and general anesthesia. Postoperative ventilatory failure requiring prolonged ventilation is rarely seen in hypothyroid patients in the absence of coexisting lung disease, obesity, or myxedema coma. Other abnormalities found in hypothyroidism include anemia, hypothermia, sleep apnea, and impaired renal free water clearance with hyponatremia. Basal plasma levels of cortisol are usually normal in hypothyroidism; however, in long-standing or severe disease, the stress response may be blunted and adrenal depression may occur.

Treatment and Anesthetic Considerations

Treatment of symptomatic hypothyroidism is with hormone replacement therapy.¹⁷ Controversy remains regarding the preoperative anesthetic management of the hypothyroid patient. Although it seems logical to recommend that all hypothyroid surgical candidates be restored to a euthyroid state before surgery, such a recommendation is, in general, based on individual case reports. There have been few controlled studies to support the position that most hypothyroid patients are unusually sensitive to anesthetic drugs, have prolonged recovery times, or have a higher incidence of cardiovascular instability or collapse.

No increase in serious complications in patients with mild or moderate hypothyroidism undergoing general anesthesia has been noted. One study¹⁸ noted a higher incidence of intraoperative hypotension and postoperative GI and neuropsychiatric complications in mild and moderately hypothyroid patients undergoing noncardiac surgery but still noted there were no compelling clinical reasons to postpone surgery in these patients. Surgery in severely hypothyroid patients should be postponed when possible until these patients are at least partially treated.

The management of hypothyroid patients with symptomatic coronary artery disease has been a subject of particular controversy.¹⁹ The need for thyroid hormone replacement therapy must be weighed against the risk of precipitating myocardial ischemia. Several studies and a literature review²⁰ found no differences in the frequency of intraoperative or postoperative complications when mild or moderately hypothyroid patients underwent cardiac surgery. In symptomatic patients or unstable patients with cardiac ischemia, thyroid replacement should probably be delayed until after coronary revascularization.

There appears to be little reason to postpone elective surgery in patients who have mild or moderate hypothyroidism. Thyroid replacement therapy is, however, indicated for patients with severe hypothyroidism or myxedema coma and for pregnant patients who are hypothyroid. Untreated hypothyroidism in pregnant patients is associated with an increased incidence of spontaneous abortion and mental and physical abnormalities in the offspring.

A number of anesthetic medications have been used without difficulty in hypothyroid patients. Although ketamine has been proposed as the ideal induction agent, thiopental has also been used in the hypothyroid patient. The maintenance of anesthesia may be safely achieved with either iv or inhaled anesthetics. There appears to be little if any decrease in the minimum alveolar concentration for volatile agents.²¹ Regional anesthesia is a good choice in the hypothyroid patient provided that the intravascular volume is well maintained. Monitoring is directed toward the early recognition of hypotension, congestive heart failure, and hypothermia. Scrupulous attention should be paid to maintaining normal body temperature.

Myxedema coma represents a severe form of hypothyroidism characterized by stupor or coma, hypoventilation, hypothermia, hypotension, and hyponatremia. This is a medical emergency with a high mortality rate (50%) and as such requires aggressive therapy (Table 41-5). Only life-saving surgery should proceed in the face of myxedema coma. Intravenous thyroid replacement is initiated as soon as the clinical diagnosis is made. An iv loading dose of T_4 (sodium levothyroxine, 200–300 μg) is given initially and followed by a maintenance dose of T_4 , 50–200 $\text{mg} \cdot \text{day}^{-1}$ iv.²² Alternatively, T_3 may be used because it has a more rapid onset. Improvements in heart rate, blood pressure, and body temperature may occur within 24 hours. Replacement therapy with either form of thyroid hormone may precipitate myocardial ischemia, however. There is also an increased likelihood of acute primary adrenal insufficiency in these patients, and they should receive stress doses of hydrocortisone. Steroid replacement continues until normal adrenal function can be confirmed.

Tracheal intubation and controlled ventilation as needed
 Levothyroxine 200–300 μg iv over 5–10 min initially, and 100 μg iv q24h
 Hydrocortisone, 100 mg iv, then 25 mg iv q6h
 Fluid and electrolyte therapy as indicated by serum electrolytes
 Cover to conserve body heat; no warming blankets

iv = intravenous.

Table 41-5. MANAGEMENT OF MYXEDEMA

PARATHYROID GLANDS

Calcium Physiology

The normal adult body contains approximately 1–2 kg of calcium (Ca^{2+}), of which 99% is in the skeleton. Plasma calcium is present in three forms: (1) a protein-bound fraction (40%); (2) an ionized fraction (50%); and (3) a diffusible but nonionized fraction (10%) that is complexed with phosphate, bicarbonate, and citrate. This division is of interest because it is the ionized fraction that is physiologically active and homeostatically regulated. The normal total serum calcium concentration is 8.8–10.4 $\text{mg} \cdot \text{dl}^{-1}$. Albumin binds approximately 90% of the protein-bound fraction of calcium, and total serum Ca^{2+} consequently depends on albumin levels. In general, an increase or decrease in albumin of 1 $\text{g} \cdot \text{dl}^{-1}$ is associated with a parallel change in total serum Ca^{2+} of 0.8 $\text{mg} \cdot \text{dl}^{-1}$. The serum ionized Ca^{2+} concentration is affected by temperature and blood pH through alterations in Ca^{2+} protein binding to albumin. Acidosis decreases protein binding (increases ionized Ca^{2+}), and alkalosis increases protein binding (decreases ionized Ca^{2+}). The concentration of free Ca^{2+} ion is of critical importance in regulating skeletal muscle contraction, coagulation, neurotransmitter release, endocrine secretion, and a variety of other cellular functions. As a consequence, the maintenance of serum Ca^{2+} concentration is subject to

exquisite hormonal control by parathyroid hormone (PTH) and vitamin D (Fig. 41-2).

Figure 41-2. Parathyroid hormone and vitamin D metabolism and action. PTH = parathyroid hormone; UV = ultraviolet. (Reproduced with permission from Geelhoed GW, Chernow B [eds]: *Endocrine Aspects of Acute Illness*. New York, Churchill Livingstone, 1985.)

Parathyroid hormone acts to maintain the extracellular fluid Ca^{2+} concentration through direct effects on bone resorption and renal Ca^{2+} resorption at the distal tubule, and indirectly through its effects on the synthesis of 1,25-dihydroxyvitamin D. The renal effects of PTH include phosphaturia and bicarbonaturia, in addition to enhanced Ca^{2+} and magnesium resorption. Most evidence suggests that rapid changes in blood Ca^{2+} levels are due primarily to hormonal effects on bone and to a lesser extent to renal Ca^{2+} clearance, whereas maintenance of Ca^{2+} balance depends more on the indirect effects of the hormone on intestinal calcium absorption. The effects of PTH are mediated by specific hormone-target cell membrane interaction. Hormone receptor activation of adenylate cyclase leads to increased intracellular cyclic adenosine monophosphate (cAMP). Presumably, the rapid rise in cAMP promotes an increase in protein kinase, leading to a phosphorylation of key effector proteins that initiate the hormonal effect. After the administration of PTH, there is a rise in urinary cAMP. This cAMP leaks from renal tubular cells and provides an index of the biologic activity of PTH.

Parathyroid hormone secretion is primarily regulated by the serum ionized Ca^{2+} concentration. This negative feedback mechanism is exquisitely sensitive in maintaining calcium levels in a normal range. Release of PTH is also influenced by phosphate, magnesium, and catecholamine levels. Acute hypomagnesemia directly stimulates PTH release, whereas chronic magnesium depletion appears to inhibit proper functioning of the parathyroid gland. The plasma phosphate concentration has an indirect influence on PTH secretion by causing reciprocal changes in the serum ionized Ca^{2+} concentration.

Vitamin D Metabolism

Vitamin D is absorbed from the GI tract and can be produced enzymatically by ultraviolet irradiation of the skin. Vitamin D (cholecalciferol) is made from cholesterol metabolites and is inactive. Calciferol is hydroxylated in the liver to 25-hydroxycholecalciferol (25-OHD) and in the kidney is further hydroxylated to 1,25-dihydroxycholecalciferol [1,25(OH)₂D] or 24,25-dihydroxycholecalciferol [24,25(OH)₂D]. 25-OHD is the major circulating form of vitamin D. The synthesis of this hormone is not regulated by a hormone or by Ca^{2+} or phosphate levels. 1,25(OH)₂D and 24,25(OH)₂D are the major active metabolites of vitamin D, and their production is reciprocally regulated at the kidney. Hypocalcemia and hypophosphatemia cause an increased production of 1,25(OH)₂D and a decreased production of 24,25(OH)₂D. 1,25(OH)₂D stimulates bone, kidney, and intestinal absorption of calcium and phosphate. Vitamin D deficiency can lead to decreased intestinal absorption of Ca^{2+} and secondary hyperparathyroidism.

Hyperparathyroidism

Primary hyperparathyroidism is most commonly due to a benign parathyroid adenoma (90% of cases) or hyperplasia (9%) and very rarely to a parathyroid carcinoma. Primary hyperparathyroidism may also exist as part of a multiple endocrine neoplastic (MEN) syndrome. Hyperplasia usually involves all four glands. Although most patients with primary hyperparathyroidism are hypercalcemic, most are asymptomatic at the time of diagnosis. When symptoms occur, they usually result from the hypercalcemia that accompanies the disease. Primary hyperparathyroidism occurring during pregnancy is associated with a high maternal and fetal morbidity rate (50%). The placenta allows the fetus to concentrate calcium, promoting fetal hypercalcemia and leading to hypoparathyroidism in the newborn. Pregnant women with primary hyperparathyroidism should be treated with surgery.

Hypercalcemia is responsible for a broad spectrum of signs and symptoms. Nephrolithiasis is the most common manifestation, occurring in 60–70% of patients. Polyuria and polydipsia are also common complaints. An increase in bone turnover may lead to generalized demineralization and subperiosteal bone resorption; however, only a small group of patients (10–15%) have clinically significant bone disease. Patients may experience generalized skeletal muscle weakness and fatigability, epigastric discomfort, peptic ulceration, and constipation. Psychiatric manifestations include depression, memory loss, confusion, or psychosis. Between 20 and 50% of patients are hypertensive, but this usually resolves with successful treatment of the disease. Cardiac function is enhanced in the early stages of hypercalcemia. Calcium flux into the cells is reflected in the plateau phase of the action potential (Phase 2). As extracellular calcium increases, the inward flux is more rapid, and Phase 2 is shortened. The corresponding ECG change is a shorter QT interval. Cardiac contractility may increase until a level between 15 and 20 $\text{mg} \cdot \text{dl}^{-1}$ is reached. At this point, there is a prolongation of the PR segment and QRS complex that can result in heart block or bundle-branch block. Bradycardia also occurs.

An elevated serum Ca^{2+} concentration is a valuable diagnostic indicator of primary hyperparathyroidism. The serum phosphate concentration is nonspecific, with many patients having normal or near-normal levels. The reported incidence of hyperchloremic acidosis varies widely in primary hyperparathyroidism, but most patients usually have a serum chloride concentration in excess of 102 $\text{mEq} \cdot \text{l}^{-1}$. Rarely does a patient with hypercalcemia secondary to ectopic PTH production (malignancy) present with hyperchloremic acidosis. The definitive diagnosis of primary hyperparathyroidism is made by RIA demonstration of an elevation in PTH levels in the presence of hypercalcemia. An elevated nephrogenous cAMP is noted in more than 90% of patients with primary hyperparathyroidism.

Hypercalcemia may also result from the ectopic production of PTH or PTH-like substances from lung, genitourinary, breast, GI, and lymphoproliferative malignancies. Tumors may also produce hypercalcemia through direct bone resorption or the production of osteoclast-activating factor. In the absence of a clinically obvious neoplasm, there may be difficulty in differentiating between PTH-producing malignancies and primary hyperparathyroidism. PTH fragments from malignant tissue differ from native PTH and aid in distinguishing between ectopic PTH production and primary hyperparathyroidism.

Secondary hyperparathyroidism represents an increase in parathyroid function as a result of conditions that produce hypocalcemia or hyperphosphatemia. Chronic renal disease is a common cause of hyperphosphatemia (due to decreased phosphate excretion) and decreased vitamin D metabolism. The hypocalcemia that results leads to an increased production of PTH. GI disorders accompanied by malabsorption may also lead to a secondary increase in parathyroid activity. Tertiary hyperparathyroidism refers to the development of hypercalcemia in a patient who has had prolonged secondary hyperparathyroidism that has caused adenomatous changes in the parathyroid gland and PTH production to become autonomous.

Treatment and Anesthetic Considerations

Surgery is the treatment of choice for the patient with symptomatic disease. Considerable controversy, however, surrounds the choice of treatment in the asymptomatic patient. It is not clear that mild primary hyperparathyroidism decreases longevity. Surgery is often chosen over medical therapy because it offers definitive treatment and is generally safe.

Preoperative preparation focuses on the correction of intravascular volume and electrolyte irregularities. It is particularly important to evaluate the patient with chronic hypercalcemia for abnormalities of the renal, cardiac, or central nervous systems. Emergency treatment of hypercalcemia is undertaken before surgery when the serum Ca^{2+} concentration exceeds 15 $\text{mg} \cdot \text{dl}^{-1}$ (7.5 $\text{mEq} \cdot \text{l}^{-1}$). Lowering of the serum Ca^{2+} concentration is initially accomplished by expanding the intravascular volume and establishing a sodium diuresis. This is achieved with the iv administration of normal saline and furosemide. Rehydration alone is capable of lowering the serum Ca^{2+} level by ≥ 2 $\text{mg} \cdot \text{dl}^{-1}$. Hydration dilutes the serum Ca^{2+} , and a sodium diuresis promotes Ca^{2+} excretion through an inhibition of sodium and Ca^{2+} resorption in the proximal tubule. Hypokalemia and hypomagnesemia may result. Another element in the treatment of hypercalcemia is the correction of hypophosphatemia. Hypophosphatemia increases GI absorption of Ca^{2+} , stimulates the breakdown of bone, and impairs the uptake of Ca^{2+} by bone. Low serum phosphate levels impair cardiac contractility and may contribute to congestive heart failure. Hypophosphatemia also causes skeletal muscle weakness, hemolysis, and platelet dysfunction.

Other medications that have a role in lowering the serum Ca^{2+} include bisphosphonates, mithramycin, calcitonin, and glucocorticoids. Bisphosphonates are pyrophosphate analogues that inhibit osteoclast action. They are the drugs of choice for severe hypercalcemia. Toxic effects include fever and hypophosphatemia. Mithramycin, a cytotoxic agent, inhibits PTH-induced osteoclast activity and can lower the serum Ca^{2+} levels by $322 \text{ mg} \cdot \text{dl}^{-1}$ in 24–48 hours. Toxic effects include azotemia, hepatotoxicity, and thrombocytopenia. Calcitonin is useful in transiently lowering the serum Ca^{2+} level $2\text{--}4 \text{ mg} \cdot \text{dl}^{-1}$ through direct inhibition of osteoclastic bone resorption. The advantages of calcitonin are that side effects are mild (urticaria, nausea) and the onset of activity is rapid. Calcitonin resistance usually develops within 24–48 hours. Glucocorticoids are effective in lowering the serum Ca^{2+} concentration in several conditions (sarcoidosis, some malignancies, hyperthyroidism, vitamin D intoxication) through their actions on osteoclast bone resorption, GI absorption of calcium, and the urinary excretion of calcium. Glucocorticoids are usually of no benefit in the treatment of primary hypercalcemia. Finally, hemodialysis or peritoneal dialysis can be used to lower the serum Ca^{2+} level when alternative regimens are ineffective or contraindicated.

There is no evidence that a specific anesthetic drug or technique has advantages over another. A thorough knowledge of the clinical manifestations attributable to hypercalcemia is of the greatest value in choosing an anesthetic technique. Special monitoring is usually not required. Because of the unpredictable response to neuromuscular blocking drugs in the hypercalcemic patient, a conservative approach to muscle paralysis makes sense. There is an increased requirement for vecuronium, and probably all nondepolarizing muscle relaxants, during onset of neuromuscular blockade.²³ Careful positioning of the osteopenic patient is necessary to avoid pathologic bone fractures.

Anesthesia for Parathyroid Surgery

General anesthesia is most commonly used, but cervical plexus block and local anesthesia with hypnosis have been used successfully.²⁴ Postoperative complications include recurrent laryngeal nerve injury, bleeding, and transient or complete hypoparathyroidism. Unilateral recurrent laryngeal nerve injury is characterized by hoarseness and usually requires no intervention. Bilateral recurrent laryngeal nerve injury is a rare complication, producing aphonia and requiring immediate tracheal intubation. After successful parathyroidectomy, a decrease in the serum Ca^{2+} level should be observed within 24 hours. Patients with significant preoperative bone disease may have hypocalcemia after removal of the PTH-secreting glands. This “hungry bone” syndrome comes as a result of the rapid remineralization of bone.²⁵ Thus, serum Ca^{2+} , magnesium, and phosphorus levels should be closely monitored until stable. The serum Ca^{2+} nadir usually occurs within 3–7 days.

Hypoparathyroidism

An underproduction of PTH or resistance of the end-organ tissues to PTH results in hypocalcemia ($<18 \text{ mg} \cdot \text{dl}^{-1}$). The normal physiologic response to hypocalcemia is an increase in PTH secretion and $1,25(\text{OH})_2\text{D}$ synthesis with an increase in Ca^{2+} mobilization from bone, GI absorption, and renal tubule reclamation. The most common cause of acquired PTH deficiency is inadvertent removal of the parathyroid glands during thyroid or parathyroid surgery. Other causes of acquired hypoparathyroidism include ^{131}I therapy for thyroid disease, neck trauma, granulomatous disease, or an infiltrating process (malignancy or amyloidosis). Idiopathic hypoparathyroidism is rare and may occur as an isolated disease or as part of an autoimmune polyglandular process (hypothyroidism, adrenal insufficiency). Pseudohypoparathyroidism is an inherited disorder in which parathyroid gland function is normal but the end-organ response to the PTH is deficient. Affected patients have hypocalcemia and hyperphosphatemia. They are characterized by mental retardation, a short stature, obesity, and shortened metacarpals. Pseudopseudohypoparathyroid patients are characterized by the same physical findings but have normal serum calcium and phosphate levels. Severe hypomagnesemia ($<10.8 \text{ mEq} \cdot \text{l}^{-1}$) from any cause can produce hypocalcemia by suppressing PTH secretion. Renal insufficiency leads to phosphorus retention and impaired $1,25(\text{OH})_2\text{D}$ synthesis, and this results in hypocalcemia. These patients are commonly treated with vitamin D, which increases intestinal calcium absorption and suppresses secondary increases in PTH secretion. Hypocalcemia due to pancreatitis and burns results from the suppression of PTH and from the sequestration of calcium.

Clinical Features and Treatment

The clinical features of hypoparathyroidism are a manifestation of hypocalcemia. Neuronal irritability and skeletal muscle spasms, tetany, or seizures reflect a reduced threshold of excitation. Latent tetany may be demonstrated by eliciting Chvostek's or Trousseau's sign. Chvostek's sign is a contracture of the facial muscle produced by tapping the facial nerve as it passes through the parotid gland. Trousseau's sign is contraction of the fingers and wrist after application of a blood pressure cuff inflated above the systolic blood pressure for approximately 3 minutes. Other common complaints of hypocalcemia include fatigue, depression, paresthesias, and skeletal muscle cramps. The acute onset of hypocalcemia after thyroid or parathyroid surgery may manifest as stridor and apnea. Cardiovascular manifestations of hypocalcemia include congestive heart failure, hypotension, and a relative insensitivity to the effects of β -adrenergic agonists. Delayed ventricular repolarization results in a prolonged QT interval on the ECG. Although prolongation of the QT interval may be a reliable sign of hypocalcemia in an individual patient, the ECG is relatively insensitive for the detection of hypocalcemia.

The treatment of hypoparathyroidism consists of electrolyte replacement. The objective is to have the patient's clinical symptoms under control before anesthesia and surgery. Hypocalcemia caused by magnesium depletion is treated by correcting the magnesium deficit. Serum phosphate excess is corrected by the removal of phosphate from the diet and the oral administration of phosphate-binding resins (aluminum hydroxide). The urinary excretion of phosphate can be increased with a saline volume infusion. Ca^{2+} deficiencies are corrected with Ca^{2+} supplements or vitamin D analogues. Patients with severe symptomatic hypocalcemia are treated with iv calcium gluconate (10–20 ml of 10% solution) given over several minutes and followed by a continuous infusion ($1\text{--}2 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) of elemental Ca^{2+} . The correction of serum Ca^{2+} levels should be monitored by measuring serum Ca^{2+} concentrations and following clinical symptoms. When oral or iv calcium is inadequate to maintain a normal serum ionized calcium level, vitamin D is added to the regimen.

ADRENAL CORTEX

The adrenal cortex functions to synthesize and secrete three types of hormones. Endogenous and dietary cholesterol is used in the adrenal biosynthesis of glucocorticoids (cortisol), mineralocorticoids (aldosterone and 11-deoxycorticosterone), and androgens (dehydroepiandrosterone). Cortisol and aldosterone are the two essential hormones, whereas adrenal androgens are of relatively minor physiologic significance in adults. The major biologic effects of adrenal cortical hyperfunction or hypofunction occur as a result of cortisol or aldosterone excess or deficiency. Abnormal function of the adrenal cortex may render a patient unable to respond appropriately during a period of surgical stress or critical illness.

Glucocorticoid Physiology

Cortisol (hydrocortisone) is the most potent glucocorticoid and is produced by the inner portions of the adrenal cortex. Cortisone is a glucocorticoid produced in small amounts. Cortisol is produced under the control of adrenocorticotropic hormone (ACTH; corticotropin), a polypeptide synthesized and released by the anterior pituitary gland. Glucocorticoids exert their biologic effects by diffusing into the cytoplasm of target cells and combining with specific high-affinity receptor proteins.

The daily production of endogenous cortisol is approximately 20 mg. The maximal output is $150\text{--}300 \text{ mg} \cdot \text{day}^{-1}$. Most of the circulating hormone is bound to the α -globulin transcortin (cortisol-binding globulin). It is the relatively small amount of free hormone that exerts the biologic effects. Glucocorticoids such as cortisol are inactivated primarily by the liver and are excreted in the urine as 17-hydroxycorticosteroids. Cortisol is also filtered at the glomerulus and may be excreted unchanged in the urine. Although the rate of cortisol secretion is decreased by approximately 30% in the elderly patient, plasma cortisol levels remain in a normal range because of a corresponding decrease in hepatic and renal clearance.

Cortisol secretion is directly controlled by ACTH, which in turn is regulated by the corticotropin-releasing factor (CRF) from the hypothalamus. ACTH is synthesized in the pituitary gland from a precursor molecule that also produces β -lipotropin and β -endorphin. The secretion of ACTH and CRF is governed chiefly by glucocorticoids, the sleep-wake cycle, and stress. Cortisol is the most potent regulator of ACTH secretion, acting by a negative feedback mechanism to maintain cortisol levels in a physiologic range. ACTH release follows a diurnal pattern, with maximal activity occurring soon after awakening. This diurnal pattern of activity occurs in normal subjects as well as in those with adrenal insufficiency. Psychological or physical stress (trauma, surgery, intense exercise) also promotes ACTH release regardless of the level of circulating cortisol or the time of day.²⁶

Cortisol has multiple effects on intermediate carbohydrate, protein, and fatty acid metabolism. Glucocorticoids enhance gluconeogenesis, elevate blood glucose, and promote hepatic glycogen synthesis.^{27,28} The catabolic effect of glucocorticoids is partially blocked by insulin. The net effect on protein metabolism is enhanced degradation of muscle tissue and negative nitrogen balance. In supraphysiologic amounts, glucocorticoids suppress growth hormone secretion and impair somatic growth. The anti-inflammatory actions of cortisol relate to its effect in stabilizing lysosomes and promoting capillary integrity. Cortisol also antagonizes leukocyte migration inhibition factor, thus reducing white cell adherence to vascular endothelium and diminishing leukocyte response to local inflammation. Phagocytic activity does not decrease, although the killing potential of macrophages and monocytes is diminished. Other diverse actions include the facilitation of free water clearance,

maintenance of blood pressure, a weak mineralocorticoid effect, promotion of appetite, stimulation of hematopoiesis, and induction of liver enzymes.

Mineralocorticoid Physiology

Aldosterone is the most potent mineralocorticoid produced by the adrenal gland. This hormone binds to receptors in sweat glands, the alimentary tract, and the distal convoluted tubule of the kidney. Aldosterone is a major regulator of extracellular volume and potassium homeostasis through the resorption of sodium and the secretion of potassium by these tissues. The major regulators of aldosterone release are the renin–angiotensin system and serum potassium (Fig. 41-3). The juxtaglomerular apparatus that surrounds the renal afferent arterioles produces renin in response to decreased perfusion pressures and sympathetic stimulation. Renin splits the hepatic precursor angiotensinogen to form the decapeptide, angiotensin I, which is then altered enzymatically by converting enzyme (primarily in the lung) to form the octapeptide angiotensin II. Angiotensin II is the most potent vasopressor produced in the body. It directly stimulates the adrenal cortex to produce aldosterone. The renin–angiotensin system is the body's most important protector of volume status. Other stimuli that increase the production of aldosterone include hyperkalemia and, to a limited degree, hyponatremia, prostaglandin E, and ACTH.

Figure 41-3. The inter-relationship of the volume and potassium feedback loops on aldosterone secretion. (Reproduced with permission from Petersdorf RG [ed]: Harrison's Principles of Internal Medicine, 10th ed. New York, McGraw-Hill, 1983.)

Glucocorticoid Excess (Cushing's Syndrome)

Cushing's syndrome, caused either by the overproduction of cortisol by the adrenal cortex or exogenous glucocorticoid therapy, results in a syndrome characterized by truncal obesity, hypertension, hyperglycemia, increased intravascular fluid volume, hypokalemia, fatigability, abdominal striae, osteoporosis, and muscle weakness. Most cases of Cushing's syndrome that occur spontaneously are due to bilateral adrenal hyperplasia secondary to ACTH produced by an anterior pituitary microadenoma or nonendocrine tumor (e.g., of the lung, kidney, or pancreas). The primary overproduction of cortisol and other adrenal steroids is caused by an adrenal neoplasm in approximately 20–25% of patients with Cushing's syndrome. These tumors are usually unilateral, and approximately half are malignant. When Cushing's syndrome occurs in patients older than 60 years of age, the most likely cause is an adrenal carcinoma or ectopic ACTH produced from a nonendocrine tumor. Finally, an increasingly common cause of Cushing's syndrome is the prolonged administration of exogenous glucocorticoids to treat a variety of illnesses.

The signs and symptoms of Cushing's syndrome follow from the known actions of glucocorticoids. Truncal obesity and thin extremities reflect increased muscle wasting and a redistribution of fat in facial, cervical, and truncal areas. Impaired calcium absorption and a decrease in bone formation may result in osteopenia. Sixty percent of patients have hyperglycemia, but overt diabetes mellitus occurs in less than 20%. Hypertension and fluid retention are seen in most patients. Profound emotional changes ranging from emotional lability to frank psychosis may be present. An increased susceptibility to infection reflects the immunosuppressive effects of corticosteroids. Hypokalemic alkalosis without distinctive physical findings is common when adrenal hyperplasia is caused by ectopic ACTH production from a nonendocrine tumor.

The biochemical diagnosis of hyperadrenocorticism is based on a variable elevation in plasma and urinary cortisol levels, urinary 17-hydroxycorticosteroids, and plasma ACTH. The diagnosis can be established by failure normally to suppress endogenous cortisol secretion after the exogenous administration of dexamethasone. Patients with pituitary adenomas frequently show depression in cortisol and 17-hydroxycorticosteroid levels when a high dose of dexamethasone is administered because the tumor retains some negative feedback control. The ectopic production of ACTH by a nonendocrine tumor usually shows no suppression with low- or high-dose dexamethasone.

Anesthetic Management

General considerations for the preoperative preparation of the patient include regulating hypertension and diabetes and normalizing intravascular fluid volume and electrolyte concentrations. Diuresis with the aldosterone antagonist spironolactone helps to mobilize fluid and normalize the potassium concentration. Careful positioning of the osteopenic patient is important to avoid fractures. Intraoperative monitoring is planned after evaluation of the patient's cardiac reserve and consideration of the site and extent of the proposed surgery. When unilateral or bilateral adrenalectomy is planned, glucocorticoid replacement therapy is initiated at a dose equal to full replacement of adrenal output during periods of extreme stress (see [Steroid Replacement During the Perioperative Period](#)). The total dosage is reduced by approximately 50% per day until a daily maintenance dose of steroids is achieved (20–30 mg · day⁻¹). Hydrocortisone given in doses of this magnitude exerts significant mineralocorticoid activity, and additional exogenous mineralocorticoid usually is not necessary during the perioperative period. The oral administration of mineralocorticoid is usually started on day 5. After bilateral adrenalectomy, most patients require 0.05–0.1 mg · day⁻¹ of fludrocortisone (9- α -fluorohydrocortisone). Slightly higher doses may be needed if prednisone is used for glucocorticoid maintenance (little intrinsic mineralocorticoid activity). The fludrocortisone dose is reduced if congestive heart failure, hypokalemia, or hypertension develops. For the patient with a solitary adrenal adenoma, unilateral adrenalectomy may be followed by normalization of function in the contralateral gland over time. Treatment plans should therefore be individualized, and adjustments in dosage may be necessary. The production of glucocorticoids or ACTH by a neoplasm may not be eliminated if the tumor is unresectable. These patients often need continuous medical therapy with steroid inhibitors such as metyrapone to control their symptoms.

There are no specific recommendations regarding the use of a particular anesthetic technique or medication in patients with hyperadrenocorticism. When significant skeletal muscle weakness is present, a conservative approach to the use of muscle relaxants is warranted.

Mineralocorticoid Excess

Hypersecretion of the major adrenal mineralocorticoid aldosterone increases the renal tubular exchange of sodium for potassium and hydrogen ions. This leads to potassium depletion, skeletal muscle weakness, fatigue, and hypokalemic alkalosis. Possibly as much as 1% of unselected hypertensive patients have primary hyperaldosteronism. The increase in renal sodium reabsorption and extracellular volume expansion is in part responsible for the high incidence of diastolic hypertension in these patients. Patients with primary hyperaldosteronism (Conn's syndrome) characteristically do not have edema. Secondary aldosteronism results from an elevation in renin production. The diagnosis of primary or secondary hyperaldosteronism should be entertained in the nonedematous hypertensive patient with persistent hypokalemia who is not receiving potassium-wasting diuretics. Hyposecretion of renin that fails to increase appropriately during volume depletion is an important finding in primary aldosteronism. The measurement of plasma renin levels is useful in distinguishing these two from one another; however, it is of limited value in differentiating patients with primary aldosteronism from those with other causes of hypertension because renin activity is also suppressed in approximately 25% of patients with essential hypertension.

Anesthetic Considerations

Preoperative preparation for the patient with primary aldosteronism is directed toward restoring the intravascular volume and the electrolyte concentrations to normal. Hypertension and hypokalemia may be controlled by restricting sodium intake and administration of the aldosterone antagonist spironolactone. This diuretic works slowly to produce an increase in potassium levels, with dosages in the range of 25–100 mg every 8 hours. Total body potassium deficits are difficult to estimate and may be in excess of 300 mEq. Whenever possible, potassium should be replaced slowly to allow equilibration between intracellular and extracellular potassium stores. The usual complications of chronic hypertension need to be assessed.

Adrenal Insufficiency

The undersecretion of adrenal steroid hormones may develop as the result of a primary inability of the adrenal gland to elaborate sufficient quantities of hormone or as the result of a deficiency in the production of ACTH.

Clinically, primary adrenal insufficiency is usually not apparent until at least 90% of the adrenal cortex has been destroyed. The predominant cause of primary adrenal insufficiency during the early part of the century was tuberculosis; however, today, the most frequent cause of Addison's disease is idiopathic adrenal insufficiency secondary to autoimmune destruction of the gland. Autoimmune destruction of the adrenal cortex causes both a glucocorticoid and a mineralocorticoid deficiency. A variety of other conditions presumed to have an autoimmune pathogenesis may also occur concomitantly with idiopathic Addison's disease. Hashimoto's thyroiditis in association with autoimmune adrenal insufficiency is termed *Schmidt's syndrome*. Other possible causes of adrenal gland destruction include certain bacterial or fungal infections, metastatic cancer, sepsis and hemorrhage.

Secondary adrenal insufficiency occurs when the anterior pituitary fails to secrete sufficient quantities of ACTH. The most important cause of hypothalamic–pituitary–adrenal axis suppression confronting the anesthesiologist is the exogenous administration of glucocorticoids. Pituitary failure may also result from tumor, infection, surgical ablation, or radiation therapy.

Clinical Presentation

Several important differences exist between primary adrenal insufficiency and hypopituitarism. The cardinal symptoms of idiopathic Addison's disease include asthenia, weight loss, anorexia, abdominal pain, nausea, vomiting, diarrhea, and constipation. Hypotension is almost always encountered in the disease process. Diffuse hyperpigmentation occurs in most patients with primary adrenal insufficiency and is secondary to the compensatory increase in ACTH and β -lipotropin. These hormones stimulate an increase in melanocyte production. Mineralocorticoid deficiency is characteristically present in primary adrenal disease, and, as a result, there is a reduction in urine sodium conservation and a decreased pressure response to circulating catecholamines. Hyperkalemia may be a cause of life-threatening cardiac dysrhythmias. Female patients may exhibit decreased axillary and pubic hair growth owing to the loss of adrenal androgen secretion. Adrenal insufficiency secondary to pituitary suppression is not associated with cutaneous hyperpigmentation or mineralocorticoid deficiency. Salt and water balance is usually maintained unless severe fluid and electrolyte losses overwhelm the subnormal aldosterone secretory capacity. Organic lesions of pituitary origin require a diligent search for coexisting hormone deficiencies.

It is important to recognize the patient with adrenal insufficiency secondary to exogenous steroid therapy because it is possible for acute adrenal crisis to occur if high-dose glucocorticoids are abruptly withdrawn or if deficient patients are subjected to surgical stress.²⁹ Because patients who have received exogenous glucocorticoids may exhibit pituitary–adrenal suppression for up to 12 months after cessation of therapy, these patients receive supplemental glucocorticoid coverage during periods of increased stress (e.g., trauma, surgery, infection). Patients receiving inhaled or topical steroids may also exhibit pituitary–adrenal suppression for up to 9 months after the cessation of therapy.

Diagnosis

The patient's pituitary-adrenal responsiveness should be determined when the diagnosis of primary or secondary adrenal insufficiency is first suspected. Biochemical evidence of impaired adrenal or pituitary secretory reserve unequivocally confirms the diagnosis. Patients who are clinically stable may undergo testing before treatment is initiated. Those thought to have acute adrenal insufficiency should receive immediate therapy.

Plasma cortisol levels are measured before and 30 and 60 minutes after the iv administration of 250 μ g of synthetic ACTH. In patients with adequate adrenal reserve, plasma cortisol rises at least 7 mg \cdot dl⁻¹ (or to a total of 18 mg \cdot dl⁻¹) 60 minutes after the injection of the synthetic ACTH.³⁰ Patients with adrenal insufficiency usually demonstrate little or no adrenal response.

Treatment and Anesthetic Considerations

Normal adults secrete 20 mg of cortisol (hydrocortisone) and 0.1 mg of aldosterone per day. Glucocorticoid therapy is usually given twice daily in sufficient dosage to meet physiologic requirements. A typical regimen may consist of prednisone, 5 mg in the morning and 2.5 mg in the evening, or hydrocortisone, 20 mg in the morning and 10 mg in the evening. The daily glucocorticoid dosage is typically 50% higher than basal adrenal output to cover the patient for mild stress. Replacement dosages are adjusted in response to the patient's clinical symptoms or the occurrence of intercurrent illnesses. Patients with Addison's disease should be instructed to increase glucocorticoid medication to three or four times their usual daily dosage during periods of increased stress. Mineralocorticoid replacement is also administered on a daily basis; most patients require 0.05–0.1 mg \cdot day⁻¹ of fludrocortisone. The mineralocorticoid dose may be reduced if severe hypokalemia, hypertension, or congestive heart failure develops, or it may be increased if postural hypotension is demonstrated. Children with Addison's disease receive lesser daily amounts of steroids. Twelve milligrams of cortisol per square meter of body surface area is usually sufficient.

Secondary adrenal insufficiency often occurs in the presence of multiple hormone deficiencies. A decrease in ACTH production results in the decreased secretion of cortisol and adrenal androgens, but aldosterone control by more dominant mechanisms remains intact. A liberal salt diet is encouraged. Glucocorticoid substitution follows the same guidelines previously outlined for primary adrenal insufficiency.

Perioperatively, patients with adrenal insufficiency require additional corticosteroids to mimic the increased output of the normal adrenal gland during stress (see [Steroid Replacement During the Perioperative Period](#)). Acute adrenal insufficiency is usually precipitated by sepsis, trauma, or surgical stress in the setting of hypovolemic shock and severe electrolyte imbalance in a patient with inadequate adrenal reserves. Immediate therapy is mandatory regardless of the etiology and consists of fluid and electrolyte resuscitation and steroid replacement ([Table 41-6](#)).

Hydrocortisone 100 mg intravenous bolus followed by hydrocortisone 100 mg q6h for 24 h
Fluid and electrolyte replacement as indicated by vital signs, serum electrolytes, and serum glucose

Table 41-6. MANAGEMENT OF ACUTE ADRENAL INSUFFICIENCY

In critically ill patients, adrenal insufficiency may not present with classic symptoms. The clinical picture may resemble that of sepsis without a source of infection.³¹ A high degree of suspicion must be maintained if the patient has cardiovascular instability without a defined cause.^{32,33}

Initial therapy of acute adrenal insufficiency begins with the rapid iv administration of an isotonic crystalloid solution (D₅NS); 100 mg of hydrocortisone is administered as an iv bolus over several minutes. Steroid replacement is continued during the first 24 hours with 100 mg iv hydrocortisone given every 6 hours. If the patient is stable, the steroid dose is reduced starting on the second day. After adequate fluid resuscitation, if the patient continues to be hemodynamically unstable, inotropic support may be necessary. Invasive monitoring is extremely valuable as a guide to both diagnosis and therapy.

Mineralocorticoid Insufficiency

Isolated mineralocorticoid insufficiency has been reported as a congenital biosynthetic defect, after unilateral adrenalectomy for removal of an aldosterone-secreting adenoma, during protracted heparin therapy, and in patients with a deficiency in renin production. This syndrome is commonly seen in patients with mild renal failure and long-standing diabetes mellitus. A feature common to all patients with hypoaldosteronism is a failure to increase aldosterone production in response to salt

restriction or volume contraction.

Most patients present with hypotension, hyperkalemia that may be life threatening, and a metabolic acidosis that is out of proportion to the degree of coexisting renal impairment. Patients with low renin secretion, hypoaldosteronism, and renal dysfunction respond to ACTH stimulation. Nonsteroidal anti-inflammatory drugs, which inhibit prostaglandin synthesis, may further inhibit renin release and exacerbate the condition. Patients with isolated hypoaldosteronism are given fludrocortisone orally in a dose of 0.05–0.1 mg · day⁻¹. Patients with low renin secretion usually require higher doses to correct the electrolyte abnormalities. Caution should be observed in patients with hypertension or congestive heart failure. An alternative approach in these patients is the administration of furosemide alone or in combination with mineralocorticoid.

Exogenous Glucocorticoid Therapy

The therapeutic use of supraphysiologic doses of glucocorticoids has expanded, and, as a consequence, the clinical implications of such therapy are important. The relative glucocorticoid and mineralocorticoid properties of the various preparations are listed in Table 41-7. Dexamethasone, methylprednisolone, and prednisone have less mineralocorticoid effect than do cortisone and hydrocortisone. The anti-inflammatory activity of a glucocorticoid depends on the hydroxyl group at the carbon 11 position. Therefore, glucocorticoids such as cortisone and prednisone must undergo hepatic conversion from 11-keto compounds to 11-β-hydroxyl compounds before anti-inflammatory activity can occur. Consequently, prednisone and cortisone should probably be avoided in the presence of severe liver disease. Because most side effects from steroids are related to the dose and duration of administration, the smallest effective dose is used for the shortest time.

| Generic Name | Trade Name | Relative Potency* | | Approximate Equivalent Dose (mg) |
|----------------------------|------------|-------------------|-------------------|----------------------------------|
| | | Anti-inflammatory | Mineralocorticoid | |
| Short-Acting | | | | |
| Hydrocortisone (cortisol) | Cortel | 1.0 | 1.0 | 20.0 |
| Cortisone | Cortigen | 0.8 | 0.8 | 25.0 |
| Prednisone | Deltasone | 4.0 | 0.25 | 5.0 |
| Prednisolone | Hydralone | 4.0 | 0.25 | 5.0 |
| Methylprednisolone | Medrol | 5.0 | 0.2 | 4.0 |
| Intermediate-Acting | | | | |
| Triamcinolone | Ariston | 5.0 | 0.2 | 4.0 |
| Long-Acting | | | | |
| Dexamethasone | Decadron | 30.0 | 0.2 | 0.75 |

*Relative potencies compared with cortisol. The glucocorticoid and mineralocorticoid properties of cortisol are set as 1.0.

Table 41-7. GLUCOCORTICOID PREPARATIONS

Patients at particular risk for development of complications related to steroid therapy include those with diabetes mellitus, pre-existing infection, hypertension, or congestive heart failure. Aseptic necrosis of the bones, subcapsular cataracts, pancreatitis, benign intracranial hypertension, and glaucoma are complications associated with exogenous steroid administration. Although the overall prevalence of steroid-associated peptic ulceration is small (2%), patients receiving exogenous steroids have approximately twice the risk for development of peptic ulceration or GI hemorrhage as do control subjects.

Steroid Replacement During the Perioperative Period

The normal adrenal gland can secrete up to 200 mg of cortisol per day or more during the perioperative period. During periods of extreme stress, the adrenal gland may be exogenously stimulated to secrete between 200 and 500 mg · day⁻¹ of cortisol.³⁴ The pituitary–adrenal axis is usually considered to be intact if a plasma cortisol level of greater than 22 mg · dl⁻¹ is measured during acute stress. The degree of adrenal responsiveness has been correlated with the duration of surgery and the extent of surgical trauma. The mean maximal plasma cortisol level measured during major surgery (colectomy, hip osteotomy) was 47 mg · dl⁻¹. Minor surgical procedures (herniorrhaphy) resulted in mean maximal plasma cortisol levels of 28 mg · dl⁻¹. Adrenal activity may also be affected by the anesthetic technique used. Regional anesthesia is effective in postponing the elevation in cortisol levels during surgery of the lower abdomen and extremities.³⁵ Deep general anesthesia may also suppress the elevation of stress hormones such as ACTH and cortisol during the surgical procedure.^{36,37 and 38}

Although symptoms indicative of clinically significant adrenal insufficiency have been reported during the perioperative period, these clinical findings have rarely been documented in direct association with glucocorticoid deficiency.³⁹ There is evidence in adrenally suppressed primates that subphysiologic steroid replacement causes perioperative hemodynamic instability and increased mortality. Because acute adrenal crisis is life threatening, and because there is relatively little risk in providing steroid coverage for isolated periods of stress, most clinicians empirically administer supplemental steroids to all patients who have received daily steroid replacement for at least 1–2 weeks in the 6–12 months before surgery. Provocative testing with ACTH stimulation to identify patients at risk is too costly to justify compared with the risk of brief steroid supplementation.

The question is how much steroid to give. There is no proven optimal regimen for perioperative steroid replacement (Table 41-8). A “low-dose” cortisol replacement program using an iv infusion of 25 mg of cortisol before the induction of anesthesia, followed by a continuous infusion of cortisol (100 mg) in the next 24 hours has been advocated⁴⁰ (Fig. 41-4). This low-dose cortisol replacement program was used in patients with proven adrenal insufficiency and resulted in plasma cortisol levels as high as those seen in healthy control subjects subjected to a similar operative stress. One study with a limited number of patients found no problems with cardiovascular instability if patients received their usual dose of steroids.⁴¹ Although the low-dose approach appears logical, many clinicians are unwilling to adopt this regimen until further trials have been undertaken in patients receiving physiologic steroid replacement. A popular regimen calls for the administration of 200–300 mg of hydrocortisone per 70 kg body weight in divided doses on the day of surgery. The lower dose is adjusted upward for longer and more extensive surgical procedures. Patients who are using steroids at the time of surgery receive their usual dose on the morning of surgery and are supplemented at a level that is at least equivalent to the usual daily replacement. Glucocorticoid coverage is reduced to the patient's normal maintenance dosage during the postoperative period. Although there is no conclusive evidence supporting an increased incidence of infection or abnormal wound healing when supraphysiologic doses of supplemental steroids are used acutely, the goal of therapy is to use the minimal drug dosage necessary adequately to protect the patient.

Hydrocortisone 25 mg iv at time of induction followed by hydrocortisone infusion 100 mg over 24 h
Hydrocortisone 100 mg iv before, during, and after surgery

iv = intravenous.

Table 41-8. MANAGEMENT OPTIONS FOR STEROID REPLACEMENT IN THE PERIOPERATIVE PERIOD

Figure 41-4. Plasma cortisol concentrations (mean \pm SEM) were measured in three groups of patients undergoing elective surgery. Group I control patients, $n = 8$ (closed circles), had never received corticosteroids. Group II patients, $n = 8$ (open circles), received preoperative corticosteroids with a normal response to preoperative adrenocorticotropic hormone (ACTH; corticotropin) stimulation testing. These patients and control patients received no corticosteroid substitution during the perioperative period. Group III, $n = 6$ (asterisks), consisted of patients receiving long-term corticosteroid therapy with an abnormal response to ACTH stimulation testing during the perioperative period. These patients (Group III) received intravenous (iv) cortisol, 25 mg, after the induction of anesthesia plus a continuous iv infusion of cortisol, 100 mg, during the next 24 hours. Plasma cortisol levels in Group III were significantly lower than in the other two groups before the induction of anesthesia. After iv administration of cortisol to Group III patients, plasma concentrations were significantly higher than in Groups I and II for the next 2 hours ($p < 1$ 0.01). Thereafter, the mean plasma concentrations were similar for all groups. There were no clinical signs of circulatory insufficiency in any group. (Reproduced with permission from Symreng T, Karlberg BE, Kagedol B, Schildt B: Physiological cortisol substitution of long-term steroid-treated patients undergoing major surgery. *Br J Anaesth* 53:949, 1981.)

ADRENAL MEDULLA

The adrenal medulla is derived embryologically from neuroectodermal cells. As a specialized part of the sympathetic nervous system, the adrenal medulla synthesizes and secretes the catecholamines epinephrine (80%) and norepinephrine (20%). Preganglionic fibers of the sympathetic nervous system bypass the paravertebral ganglia and pass directly from the spinal cord to the adrenal medulla. The adrenal medulla is analogous to a postganglionic neuron, although the catecholamines secreted by the medulla function as hormones, not as neurotransmitters.

The synthesis of norepinephrine begins with hydroxylation of tyrosine to dopa (Fig. 41-5). This rate-limiting step in catecholamine biosynthesis is regulated so that synthesis is coupled to release. In the adrenal medulla and in those rare central neurons using epinephrine as a neurotransmitter, most of the norepinephrine is converted to epinephrine by the enzyme phenylethanolamine-*N*-methyltransferase. It is likely that the capacity of the adrenal medulla to synthesize epinephrine is influenced by the flow of glucocorticoid-rich blood from the adrenal cortex through the intra-adrenal portal system because it is known that high concentrations of glucocorticoid are able to induce the enzyme phenylethanolamine-*N*-methyltransferase.

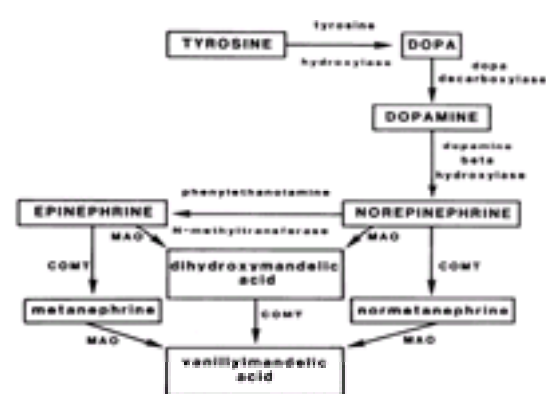

Figure 41-5. The synthesis and metabolism of endogenous catecholamines. COMT = catechol-*O*-methyltransferase; MAO = monoamine oxidase. (Reproduced with permission from Stoelting RK, Dierdorf SF [eds]: *Anesthesia and co-existing disease*. New York, Churchill-Livingstone, 1983.)

In the adrenal medulla, catecholamines are stored in chromaffin granules complexed with adenosine triphosphate and Ca^{2+} . The normal adrenal releases epinephrine and norepinephrine by exocytosis in response to stimulation by preganglionic sympathetic neurons. The circulatory half-life (10–30 seconds) of these catechols is considerably longer than the brief receptor activity of norepinephrine released as a neurotransmitter from postganglionic sympathetic nerve endings. Biotransformation of circulating norepinephrine and epinephrine is accomplished chiefly by the enzyme catechol-*O*-methyltransferase, located in the liver and kidney. Monoamine oxidase is of less importance in the metabolism of circulating catechols. Metanephrines and vanillylmandelic acid (VMA) are the major end products of catecholamine metabolism. These metabolites and a small amount of unchanged catecholamine (1%) appear in the urine.

The outflow of postganglionic sympathetic neurotransmitters and circulating catecholamine from the adrenal medulla is coordinated by higher cortical centers connected to the brain stem. The intrinsic activity of the brain stem sympathetic areas is modulated by higher cortical functions, emotional reactions (anger, fear), and various physiologic stimuli, including changes in the physical and chemical properties of the extracellular fluid (hypoglycemia, hypotension). The adrenal medulla and sympathetic nervous system are often stimulated together in a generalized fashion, although many physiologic conditions exist in which they act independently.

Pheochromocytoma

The only important disease process associated with the adrenal medulla is pheochromocytoma. These tumors produce, store, and secrete catecholamines. Most pheochromocytomas secrete both epinephrine and norepinephrine, with the percentage of secreted norepinephrine being greater than that secreted by the normal gland. Although pheochromocytomas occur in fewer than 0.1% of hypertensive patients, it is important aggressively to evaluate the patient with clinically suspect symptoms because surgical extirpation is curative in more than 90% of patients and complications are often lethal in undiagnosed cases. Postmortem series have reported high perioperative mortality rates in undiagnosed patients undergoing relatively minorsurgical procedures. Most deaths are from cardiovascular causes. Of particular importance to the anesthesiologist is that anesthetic drugs, in particular, halothane and histamine-releasing drugs, can exacerbate the life-threatening cardiovascular effects of the catecholamines secreted by these tumors.

Most (85–90%) pheochromocytomas are solitary tumors localized to a single adrenal gland, usually the right. Approximately 10% of adults and 25% of children have bilateral tumors. The tumor may originate in extra-adrenal sites (10%) anywhere along the paravertebral sympathetic chain; however, 95% are located in the abdomen, and a small percentage are located in the thorax, urinary bladder, or neck. Malignant spread of these highly vascular tumors occurs in approximately 10% of cases.

In approximately 5% of cases, this tumor is inherited as a familial autosomal dominant trait. It may be part of the polyglandular syndrome referred to as MEN Type IIA or IIB. Type IIA includes medullary carcinoma of the thyroid, parathyroid hyperplasia, and pheochromocytoma; Type IIB consists of medullary carcinoma of the thyroid, pheochromocytoma, and neuromas of the oral mucosa. Pheochromocytomas may also arise in association with von Recklinghausen's neurofibromatosis or von Hippel-Lindau disease (retinal and cerebellar angiomas). The pheochromocytoma of the familial syndromes is rarely extra-adrenal or malignant. Bilateral tumors occur in approximately 75% of cases. When these patients present with a single adrenal pheochromocytoma, the chances of subsequent development of a second adrenal pheochromocytoma are sufficiently high that bilateral adrenalectomy should be considered. Every member of a MEN family should be considered at risk for pheochromocytoma.

Clinical Presentation

Pheochromocytoma may occur at any age, but it is most common in young to mid-adult life. The clinical manifestations are mainly due to the pharmacologic effects of the catecholamines released from the tumor. These tumors are not innervated, and catecholamine release is independent of neurogenic control. Although most patients (90%) are hypertensive, the blood pressure profile is labile in half of these cases. Forty percent have only paroxysmal hypertension. When true paroxysms

occur, the blood pressure may rise to alarmingly high levels, placing the patient at risk for cerebrovascular hemorrhage, heart failure, dysrhythmias, or myocardial infarction. Headache, palpitations, tremor, profuse sweating, and either pallor or flushing may accompany an attack. There are reports of pheochromocytoma manifesting as malignant hyperthermia.⁴² Physical examination of the patient with pheochromocytoma may be unrevealing during the period between attacks unless the patient presents with symptoms and signs of sequelae related to long-standing hypertension. A well described catecholamine-induced cardiomyopathy may manifest as myocarditis accompanied by heart failure and cardiac dysrhythmias. Paroxysms commonly are not associated with clearly defined events but may be precipitated by displacement of the abdominal contents or, in the case of a bladder tumor, by micturition.

Diagnosis

Biochemical determination of free catecholamine concentration and catecholamine metabolites in the urine is the most common screening test used to establish the diagnosis of pheochromocytoma.⁴³ Urinary VMA and unconjugated norepinephrine and epinephrine levels are measured in a 24-hour urine collection and are expressed as a function of the creatinine clearance. The VMA level is elevated in most cases. Urinary metanephrine is not quantified because it is not predictably elevated in pheochromocytoma. Free catecholamines represent less than 1% of the originally released hormone, and urinary levels are not always elevated to a significant degree. Hence, differentiation from normal subjects may be difficult. A change in the ratio of unconjugated epinephrine to norepinephrine may be the only biochemical finding. Certain drugs interfere with urinary assays, and some patients with paroxysmal hypertension have normal values between attacks.

Although routine laboratory data are unlikely to provide specific diagnostic insight, the ECG, chest radiograph, and complete blood cell count can provide valuable information to the clinician who entertains the diagnosis. Left ventricular hypertrophy and nonspecific T-wave changes are two of the more common ECG findings. Evidence of acute myocardial infarction or tachyarrhythmia has also been reported. The chest radiograph may reveal cardiomegaly, and the blood count often shows an elevated hematocrit consistent with a reduced intravascular volume and hemoconcentration. Standardized imaging methods such as computed tomography and magnetic resonance imaging (MRI) are used in the noninvasive localization of these tumors.⁴⁴ Improvements in imaging may obviate the need for abdominal exploration or venous sampling to localize the tumor in selected patients.⁴⁵ Ultrasound and MRI are especially useful in pregnant patients. ¹³¹I-Metaiodobenzylguanidine (¹³¹I-MIBG) scintigraphy is also effective in localizing recurrent or extra-adrenal masses. Arteriography must be performed with extreme care in these patients because a hypertensive crisis can be precipitated.

Anesthetic Considerations

Preoperative Preparation. The reduction in perioperative mortality rates from a high of 45% to between zero and 3% with the excision of pheochromocytoma followed the introduction of α -antagonists for preoperative therapy. Perioperative blood pressure fluctuations, myocardial infarction, congestive heart failure, cardiac dysrhythmias, and cerebral hemorrhage all appear to be reduced in frequency when the patient has been treated before surgery with α blockers and the intravascular fluid compartment has been re-expanded. Extended treatment with α antagonists is also effective in treating the clinical manifestations of catecholamine myocarditis. However, a blocker therapy has never been studied in a controlled way and there are some groups that question its necessity.⁴⁶ A list of drugs frequently used in the management of pheochromocytoma is given in [Table 41-9](#).

| Drug | Action | Dosage | Comments |
|------------------|------------------------------|-------------|--|
| Phenoxybenzamine | α Blocker | 10–20 mg | Long-acting, noncompetitive α_1 and α_2 blocker. Side effects include nasal stuffiness, postural hypotension, and decreased ejaculation. |
| Phentolamine | α Blocker | 1–2 mg | Short-acting, competitive α_1 and α_2 blocker. Side effects include nasal stuffiness, postural hypotension, and decreased ejaculation. |
| Prazosin | α_1 Blocker | 1–2 mg | Competitive α_1 blocker. Side effects include dizziness, postural hypotension, and decreased ejaculation. |
| Labetalol | α and β Blocker | 10–20 mg | Competitive α_1 and β_1 blocker. Side effects include dizziness, postural hypotension, and decreased ejaculation. |
| Esmolol | β_1 Blocker | 0.5–1 mg | Short-acting, selective β_1 blocker. Side effects include bradycardia and hypotension. |
| Nitroglycerin | Vasodilator | 0.2–0.5 mg | Short-acting vasodilator. Side effects include headache and hypotension. |
| Nitroprusside | Vasodilator | 0.2–0.5 mg | Short-acting vasodilator. Side effects include cyanide toxicity and hypotension. |
| Propofol | Anesthetic | 0.5–1 mg | Short-acting general anesthetic. Side effects include hypotension and bradycardia. |
| Etomidate | Anesthetic | 0.2–0.3 mg | Short-acting general anesthetic. Side effects include nausea and vomiting. |
| Midazolam | Anesthetic | 0.05–0.1 mg | Short-acting sedative. Side effects include hypotension and respiratory depression. |
| Propofol | Anesthetic | 0.5–1 mg | Short-acting general anesthetic. Side effects include hypotension and bradycardia. |
| Etomidate | Anesthetic | 0.2–0.3 mg | Short-acting general anesthetic. Side effects include nausea and vomiting. |
| Midazolam | Anesthetic | 0.05–0.1 mg | Short-acting sedative. Side effects include hypotension and respiratory depression. |

Table 41-9. DRUGS USED IN THE MANAGEMENT OF PHEOCHROMOCYTOMA

α -Adrenergic blockade is initiated once the diagnosis of pheochromocytoma is established. The patient receives phenoxybenzamine, a long-acting (24–48 hours), noncompetitive presynaptic (α_2) and postsynaptic (α_1) blocker, at doses of 10 mg every 8 hours. Increments are added until the blood pressure is controlled and paroxysms disappear. Most patients need between 80 and 200 mg \cdot day⁻¹. The absorption after oral administration is variable, and side effects are common. Certain cardiovascular reflexes, such as the baroreceptor reflex, are blunted, and postural hypotension is common. α -adrenergic blockade also causes nasal stuffiness and impairs ejaculation. Prazosin, a competitive postsynaptic (α_1) blocking agent with a shorter half-life than phenoxybenzamine, has also been used effectively. Because postural hypotension can be pronounced with the commencement of therapy, the initial 1-mg dose is given at bedtime. Postural changes are also seen with maintenance therapy (6–10 mg \cdot day⁻¹). A comparison of patients with pheochromocytoma receiving phenoxybenzamine and prazosin has shown both drugs to be equally effective in controlling the blood pressure. A case report of severe hypertension in a prazosin-treated patient after the initiation of β blocker therapy suggested that a less selective blockade of both α_1 and α_2 receptors (phenoxybenzamine) might be preferable in patients with severe hypertension.⁴⁷ Although the optimal period of preoperative treatment has not been established, most clinicians recommend beginning a blockade therapy at least 10–14 days before the proposed surgery; however, periods as short as 3–5 days have been used.⁴⁸ During this time, the contracted intravascular volume and hematocrit return toward normal and the blood pressure is stabilized. Despite the real possibility of hypotension after vascular isolation of the tumor, most clinicians continue α blockers up until the morning of surgery.

β -Adrenergic blockade is often added after a blockade has been established. This addition is considered in patients with persistent tachycardia or cardiac dysrhythmias that may be exacerbated by a blockade. β Blockers should not be given until adequate α blockade is ensured to avoid the possibility of unopposed α -mediated vasoconstriction. There is no clear preoperative advantage of one β antagonist over another, although the short half-life of esmolol may allow better control of heart rate and arrhythmias in the perioperative setting. Labetalol, a β -adrenergic antagonist with α -blocking activity, is effective as a second-line medication, but there are reports of increases in blood pressure when this drug is used alone.⁴⁹

Acute hypertensive crises are treated with iv infusions of nitroprusside or phentolamine. Phentolamine is a short-acting α -adrenergic antagonist that may be given as an iv bolus (2–5 mg) or by continuous infusion. Tachydysrhythmias are controlled with iv boluses of propranolol (1-mg increments) or by a continuous infusion of the ultrashort-acting selective β_1 -adrenergic antagonist esmolol. The disadvantage of long-acting β blockers may be persistence of bradycardia and hypotension after the tumor is removed. Even esmolol may be problematic because there are cases of cardiac arrest after clamping of the venous drainage in patients on large doses of esmolol.

α -Methyl tyrosine is an agent that inhibits the enzyme tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. This medication is currently reserved for patients with metastatic disease or for situations in which surgery is contraindicated and long-term medical therapy is required. When α -methyl tyrosine is used in combination with α -adrenergic-blocking agents, there is a significant reduction in catecholamine biosynthesis.

Unrecognized pheochromocytoma during pregnancy may be life threatening to the mother and fetus. Although the safety of adrenergic-blocking agents during pregnancy has not been established, these agents probably improve fetal survival in pregnant patients with pheochromocytoma. The trend is to perform surgery during the first trimester or at the time of cesarean delivery. There is no reason to terminate an early pregnancy, but the patient should be aware of the risk of spontaneous abortion resulting from abdominal surgery to remove the tumor.⁵⁰

Perioperative Anesthetic Management. Symptomatic patients continue to receive medical therapy until tachycardia, cardiac dysrhythmias, and paroxysmal elevations in blood pressure are well controlled. Occasionally, a patient with pheochromocytoma unaccompanied by hypertension is referred for consultation before surgery. These patients are difficult to manage with a blockade therapy on an outpatient basis because of the fear of clinically significant orthostatic hypotension. These patients are admitted to the hospital at least 24 hours before surgery to institute bed rest, “prophylactic” α -adrenergic blockade (prazosin), and fluid therapy. Central venous and peripheral artery pressure monitoring is routinely used to guide preoperative intervention. Because of the unpredictable and potentially lethal nature of the patient response to the stress of anesthesia and surgery, all patients presenting for pheochromocytoma surgery should receive a preoperative anesthesiology consultation. Experience suggests that pretreated patients have fewer cardiac dysrhythmias and less fluctuation in blood pressure and heart rate during the induction of anesthesia than other, “normotensive” patients who do not receive preoperative α blockade therapy. If it is not possible to initiate α -blocking therapy before surgery, or if the patient has received less than 48 hours of intensive treatment, it is frequently necessary to infuse nitroprusside during the induction of anesthesia. A low-dose

infusion is often initiated in anticipation of the marked blood pressure elevations that can occur with laryngoscopy and surgical stimulation.

Until recently, a transperitoneal approach was necessary to allow the surgeon to assess for multiple or bilateral disease. Improvements in imaging now allow selected patients with solitary tumors less than 5 cm to undergo a retroperitoneal or laparoscopic approach. During laparoscopic surgery, creation of the pneumoperitoneum may cause release of catecholamines and large changes in hemodynamics that can be controlled with a vasodilator.⁵¹

Although there is no clear advantage to one anesthetic technique over another, drugs that are known to liberate histamine are avoided. Because of the potential for ventricular irritability, halothane is not administered. A potent sedative–hypnotic in combination with an opioid analgesic is used for induction. It is extremely important to achieve an adequate depth of anesthesia before proceeding with laryngoscopy to minimize the sympathetic nervous system response to this maneuver. Maintenance is provided with an opioid analgesic and a potent inhalation agent. Manipulation of the tumor may produce marked elevations in blood pressure, which are controlled with nitroprusside and, if necessary, phentolamine. Tachydysrhythmias are treated with iv β blockers. Many adjuvant drugs have been tried and recommended to control arterial pressure often seen during surgery. Magnesium sulfate given as an infusion with intermittent boluses has successfully controlled blood pressure.⁵² Nicardipine, nitroglycerin, diltiazem, and prostaglandin E_1 have all been used anecdotally. The reduction in blood pressure that may occur after ligation of the tumor's venous supply should be anticipated through close communication with the surgical team. Restitution of any intravascular fluid deficit is the initial therapy in this situation. After replenishment of the intravascular volume, if the patient remains hypotensive, phenylephrine is administered. After surgery, catecholamine levels return to normal over several days. Approximately 75% of patients become normotensive within 10 days.⁵³

DIABETES MELLITUS

Diabetes mellitus is the most commonly occurring endocrine disease found in surgical patients.⁵⁴ It has a broad spectrum of severity, and its manifestations can be altered in reaction to the patient's metabolic stress. Although the most serious complications of diabetes mellitus are related to its character as a chronic disease, it can cause difficulties in the short-term management of acute illness. Occasionally, diabetes remains clinically inapparent until exacerbated by the stress of trauma or surgery.

The principles of the treatment of diabetes will be easier to understand if we review the physiology of glucose metabolism and the stress response and then consider some of the specific pathologic entities that make up the clinical picture of diabetes mellitus.

Classification

Diabetes mellitus is primarily a disease of carbohydrate metabolism; however, it has numerous manifestations and interactions with a large range of hormonal and endocrinologic functions. Despite a variety of etiologic factors, its hallmark is a deficiency, either absolute or relative, in the amount of insulin available to the tissues.

Diabetes is often divided into two broad types. Type I, or insulin-dependent diabetes mellitus (IDDM), is distinguished from Type II, or non–insulin-dependent diabetes mellitus (NIDDM). The patient with IDDM typically experiences the onset of disease early in life.⁵⁵ Consequently, this form is also referred to as juvenile-onset diabetes. In general, the patient with IDDM is not obese, had an abrupt onset of the disease, and has very low levels of circulating insulin. Disease in these patients cannot be controlled with diet or oral hypoglycemic agents and mandates treatment with insulin. Patients in this group are often difficult to maintain in good glucose balance, are more likely to become ketotic, and are likely to sustain the end-organ complications of diabetes if they live long enough.

Patients with NIDDM, also called maturity-onset diabetes, typically experience a gradual onset of the disease later in life. They are often obese and have some degree of resistance to the effects of insulin. They may have normal or even elevated levels of insulin. In milder forms, this version of diabetes can often be treated with diet or oral hypoglycemic agents. Because these patients are relatively resistant to ketosis, their disease may be clinically inapparent until exacerbated by the stress of surgery or intercurrent illness.

This classification of diabetes mellitus is only a generalization. The milder, NIDDM form occasionally occurs in young people, and many older adults acquire a severe and brittle form of IDDM. Diabetes can also be a secondary result of a disease that damages the pancreas and thus impairs insulin secretion. Pancreatic surgery, chronic pancreatitis, cystic fibrosis, and hemochromatosis can damage the pancreas and thus impair insulin secretion sufficiently to produce clinical diabetes. Diabetes can result from one of the endocrine diseases that produces a hormone that opposes the action of insulin. Hence, a patient with a glucagonoma, pheochromocytoma, or acromegaly may be diabetic. An increased effect of glucocorticoids, either from Cushing's disease or steroid therapy, may also oppose the effect of insulin enough to elicit clinical diabetes and would certainly complicate the management of pre-existing diabetes. Patients with circulating anti-insulin receptor antibodies in association with other autoimmune processes are also diabetic. Finally, there is a clinical triad of severe insulin resistance in young, hirsute women with polycystic ovaries who have decreased insulin receptors.

Physiology

Insulin has multiple and complex interactions with lipid, protein, and glucose metabolism.⁵⁶ For our purposes, it is easiest to regard the effects of insulin on glucose metabolism as primary and to view its effects on other metabolic functions only as they relate to glucose.

Insulin is a small protein produced by the β cells of the is-lets of Langerhans in the pancreas. Normal production in the adult human is approximately $40\text{--}50$ units \cdot day⁻¹. Insulin acts through receptor sites on cells. The half-life of insulin in the circulation is only a few minutes. However, it may clinically appear to have a longer duration of action, owing to delays in binding and release from the cellular receptors. These facts lead us to the important principle that once a high level of insulin saturates all the binding sites, insulin will not have a more potent effect, just a more long-lasting effect. This is crucial to understanding insulin therapy, which is discussed in the following paragraphs.

Insulin is metabolized in the liver and kidney. In patients with hepatic dysfunction, the loss of gluconeogenesis as well as a prolongation of insulin effect increases the risk of hypoglycemia. Renal disease is another risk factor for hypoglycemia and is an important consideration in managing the use of exogenous insulin in diabetic patients.

Insulin release is related to a number of events. First is the direct effect of glucose (and amino acids) to stimulate insulin release. The mechanism involves interaction with hormones from the GI tract released during enteral feeding. The autonomic nervous system, also through vagal stimulation, increases insulin release, as does β -adrenergic stimulation and α -adrenergic blockade.

The most fundamental action of insulin is to stimulate increased cellular uptake of glucose. This is particularly important in skeletal muscle cells, where muscle activity also increases glucose uptake and is an important variable in the management of the physically active diabetic patient. (The brain and liver are exceptional areas where insulin does not affect glucose transport.) Hence, the diabetic patient has hyperglycemia because of inadequate cellular uptake of glucose. Along with glucose, potassium enters the cells under the influence of insulin, so the diabetic patient is also likely to have an imbalance of potassium concentrations across cell membranes.

Other important metabolic functions of insulin include the stimulation of glycogen formation and the suppression of gluconeogenesis and lipolysis. The patient with insulin deficiency has low glycogen stores and active gluconeogenesis. This implies that in the diabetic patient, owing to an absence of glycogen, protein must be broken down to make glucose. Insulin also increases the uptake of amino acids into muscle cells. Hence, an insulin deficiency leads to catabolism and negative nitrogen balance.

Fat metabolism is also abnormal in the diabetic state, with acceleration of lipid catabolism and increased formation of ketone bodies. A deficiency of insulin leads to increased fatty acid liberation from adipose tissue. These fatty acids have multiple metabolic effects, including interference with carbohydrate phosphorylation in muscle, which leads to further hyperglycemia. Low concentrations of insulin, which may be inadequate to prevent hyperglycemia, are often sufficient to block lipolysis. This effect explains the common clinical situation in which a patient is hyperglycemic without being ketotic.

Glucagon is a polypeptide released from the α cells of the pancreas and acts both to stimulate the release of insulin and oppose some of the effects of insulin. Hence, it has both a direct and an indirect ability to increase circulating glucose levels. In some patients, after total pancreatic resection, glucose balance is not as poor as might be expected because of the concomitant absence of glucagon. Glucagon release is stimulated by hypoglycemia as well as by epinephrine and cortisol, and is suppressed by glucose ingestion.

The metabolic effects of stress are intricately involved with the same pathways as those involved in diabetes mellitus. During stress, elevations in the circulating levels of cortisol, glucagon, catecholamines, and growth hormones all act to cause hyperglycemia. In addition, glucagon and epinephrine exert a suppressive effect on insulin release. Mild hyperglycemia may occur in the stressed patient who does not have diabetes mellitus. In the diabetic patient, stress makes the diabetes more difficult to control. In a patient with minimal or subclinical diabetes before the stressful episode, the glucose balance may become difficult to manage during the stress-related

event.

Treatment

Patients with Type I diabetes require insulin to survive. Further, the risk of microvascular complications can be decreased if tight glycemic control maintains near-normal levels of blood glucose. Patients may be on a range of doses of both short- and intermediate-acting insulin, with doses given one to six times a day depending on the desire for tight control.

Patients with Type II diabetes may initially be treated with diet control and exercise. If this fails to control glucose levels, or if the diabetes worsens, therapy with an oral agent is indicated.⁵⁷ Sulfonylureas enhance b-cell insulin secretion. Metformin is a biguanide that enhances the sensitivity of both hepatic and peripheral tissues to insulin.⁵⁸ Rosiglitazone (Avandia) and pioglitazone (Actos) are thiazolidinediones that also increase insulin sensitivity. If oral agents cannot maintain acceptable glucose levels, insulin is used.

Anesthetic Management

Successful management of the diabetic patient depends as much, if not more, on the proper management of the chronic complications of the disease as on acute glycemic management.

Preoperative

A thorough preoperative search must be done for end-organ complications of diabetes. In addition to a thorough history and physical, a recent ECG, blood urea nitrogen, potassium, creatinine, glucose, and urinalysis are essential.

Atherosclerosis develops earlier and is more widespread in diabetic patients compared with nondiabetic people. Manifestations include coronary artery disease, peripheral vascular disease, cerebrovascular disease, and renovascular disease. The incidence of postoperative myocardial infarction is increased in diabetic patients.⁵⁹ Silent myocardial ischemia and infarction occur more commonly in diabetic patients, perhaps because of sensory neuropathy of the visceral afferents to the heart. Diabetes may be associated with a cardiomyopathy in the face of angiographically normal coronary arteries, possibly with diffuse disease in arteries too small to be visualized.

Laryngoscopy in up to 40% of juvenile patients with diabetes presenting for renal transplantation can be difficult.⁶⁰ This may be due to diabetic stiff joint syndrome, a frequent complication of IDDM, leading to decreased mobility of the atlanto-occipital joint. The "prayer sign," an inability to approximate the palmar surfaces of the interphalangeal joints, is associated with stiff joint syndrome and may predict difficult laryngoscopy.

Diabetic nephropathy eventually occurs in up to 40–50% of patients with IDDM. Albuminuria usually precedes a steady decline in renal function.

Diabetic patients with autonomic neuropathy are at increased risk for intraoperative hypotension requiring vasopressor support, and perioperative cardiorespiratory arrest.^{61,62,63} and ⁶⁴ There may be an exaggerated pressor response to tracheal intubation.⁶⁵ Autonomic function may be tested by measuring the beat-to-beat variation in heart rate during breathing, heart rate response to a Valsalva maneuver, and orthostatic changes in diastolic blood pressure and heart rate.

Diabetic patients may have delayed gastric emptying as a result of diabetic autonomic neuropathy, and therefore be at increased risk of aspiration. Autonomic function tests can predict the presence of solid food particles in gastric contents but not increased gastric volume or acidity.⁶⁶ Metoclopramide may be useful in emptying the stomach of solid food.

It is axiomatic that the patient should attain the best possible preoperative metabolic control. If the patient's glucose level has been unstable, especially with episodes of hypoglycemia, adjustment of insulin therapy is required. Traditionally, oral hypoglycemics have been held before surgery because of fear of hypoglycemia in the fasted patient. With today's shorter-acting agents, this may be unnecessary because the risk is much reduced. Metformin should be discontinued preoperatively because it has been associated with severe lactic acidosis during episodes of hypotension, poor perfusion, or hypoxia. Unless the patient has a surgical emergency, patients with diabetic ketoacidosis or hyperosmolar coma should receive intensive medical management before coming to the operating room (see [Emergencies](#)).

Intraoperative

The details of the anesthetic plan depend intimately on the end-organ complications. Invasive monitoring may be indicated for the patient with heart disease; awake intubation may be necessary if a difficult intubation is predicted; fluid management and drug choices may depend on renal function; and aspiration must be considered if there is gastroparesis.

Blood glucose levels should be measured before and after surgery. The need for additional measurements is determined by the duration and magnitude of surgery and the brittleness of the diabetes. Hourly measurements are reasonable in high-risk patients.

On the basis of a preoperative osmotic diuresis, the diabetic patient may reach the operating room with clinically significant dehydration. In addition to the usual principles of perioperative fluid management, it is important to note the amount of glucose administered iv to avoid a massive overdose of glucose. The standard glucose dosage for an adult patient is $5\text{--}10\text{ g} \cdot \text{h}^{-1}$ (100–200 ml of 5% dextrose solution hourly). It is best to monitor and record the dextrose administered separately from the fluids given. It would be wrong to give large amounts of dextrose (contained in the iv solutions) just because that patient needed vigorous fluid replacement. If this happens, the patient is likely to be very hyperglycemic in the postanesthesia care unit. It is difficult to determine the proper dose of insulin to correct this iatrogenic hyperglycemia, and prolonged observation and therapy may be required.

Monitoring of the patient who arrives in the operating room with significant metabolic impairment, such as diabetic ketoacidosis, is similar to management in the medical intensive care unit, including hourly determinations of blood glucose, arterial pH, electrolytes, and fluid balance. Frequent reassessments with medical consultation as necessary guide the use of fluids, electrolytes (especially potassium), insulin, phosphate, and glucose.⁶⁷

Another area of patient monitoring that is extremely important in the diabetic patient is positioning on the operating table. Injuries to the limbs or nerves are more likely in the patient who arrives in the operating room already compromised by diabetic peripheral vascular disease or neuropathy. The peripheral nerves may already be partly ischemic and therefore particularly vulnerable to pressure or stretch injuries.⁶⁸

Management Regimens

There is no consensus about the optimal way to manage perioperative metabolic changes in diabetic patients; many options are available. Factors to consider in selecting a plan include whether the patient is insulin dependent, whether the surgery is minor and in an ambulatory unit, whether the surgery is elective or an emergency, the desire to maintain "tight" perioperative control of glucose levels, and the ability of hospital resources safely to administer a complex plan. The goal of any regimen should be to minimize metabolic derangements and, most obviously, to avoid hypoglycemia. Because hypoglycemia may develop insidiously and be difficult to detect quickly, insulin and glucose therapy is usually administered to bring about a mild, transient hyperglycemia that can gradually be corrected in the postoperative period. Mild hyperglycemia is not an acute problem, and there is no need for it to be corrected rapidly. It is never simple to determine the precise dose of insulin needed to correct hyperglycemia. Excessively rapid correction may lead to glucose instability and fluctuations that can persist for hours to days. There are clinical situations in which lower glucose levels may be desirable. Hyperglycemia may exacerbate neuronal ischemic damage. Patients undergoing surgical procedures associated with cerebral ischemia such as intracranial surgery, carotid endarterectomy, and cardiopulmonary bypass may benefit from maintenance of glucose levels less than $200\text{ mg} \cdot \text{dl}^{-1}$.^{69,70} Wound strength, wound healing, and phagocyte activity may all be impaired by hyperglycemia.

For some diabetic patients, the best method of diabetic management is to give no insulin. For short procedures in unstressed patients, especially if they are not chronically receiving insulin, there may be enough endogenous production of insulin to maintain reasonable glucose balance in the unfed state. Glucose should still be given during surgery as protection against the delayed effects of prior oral hypoglycemic agents or long-acting insulin and to prevent the occurrence of mild ketosis.

Patients receiving short-acting oral hypoglycemic agents should omit them the morning of surgery. Long-acting agents should be converted to short-acting agents several days before surgery.

Another common method of management is to administer a fraction of the patient's usual morning NPH insulin dose the morning of the day of surgery. Often, half the

usual NPH dose suffices to maintain the patient through the day. It is critical for the patient who is NPO and receiving insulin also to receive an iv infusion of a dextrose solution. If $5\text{--}10\text{ g} \cdot \text{h}^{-1}$ of dextrose ($100\text{--}200\text{ ml} \cdot \text{h}^{-1}$ of 5% dextrose solution) is administered to the adult, the risk of hypoglycemia is small. Nevertheless, the patient's usual dosage depends on caloric intake and physical activity, which are different in the hospital setting.

The "sliding scale" regimen for insulin administration is popular and easy to use. Varying doses of regular insulin are administered on a 4- to 6-hour schedule, depending on the blood or urine glucose levels and the patient's prior responses to insulin. This method of management guarantees that the glucose levels are checked frequently. Large fluctuations in blood glucose can occur if insulin is administered in the presence of high glucose levels and no insulin is given for normal or intermediate levels. This can be avoided if some insulin is always present. Small doses of insulin can be prescribed for all but the lowest levels of blood glucose, or the sliding scale can be combined with a small morning dose of long-acting NPH insulin.

A continuous, carefully titrated variable-rate infusion of insulin has been advocated as the ideal method for perioperative diabetic management.⁷¹ Except in the patient with renal failure, in whom insulin effects are difficult to predict, the continuous-infusion method has the advantage of allowing rapid adjustment of the insulin effect by changing the rate of infusion. Also, alterations in cutaneous blood flow need not result in unpredictable serum insulin concentrations. In the adult with normal renal function, 7–10 units of regular insulin in 1 liter of 5% dextrose, infused at a rate of $75\text{--}100\text{ ml} \cdot \text{h}^{-1}$, provides $0.5\text{--}1\text{ unit} \cdot \text{h}^{-1}$ of insulin. This tends to be a low dose, and many patients need more insulin, which can be given either as an increased insulin concentration in the infusion or as a sliding scale subcutaneous regimen. Alternatively, 50 units of regular insulin can be mixed in 500 ml of normal saline and administered at $10\text{ ml} \cdot \text{h}^{-1}$. Sufficient glucose can be administered by a separate iv infusion. Glucose–insulin–potassium infusions have been used. The advantage of a combination solution is that any accidental variation in the infusion rate affects all components equally. The disadvantage is that a new bag must be prepared if the nominal concentrations do not achieve good control. In all iv regimens, a small amount of iv insulin is lost by adherence to the wall of the tubing and containers, but this loss is not clinically significant and should not be a deterrent to this route of administration.

Emergencies

Patients may present with metabolic instability, or it may develop perioperatively. Stress, trauma, and infection may all lead to increased insulin requirements and insulin resistance.

Hyperosmolar Nonketotic Coma

An occasional elderly patient with minimal or mild diabetes may present with remarkably high blood glucose levels and profound dehydration. Such patients usually have enough endogenous insulin activity to prevent ketosis; even with blood sugar concentrations of $1000\text{ mg} \cdot \text{dl}^{-1}$, they are not in ketoacidosis. Presumably, it is the combination of an impaired thirst response and mild renal insufficiency that allows the hyperglycemia to develop. The marked hyperosmolarity may lead to coma and seizures, with the increased plasma viscosity producing a tendency to intravascular thrombosis. It is characteristic of this syndrome that the metabolic disturbance responds quickly to rehydration and small doses of insulin. One to 2 liters of normal saline, or equivalent, should be infused over 1–2 hours if there are no cardiovascular contraindications. Insulin, by bolus or infusion, should be administered. With rapid correction of the hyperosmolarity, cerebral edema is a risk, and recovery of mental acuity may be delayed after the blood glucose level and circulating volume have been normalized.

Diabetic Ketoacidosis

If the diabetic patient has insufficient insulin effect to block the mobilization and metabolism of free fatty acids, the metabolic by-products acetoacetate and b-hydroxybutyrate accumulate.⁷² These ketone bodies are organic acids and cause a metabolic acidosis with an increased unmeasured anion gap. Clinically, the patient often presents because of intercurrent illness, trauma, or the untoward cessation of insulin therapy. Although hyperglycemia is almost always present, the degree of hyperglycemia does not correlate with the severity of the acidosis. Blood sugar levels are often in the $300\text{--}500\text{ mg} \cdot \text{dl}^{-1}$ range. The patient is always dehydrated because of the combination of the hyperglycemia-induced osmotic diuresis and the nausea and vomiting typical of this syndrome. Because leukocytosis, abdominal pain, GI ileus, and mildly elevated amylase levels are all common in ketoacidosis, an occasional patient is misdiagnosed as having an intra-abdominal surgical problem.

Treatment of diabetic ketoacidosis includes insulin administration and fluid and electrolyte replacement (Table 41-10). An iv bolus of 10–20 units of insulin achieves rapid maximal effect. Further insulin can be administered by iv infusion or intermittent bolus every 30–60 minutes. When blood glucose levels decrease below $250\text{ mg} \cdot \text{dl}^{-1}$, glucose should be added to the iv fluid while insulin therapy continues. Fluid requirements can be marked; 1–2 liters of normal saline, or equivalent, should be given over 1–2 hours. Further deficits can be replaced more gradually. Potassium replacement is a key concern in patients with diabetic ketoacidosis. Because of the diuresis, the total body potassium stores are reduced. However, acidosis by itself causes a shift of potassium ions out of the cell. Thus, the serum potassium concentration may be normal or even slightly elevated while the patient is acidotic. As soon as the metabolic acidosis is corrected, the potassium ions shift back into the cells. Consequently, the serum potassium concentration can decline acutely. Therefore, early and vigorous potassium replacement is required in these patients, with the exception of those patients in renal failure. Hypophosphatemia also occurs with the correction of the acidosis and, if severe, may cause impairment of ventilation resulting from skeletal muscle weakness in the vulnerable patient. Instead of diabetic ketoacidosis, the diabetic patient with a metabolic acidosis may have lactic acidosis, which results from poor tissue perfusion or sepsis. It is diagnosed by the presence of an increased serum lactate concentration without an elevated ketone concentration.

Regular insulin 10 units iv bolus followed by an insulin infusion
nominally at $(\text{blood glucose}/150)\text{ units} \cdot \text{h}^{-1}$
Isotonic iv fluids as guided by vital signs and urine output; antici-
pate 4–10 l deficit
When urine output is $>0.5\text{ ml} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$, give potassium chloride
 $10\text{--}40\text{ mEq} \cdot \text{h}^{-1}$ (with continuous ECG monitoring when the rate
is greater than $10\text{ mEq} \cdot \text{h}^{-1}$)
When serum glucose decreased to $250\text{ mg} \cdot \text{dl}^{-1}$, add dextrose 5% at
 $100\text{ ml} \cdot \text{h}^{-1}$
Consider sodium bicarbonate to correct pH <7.1

iv = intravenous.

Table 41-10. MANAGEMENT OF DIABETIC KETOACIDOSIS

Diabetic ketoacidosis must also be distinguished from the syndrome of alcoholic ketoacidosis. This typically occurs in the poorly nourished alcoholic patient after acute intoxication. Except for the presence of chemical ketoacidosis, alcoholic ketoacidosis is not clinically related in any way to diabetes mellitus. The alcoholic patient may be hypoglycemic or mildly hyperglycemic. The predominant ketone in this syndrome is b-hydroxybutyrate, which tends to react less sensitively in the standard laboratory nitroprusside reaction measurement of ketones. Hence, the diagnosis may be obscured. Administration of dextrose and parenteral fluids is the specific treatment for alcoholic ketoacidosis; insulin is not indicated (except in the rare circumstance in which the patient also has clear-cut diabetes mellitus).

Hypoglycemia

Hypoglycemia is the clinical occurrence most feared in the management of diabetic patients.⁷³ The precise level at which symptomatic hypoglycemia occurs is variable. The normal, fasted patient may have blood sugar levels lower than $50\text{ mg} \cdot \text{dl}^{-1}$ without symptoms. However, the diabetic patient who has a chronically elevated blood sugar level may be symptomatic at levels significantly above this glucose concentration. Hypoglycemia is almost impossible to diagnose clinically in the unconscious patient.

In the awake patient, hypoglycemia often produces central nervous system changes ranging from light-headedness to coma with seizures. Often the patient recognizes the symptoms and can tell that the blood sugar is low before any overt clinical signs develop. With hypoglycemia, there is a reflex catecholamine release that produces overt sympathetic hyperactivity causing tachycardia, lacrimation, diaphoresis, and hypertension. In the anesthetized patient, these signs of sympathetic hyperactivity can easily be misinterpreted as inadequate or "light" anesthesia. In the anesthetized, sedated, or seriously ill patient, the mental changes of hypoglycemia are also unrecognizable. Furthermore, in patients being treated with b-adrenergic blocking agents or in patients with advanced diabetic autonomic neuropathy, the sympathetic hyperactivity of hypoglycemia may be obscured. Thus, the clinical diagnosis of hypoglycemia in the surgical patient may be difficult to make, and only a high degree of

suspicion and frequent blood glucose checks can prevent this complication.

Hypoglycemia is more likely to occur in the diabetic surgical patient under certain circumstances. With renal insufficiency, the action of insulin and oral hypoglycemic agents is prolonged. This is a common problem owing to the prevalence of renal disease in the diabetic. Because some of the oral agents, especially chlorpropamide, can have long-lasting effects, an accurate medical history with attention to medications taken in the past day or two is essential. A frequent and totally avoidable cause of inadvertent hypoglycemia is the administration of insulin to a patient who is not receiving sufficient oral or iv caloric input. For the purpose of preventing hypoglycemia, transfused blood has a low glucose concentration (even with citrate–phosphate–dextrose added, it contains only ~2 g of glucose per unit); lactated Ringer's solution is also inadequate (the lactate is metabolized to produce ~9 kcal · l⁻¹).

The anesthesiologist must recognize that hypoglycemia in the critically ill or anesthetized patient is a serious hazard that may be difficult to diagnose. It is therefore reasonable to aim for mild hyperglycemia as the goal in diabetes management in these patients. There is considerable discussion by endocrinologists over how close to normal the blood sugar level should be maintained (chronic management) in long-standing diabetes to avoid the end-organ damage that diabetes can produce in the eyes, kidneys, nerves, and blood vessels. In the perioperative period, it is unlikely that such chronic damage is exacerbated by mild hyperglycemia.

PITUITARY GLAND

The pituitary gland is located below the base of the brain in a bony structure, the sella turcica. The pituitary gland and the hypothalamus together form a central unit that regulates the release of various hormones. The pituitary gland is divided into two components. The anterior pituitary (adenohypophysis) secretes prolactin, growth hormone, gonadotropins (luteinizing hormone and follicle-stimulating hormone), TSH, and ACTH. The posterior pituitary (neurohypophysis) secretes the hormones vasopressin and oxytocin. Hormone release from the anterior and posterior pituitary is regulated by the hypothalamus. Regulatory peptides or preformed hormones from the hypothalamus are transported to the pituitary gland through vascular or tissue connections.

Anterior Pituitary

Hyposecretion of anterior pituitary hormones is usually due to compression of the gland by tumor. This may begin as an isolated deficiency, but it usually develops into multiglandular dysfunction. Male impotence or secondary amenorrhea in the woman is an early manifestation of panhypopituitarism. Panhypopituitarism after postpartum hemorrhagic shock (Sheehan's syndrome) is due to necrosis of the anterior pituitary gland. Radiation therapy delivered to the sella turcica or nearby structures and surgical hypophysectomy are other causes of panhypopituitarism. Panhypopituitarism is treated with specific hormone replacement therapy, which should be continued in the perioperative period. Stress doses of corticosteroids are necessary for patients receiving steroid replacement due to inadequate ACTH.

The hypersecretion of various anterior pituitary hormones is usually caused by an adenoma. Excess prolactin secretion with galactorrhea is a common hormonal abnormality associated with pituitary adenoma. Cushing's disease may occur secondary to excess ACTH production, and gigantism or acromegaly may occur as a consequence of excess growth hormone production in the child or adult, respectively. Excessive secretion of TSH is rare.

Acromegaly in the adult patient may pose several problems for the anesthesiologist.⁷⁴ Excess hypertrophy occurs in skeletal, connective, and soft tissues.⁷⁵ The tongue and epiglottis are enlarged, making the patient susceptible to upper airway obstruction. Hoarseness may reflect thickening of the vocal cords or paralysis of a recurrent laryngeal nerve due to stretching. Dyspnea or stridor is associated with subglottic narrowing. Peripheral nerve or artery entrapment, hypertension, and diabetes mellitus are other common findings. The anesthetic management of these patients is complicated by distortion of the facial anatomy and upper airway. Induction of general anesthesia may put the patient at increased risk if mask fit or vocal cord visualization is impaired. When the preoperative history suggests upper airway or vocal cord involvement, it is prudent to consider intubation of the trachea while the patient is awake.

Posterior Pituitary

The posterior pituitary, or neurohypophysis, is composed of terminal nerve endings that extend from the ventral hypothalamus. Vasopressin (antidiuretic hormone [ADH]) and oxytocin are the two principal hormones secreted by the posterior pituitary. Both hormones are synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. They are bound to inactive carrier proteins, neurophysins, and transported by axons to membrane-bound storage vesicles located in the posterior pituitary. ADH is a nonapeptide that circulates as a free peptide after its release. The primary functions of ADH are the maintenance of extracellular fluid volume and regulation of plasma osmolality. Oxytocin elicits contraction of the uterus and promotes milk secretion and ejection by the mammary glands.

Vasopressin

Antidiuretic hormone promotes resorption of solute-free water by increasing cell membrane permeability to water alone. The target sites for ADH are the collecting tubules of the kidneys. A decrease in free water clearance causes a decrease in serum osmolality and a corresponding increase in circulating blood volume. Under normal conditions, the primary stimulus for the release of ADH is an increase in serum osmolality.

Osmoreceptors located in the hypothalamus are sensitive to changes in the normal serum osmolality of as little as 1% (normal osmolality is approximately 285 mOsm · l⁻¹). Stretch receptors in the left atrium and perhaps pulmonary veins, which are sensitive to moderate reductions in the blood volume, are also capable of stimulating ADH secretion. The need to restore plasma volume may at times override osmotic inhibition of ADH release. Various physiologic and pharmacologic stimuli also influence the secretion of ADH. Positive pressure ventilation of the lungs, stress, anxiety, hyperthermia, b-adrenergic stimulation, and any histamine-releasing stimulus can promote the release of ADH.

Antidiuretic hormone also has other actions. ADH can increase blood pressure by constricting vascular smooth muscle. This activity is most significant in the splanchnic, renal, and coronary vascular beds and provides the rationale for administering exogenous vasopressin in the management of hemorrhage due to esophageal varices. Caution must be taken when this drug is used in patients with coronary artery disease. ADH (even in small doses) can precipitate myocardial ischemia through vasoconstriction of the coronary arteries. It is unclear whether selective arterial infusion is safer than systemic administration with regard to cardiac and vascular side effects.

Antidiuretic hormone also promotes hemostasis through an increase in the level of circulating von Willebrand factor and factor VIII. Desmopressin (DDAVP), an analogue of ADH, administered to patients after cardiopulmonary bypass in a dose of 0.3 µg · kg⁻¹ significantly decreased blood loss and reduced transfusion requirements compared with a group of patients who did not receive the drug. DDAVP is also frequently used to reverse the coagulopathy of renal failure.

Diabetes Insipidus

This disorder results from inadequate secretion of ADH or resistance on the part of the renal tubules to ADH (nephrogenic diabetes insipidus). Failure to secrete adequate amounts of ADH results in polydipsia, hypernatremia, and a high output of poorly concentrated urine. Hypovolemia and hypernatremia may become so severe as to be life threatening. This disorder usually occurs after destruction of the pituitary gland by intracranial trauma, infiltrating lesions, or surgery. Patients in whom diabetes insipidus develops secondary to severe head trauma or subarachnoid hemorrhage often have impending brain death.⁷⁶ The treatment of diabetes insipidus depends on the extent of the hormonal deficiency. During surgery, the patient with complete diabetes insipidus receives an iv infusion of aqueous ADH (100–200 mU · h⁻¹) combined with administration of an isotonic crystalloid solution. The serum sodium and plasma osmolality are measured on a regular basis, and therapeutic changes are made accordingly. ADH also may be given intramuscularly (as vasopressin tannate in oil). DDAVP administered intranasally has prolonged antidiuretic activity (12–24 hours) and is associated with a low incidence of pressor effects. As a consequence of the large outpouring of ADH in response to surgical stress, patients with a residually functioning gland usually do not need parenteral ADH during the perioperative period unless the plasma osmolality rises above 290 mOsm · l⁻¹. Nonhormonal agents that have efficacy in the treatment of incomplete diabetes insipidus include the oral hypoglycemic chlorpropamide (200–500 mg · day⁻¹). This drug stimulates the release of ADH and sensitizes the renal tubules to the hormone. Hypoglycemia is a serious side effect that limits the usefulness of the drug. Clofibrate, a hypolipidemic agent, is also capable of stimulating ADH release and has been used in the outpatient setting. None of these medications is effective in the patient with nephrogenic diabetes insipidus. Paradoxically, the thiazide diuretics exert an antidiuretic action in patients with this disorder.

Inappropriate Secretion of Antidiuretic Hormone

The inappropriate and excessive secretion of ADH may occur in association with a number of diverse pathologic processes, including head injuries, intracranial tumors, pulmonary infections, small cell carcinoma of the lung, and hypothyroidism. The clinical manifestations occur as a result of a dilutional hyponatremia, decreased serum osmolality, and a reduced urine output with a high osmolality. Weight gain, skeletal muscle weakness, and mental confusion or convulsions are presenting symptoms. Peripheral edema and hypertension are rare. The diagnosis of the syndrome of inappropriate ADH (SIADH) secretion is one of exclusion, and other causes of hyponatremia must first be ruled out. The prognosis is related to the underlying cause of the syndrome.

The treatment of patients with mild or moderate water intoxication is restriction of fluid intake to 800 ml · day⁻¹. Patients with severe water intoxication associated with hyponatremia and mental confusion may require more aggressive therapy, with the iv administration of a hypertonic saline solution. This may be administered in conjunction with furosemide. Caution must be observed in patients with poor left ventricular function. Isotonic saline is substituted for hypertonic solutions once the serum sodium is brought into a safe range. Too-rapid correction of hyponatremia may induce central pontine myelinolysis and cause permanent brain damage. Serum sodium should not be raised by more than 12 mEq · l⁻¹ in 24 hours. Other drugs that may be used in the patient with SIADH are demeclocycline and lithium. Demeclocycline interferes with the ability of the renal tubules to concentrate urine and is frequently used in outpatients. Lithium usually is not used because of the high incidence of toxicity.

ENDOCRINE RESPONSE TO SURGICAL STRESS

Anesthesia, surgery, and trauma elicit a generalized endocrine metabolic response characterized by an increase in the plasma levels of cortisol, ADH, renin, catecholamines, and endorphins and by metabolic changes such as hyperglycemia and a negative nitrogen balance.^{77,78} Various neural and humoral factors (e.g., pain, anxiety, acidosis, local tissue factors, hypoxia) play a role in activating this stress response.

The induction of anesthesia increases the levels of circulating catecholamines and is a form of metabolic stress. Regional anesthesia may block part of the metabolic stress response during surgery, probably by blockade of the neural communications from the surgical area. It is theorized that the persistently high levels of circulating catecholamines in trauma and critical illness lead to stress hyperglycemia through a direct inhibition of insulin release. Bypass of the gut hormonal actions in patients receiving iv glucose feedings, especially if given in large amounts, contributes to the impairment of insulin release during illness and can create a particularly difficult management problem for diabetic patients.

Endorphins are a group of endogenous peptides with opioid activity that have been isolated from the central nervous system. It is well documented that b-endorphin is released from the anterior pituitary, where it is contained as part of b-lipoprotein, a 91-chain amino acid, which is a cleavage product of the precursor peptide for ACTH. Large increases in the central nervous system and plasma concentrations of endorphins in response to emotional or surgical stimuli suggest that these substances play a role in the body's response to stress. These substances modulate painful stimuli by binding to opiate receptors located throughout the brain and spinal cord.

Numerous experiments have focused on the stress response and its relationship to the depth of anesthesia. Regional anesthesia and general anesthesia appear to blunt the release of various stress hormones during the period of surgical stimulation in a dose-dependent fashion. Historically, anesthesiologists have relied on the indirect measurement of hemodynamic variables such as blood pressure and heart rate to evaluate the level of autonomic activity in response to anesthesia and surgery. It is assumed that the physiologic manifestations of stress are potentially harmful, especially in patients with limited functional reserve. As such, our anesthetic techniques and pain management strategies are designed to limit this neurohormonal response, in the hope of providing the patient with some benefit. Further investigations are needed to assess the impact of these efforts on perioperative morbidity and mortality.

PHYSIOLOGIC CHANGES OF PREGNANCY

During pregnancy, there are major alterations in nearly every maternal organ system. These changes are initiated by hormones secreted by the corpus luteum and placenta. The mechanical effects of the enlarging uterus and compression of surrounding structures play an increasing role in the second and third trimesters. This altered physiologic state has relevant implications for the anesthesiologist caring for the pregnant patient. The most relevant changes, involving hematologic, cardiovascular, ventilatory, metabolic, and gastrointestinal functions, are considered here ([Table 42-1](#)).

| Variable | Change | Amount |
|---------------------------------|----------|----------|
| Total blood volume | Increase | 25–40% |
| Plasma volume | Increase | 40–50% |
| Fibrinogen | Increase | 50% |
| Serum cholinesterase activity | Decrease | 20–30% |
| Cardiac output | Increase | 30–50% |
| Minute ventilation | Increase | 50% |
| Alveolar ventilation | Increase | 70% |
| Functional residual capacity | Decrease | 20% |
| Oxygen consumption | Increase | 20% |
| Arterial carbon dioxide tension | Decrease | 10 mm Hg |
| Arterial oxygen tension | Increase | 10 mm Hg |
| Minimum alveolar concentration | Decrease | 32–40% |

Table 42-1. SUMMARY OF PHYSIOLOGIC CHANGES OF PREGNANCY AT TERM

Hematologic Alterations

Increased mineralocorticoid activity during pregnancy produces sodium retention and increased body water content.¹ Thus, plasma volume and total blood volume begin to increase in early gestation, resulting in a final increase of 40–50% and 25–40% respectively, at term. The relatively smaller increase in red blood cell volume (20%) accounts for a reduction in hemoglobin (to 11–12 g · dl⁻¹) and hematocrit (to 35%).¹ The leukocyte count ranges from 8000–10,000 per mm³ throughout pregnancy, whereas the platelet count remains unchanged. Plasma fibrinogen concentrations increase during normal pregnancy by approximately 50%, whereas clotting factor activity is variable.² Serum cholinesterase activity declines to a level of 20% below normal by term, and reaches a nadir in the puerperium. However, it is doubtful that moderate succinylcholine doses lead to prolonged apnea in otherwise normal circumstances.³ Total plasma protein concentration declines to less than 6 g · dl⁻¹ at term, whereas the total amount in the circulation increases.⁴ The albumin–globulin ratio declines because of the relatively greater reduction in albumin concentration. A decrease in serum protein concentration may be clinically significant, in that the free fractions of protein-bound drugs can be expected to increase.

Cardiovascular Changes

As oxygen consumption increases during pregnancy, the maternal cardiovascular system adapts to meet the metabolic demands of a growing fetus. Decreased vascular resistance due to estrogens, progesterone, and prostacyclin may be the initiating factor.⁵ Lowered resistance is found in the uterine, renal, and other vascular beds; at term, there is an increase in heart rate (15–25%), and cardiac output (up to 50%) above that of the nonpregnant state. Arterial blood pressure decreases slightly because the decrease in peripheral resistance exceeds the increase in cardiac output. Additional increases in cardiac output occur during labor (when cardiac output may reach 12–14 · min⁻¹) and also in the immediate postpartum period owing to added blood volume from the contracted uterus.

From the second trimester, aortocaval compression by the enlarged uterus becomes progressively more important, reaching its maximum at 36–38 weeks, after which it may decrease as the fetal head descends into the pelvis.⁶ Studies of cardiac output, measured with the patient in the supine position during the last weeks of pregnancy, have indicated a decrease to nonpregnant levels; however, this decrease was not observed when patients were in the lateral decubitus position.⁶ Supine hypotensive syndrome, which occurs in 10% of pregnant women because of venous occlusion, results in maternal tachycardia, arterial hypotension, faintness, and pallor.⁷ Compression of the lower aorta in this position may further decrease uteroplacental perfusion and result in fetal asphyxia. Therefore, uterine displacement or lateral pelvic tilt should be applied routinely during the second and third trimesters of pregnancy.

Changes in the electrocardiogram may also occur. Left axis deviation results from the upward displacement of the heart by the gravid uterus, and there is also a tendency toward premature atrial contractions, sinus tachycardia, and paroxysmal supraventricular tachycardia.

Ventilatory Changes

Increased extracellular fluid and vascular engorgement may not only lead to edema of the extremities but may compromise the upper airway. Many pregnant women complain of difficulty with nasal breathing, and the friable nature of the mucous membranes during pregnancy can cause severe bleeding, especially on insertion of nasopharyngeal airways or nasogastric and endotracheal tubes. Airway edema may be particularly severe in women with pre-eclampsia, in patients placed in the Trendelenburg position for prolonged periods, or with concurrent use of tocolytic agents. It may also be difficult to perform laryngoscopy in obese, short-necked parturients with enlarged breasts. Use of a short-handled laryngoscope has proved helpful.

The level of the diaphragm rises as the uterus increases in size, and is accompanied by an increase in the anteroposterior and transverse diameters of the thoracic cage. From the fifth month, the expiratory reserve volume, residual volume, and functional residual capacity (FRC) decrease, the latter to 20% less than in the nonpregnant state.⁸ Concomitantly, there is an increase in inspiratory reserve volume, so that total lung capacity remains unchanged. In most pregnant women, a decreased FRC does not cause problems, but those with pre-existing alterations in closing volume as a result of smoking, obesity, or scoliosis may experience early airway closure with advancing pregnancy, leading to hypoxemia. The Trendelenburg and supine positions also exacerbate the abnormal relationship between closing volume and FRC. The residual volume and functional residual capacity return to normal shortly after delivery.

Progesterone-induced relaxation of bronchiolar smooth muscle decreases airway resistance, whereas lung compliance remains unchanged. Minute ventilation increases from the beginning of pregnancy to a maximum of 50% above normal at term.⁸ This is accomplished by a 40% increase in tidal volume and a 15% increase in respiratory rate. Dead space does not change significantly, and thus alveolar ventilation is increased by 70% at term. After delivery, as blood progesterone levels decline, ventilation returns to normal within 1–3 weeks.⁹

Metabolism

Basal oxygen consumption increases during early pregnancy, with an overall increase of 20% by term.⁸ However, increased alveolar ventilation leads to a reduction in the partial pressure of carbon dioxide in arterial blood (PaCO₂) to 32 mm Hg and an increase in the partial pressure of oxygen in arterial blood (PaO₂) to 106 mm Hg. The plasma buffer base decreases from 47 to 42 mEq · l⁻¹, and therefore the pH remains practically unchanged. The maternal uptake and elimination of inhalational anesthetics is enhanced because of the increased alveolar ventilation and decreased FRC.⁹ However, the decreased FRC and increased metabolic rate predispose the mother to development of hypoxemia during periods of apnea/hypoventilation, such as may occur during airway obstruction or prolonged attempts at tracheal intubation.¹⁰

Human placental lactogen and cortisol increase the tendency toward hyperglycemia and ketosis, which may exacerbate pre-existing diabetes mellitus. The patient's ability to handle a glucose load is decreased, and the transplacental passage of glucose may stimulate fetal secretion of insulin, leading in turn to neonatal hypoglycemia in the immediate postpartum period.¹¹

Gastrointestinal Changes

Enhanced progesterone production causes decreased gastrointestinal motility and slower absorption of food. Gastric secretions are more acidic and lower esophageal sphincter (LES) tone is decreased. A delay in gastric emptying can already be demonstrated by the end of the first trimester.¹² Uterine growth leads to upward displacement and rotation of the stomach, with increased pressure and a further delay in gastric emptying. By the 34th week, evacuation of a watery meal may be prolonged by 60%.¹³ Pain, anxiety, and administration of opioids (systemic or neuraxial) and belladonna alkaloids may further exacerbate this delay.

The risk of regurgitation on induction of general anesthesia depends, in part, on the gradient between the LES and intragastric pressures. In most patients, the gradient increases after succinylcholine administration because the increase in LES pressure exceeds the increase in intragastric pressure. However, in parturients with "heartburn," the LES tone is greatly reduced.¹⁴ The efficacy of prophylactic nonparticulate antacids is diminished by inadequate mixing with gastric contents, improper timing of administration, and the tendency for antacids to increase gastric volume. Administration of histamine (H₂) receptor antagonists, such as cimetidine and ranitidine, requires careful timing. A good case can be made for the administration of intravenous (iv) metoclopramide before elective cesarean section. This dopamine antagonist hastens gastric emptying and increases resting LES tone in both nonpregnant and pregnant women.¹⁵ However, conflicting reports have appeared on its efficacy and on the frequency of side effects such as extrapyramidal reactions and transient neurologic dysfunction.^{16,17} Although no routine prophylactic regimen can be recommended with certainty, it is the authors' preference to administer at least a nonparticulate antacid before cesarean section and to use regional anesthesia whenever possible. A rapid-sequence induction of anesthesia, application of cricoid pressure, and intubation with a cuffed endotracheal tube are required for all pregnant women receiving general anesthesia from the 12th week of gestation.¹² These recommendations also pertain to women in the immediate postpartum period because there is uncertainty as to when gastric volume returns to normal.

Altered Drug Responses

The minimum alveolar concentration (MAC) for inhalational agents is decreased by 8–12 weeks of gestation and may be related to an increase in progesterone levels.¹⁸ In addition, lower doses of local anesthetic are needed per dermatomal segment of epidural or spinal block. This has been attributed to an increased spread of local anesthetic in the epidural and subarachnoid spaces, which occurs as a result of epidural venous engorgement. An increased neural sensitivity to local anesthetics also has been suggested, which may be mediated by progesterone.¹⁹

FETAL EXPOSURE TO DRUGS USED IN OBSTETRIC ANESTHESIA

It is generally accepted that most drugs, including anesthetic agents, readily cross the placenta. The development of highly sensitive and specific techniques for drug analysis and a better understanding of the fetal circulation have improved our comprehension of fetal drug exposure.

Placental Transfer

Several factors influence the placental transfer of drugs, including the physicochemical characteristics of the drug itself, maternal drug concentrations in the plasma, properties of the placenta, and hemodynamic events within the fetomaternal unit.

Drugs cross biologic membranes by simple diffusion, the rate of which is determined by the Fick principle, which states that:

$$Q/t = KA(C_m - C_f)/D$$

where Q/t = rate of diffusion, K = diffusion constant, A = surface area available for exchange, C_m = concentration of free drug in maternal blood, C_f = concentration of

free drug in fetal blood, and D = thickness of diffusion barrier.

The diffusion constant (K) of the drug depends on physicochemical characteristics such as molecular size, lipid solubility, and degree of ionization. Compounds with a molecular weight of less than 500 daltons are unimpeded in crossing the placenta, whereas those with molecular weights of 500–1000 daltons are more restricted. Most drugs commonly used by the anesthesiologist have molecular weights that permit easy transfer.

If blood flow to the fetal side of the placenta can be measured, as in some animal models, calculating the placental clearance may be a more appropriate way of expressing drug transfer to the fetus.²⁰

Drugs that are highly lipid soluble cross biologic membranes more readily, and the degree of ionization is important because the nonionized moiety of a drug is more lipophilic than the ionized one. Local anesthetics and opioids are weak bases, with a relatively low degree of ionization and considerable lipid solubility. In contrast, muscle relaxants are less lipophilic and more ionized, and their rate of placental transfer is therefore more limited. The relative concentrations of drug existing in the nonionized and ionized forms can be predicted from the Henderson-Hasselbalch equation:

$$pH = pKa + \log(\text{base}) / (\text{cation})$$

The ratio of base to cation becomes particularly important with local anesthetics because the nonionized form penetrates tissue barriers, whereas the ionized form is pharmacologically active in blocking nerve conduction. The pKa is the pH at which the concentrations of free base and cation are equal. For the amide local anesthetics, the pKa values (7.7–8.1) are sufficiently close to physiologic pH that changes in maternal or fetal biochemical status may significantly alter the proportion of ionized and nonionized drug present (Fig. 42-1). At equilibrium, the concentrations of nonionized drug in the fetal and maternal plasma are equal. In the case of the acidotic fetus, a greater tendency for drug to exist in the ionized form, which cannot diffuse back across the placenta into the maternal plasma, causes a larger total amount of drug to accumulate in the fetal plasma and tissues. This is the mechanism for the phenomenon termed *ion trapping*.²¹

The effects of maternal plasma protein binding on the rate and amount of drug transferred to the fetus are not so well understood. Animal studies have shown that the transfer rate is slower for drugs that are extensively bound to maternal plasma proteins, such as bupivacaine.²² In sheep, the low fetomaternal ratio of bupivacaine plasma concentrations has been attributed to the difference between fetal and maternal plasma protein binding, rather than to extensive fetal tissue uptake.²³ However, if enough time is allowed for fetomaternal equilibrium to be approached, substantial accumulation of highly protein-bound drugs, such as bupivacaine, can occur in the fetus.²⁴

As already stated, the driving force for placental drug transfer is the concentration gradient of free drug between the maternal and fetal blood. On the maternal side, the following factors interact: the dose administered, the mode and site of administration, and, in the case of local anesthetics, the use of vasoconstrictors. The rates of distribution, metabolism, and excretion of the drug, which may vary at different stages of pregnancy, are equally important. In general, higher doses result in higher maternal blood concentrations. The absorption rate varies with the site of drug injection. Compared with other forms of administration, an iv bolus results in the highest blood concentrations. It was believed that intrathecal administration of local anesthetics resulted in negligible plasma concentrations because of the small doses used and the relatively poor vascularity of this area. However, spinal anesthesia induced with lidocaine 75 mg has resulted in maternal plasma concentrations of drug that were similar to those reported by others after epidural anesthesia.²⁵ Furthermore, significant levels of the drug were found in the umbilical vein at birth.

Increased maternal blood concentrations after repeated administration of a drug greatly depend on the dose and frequency of reinjection, in addition to the kinetic characteristics of the drug. The elimination half-life of amide local anesthetic agents is relatively long, so that repeated injection may lead to accumulation in the maternal plasma²⁶ (Fig. 42-2). In contrast, 2-chloroprocaine, an ester local anesthetic, undergoes rapid enzymatic hydrolysis in the presence of pseudocholinesterase. After epidural injection, the mean half-life in the mother was shown to be approximately 3 minutes; after reinjection, 2-chloroprocaine could be detected in the maternal plasma for only 5–10 minutes, and no accumulation of this drug was evident²⁷ (Fig. 42-3).

(Reprinted with permission from Kuhnert BR, Kuhnert PM, Prochaska AL *et al*: Plasma levels of 2-chloroprocaine in obstetric patients and their neonates after

Pregnancy is associated with physiologic changes that may influence maternal pharmacokinetics and the action of anesthetic drugs. These changes may be progressive during the course of gestation and are often difficult to predict. Kinetic studies after thiopental injection for induction of anesthesia showed a longer elimination half-life and a larger volume of distribution than were noted in a group of nonpregnant women.²⁸ In contrast, the elimination half-life of bupivacaine after epidural injection was similar in pregnant and nonpregnant women.²⁹ Alterations in ventilation and lung volumes have a significant effect on the rate of uptake and excretion of inhalation agents. Of most concern to the anesthesiologist is a 20% reduction in FRC.⁸ As a result, the equilibration time between the alveolar and inspired concentrations of inhalation agents is shortened.

Placenta

Maturation of the placenta can affect the rate of drug transfer to the fetus, as the thickness of the trophoblastic epithelium decreases from 25 to 2 mm at term. In pregnant mice, diazepam and its metabolites are transferred more rapidly in late than in early pregnancy.³⁰

Uptake and biotransformation of anesthetic drugs by the placenta would decrease the amount transferred to the fetus. However, placental drug uptake is limited, and there is no evidence to suggest that this organ metabolizes any of the agents commonly used in obstetric anesthesia.

Hemodynamic Factors

Any factor decreasing placental blood flow, such as aortocaval compression, hypotension resulting from sympathetic blockade, or hemorrhage, can decrease drug delivery to the fetus. During labor, uterine contractions intermittently reduce perfusion of the placenta. If a uterine contraction coincides with a rapid decline in plasma drug concentration after an iv bolus injection, by the time perfusion has returned to normal, the concentration gradient across the placenta has been greatly reduced. When women were given an iv injection of diazepam, administered at the onset of contraction in one group and during uterine diastole in the other, less drug was found in infants born to mothers in the former group.³¹

Several characteristics of the fetal circulation delay equilibration between the umbilical arterial and venous blood, and thus delay the depressant effects of anesthetic drugs (Fig. 42-4). The liver is the first fetal organ perfused by umbilical vein blood, which carries drug to the fetus. Substantial uptake by this organ has been demonstrated for a variety of drugs, including thiopental, lidocaine, and halothane. During its transit to the arterial side of the fetal circulation, the drug is progressively diluted as blood in the umbilical vein becomes admixed with fetal venous blood from the gastrointestinal tract, the lower extremities, the head and upper extremities, and, finally, the lungs. Because of this unique pattern of fetal circulation, continuous administration of anesthetic concentrations of nitrous oxide or cyclopropane during elective cesarean sections caused newborn depression only if the induction-to-delivery interval exceeded 5–10 minutes. Because of the rapid decline in maternal plasma drug concentrations, administration of thiopental or thiamylal as a single bolus injection not exceeding 4 mg · kg⁻¹ was followed by fetal arterial concentrations of barbiturate below a level that would result in neonatal depression³² (Fig. 42-5).

Figure 42-4. Diagram of the circulation in the mature fetal lamb. The numerals indicate the mean oxygen saturation (%) in the great vessels of six lambs: right ventricle (RV); left ventricle (LV); superior vena cava (SVC); inferior vena cava (IVC); brachiocephalic artery (BCA); foramen ovale (FO); ductus arteriosus (DA); ductus venosus (DV). (Reprinted with permission from Kosaka Y, Takahashi T, Mark LS: Intravenous thiobarbiturate anesthesia for cesarean section. *Anesthesiology* 31:489, 1969.)

Fetal regional blood flow changes can also affect the amount of drug taken up by individual organs. For example, during asphyxia and acidosis, a greater proportion of the fetal cardiac output perfuses the fetal brain, heart, and placenta. Infusion of lidocaine resulted in increased drug uptake in the heart, brain, and liver of asphyxiated baboon fetuses compared with nonasphyxiated control fetuses.³³

Fetus and Newborn

Any drug that reaches the fetus undergoes metabolism and excretion. In this respect, the fetus has an advantage over the newborn in that it can excrete the drug back to the mother once the concentration gradient of the free drug across the placenta has been reversed. With the use of local anesthetics, this may occur even though the total plasma drug concentration in the mother may exceed that in the fetus, because there is lower protein binding in fetal plasma.²³ There is only one drug, 2-chloroprocaine, that is metabolized in the fetal blood so rapidly that even in acidosis, substantial accumulation in the fetus is avoided.²⁷

In the term as well as the preterm newborn, the liver contains enzymes essential for the biotransformation of amide local anesthetics. A study comparing the pharmacokinetics of lidocaine among adult ewes and lambs (fetal and neonatal) showed that the metabolic clearance in the newborn was similar to, and renal clearance greater than, that in the adult.³⁴ Nonetheless, the elimination half-life was prolonged in the newborn. This was attributed to a greater volume of distribution and tissue uptake of the drug, so that at any given time the neonate's liver and kidneys were exposed to a smaller fraction of lidocaine accumulated in the body. Similar results were reported in another study involving lidocaine administration to human infants in a neonatal intensive care unit.³⁵ Prolonged elimination half-lives in the newborn compared with the adult have been noted for other amide local anesthetics.

The question remains whether the fetus and newborn are more sensitive than adults to the depressant and toxic effects of drugs. Laboratory investigations have shown

that the newborn is, in fact, more sensitive to the depressant effects of opioids. With local anesthetics, neonatal depression occurred at blood concentrations of mepivacaine or lidocaine that were approximately 50% less than those producing toxic manifestations in the adult. However, infants accidentally injected *in utero* with mepivacaine, intended for maternal caudal anesthesia, stopped convulsing when the drug concentration decreased below the threshold level for convulsions in the adult.³⁶ The relative central nervous and cardiorespiratory toxicity of several local anesthetics has been studied in adult ewes and lambs (fetal and neonatal).³⁷ The doses required to produce toxicity in the fetus and newborn were greater than those required in the adult. In the fetus, this difference was attributed to placental clearance of drug into the mother and better maintenance of blood gas tensions during convulsions, whereas in the newborn, a larger volume of distribution is probably responsible for the higher doses needed to induce toxic effects.

Bupivacaine has been implicated as a possible cause of neonatal jaundice because its high affinity for fetal erythrocyte membranes may lead to a decrease in filterability and deformability, rendering them more prone to hemolysis. However, a more recent study has failed to show increased bilirubin production in newborns whose mothers received bupivacaine for epidural anesthesia during labor and delivery.³⁸ Finally, neurobehavioral studies have revealed subtle changes in newborn neurologic and adaptive function. In the case of most anesthetic agents, these changes are minor and transient, lasting for only 24–48 hours.³⁹

ANESTHESIA FOR LABOR AND VAGINAL DELIVERY

Most women experience moderate to severe pain during parturition. In the first stage of labor, pain is caused by uterine contractions, associated with dilation of the cervix and stretching of the lower uterine segment. Pain impulses are carried in visceral afferent type C fibers accompanying the sympathetic nerves. In early labor, only the lower thoracic dermatomes (T11–12) are affected, but with progressing cervical dilation in the transition phase, adjacent dermatomes may be involved and pain referred from T10 to L1. In the second stage, additional pain impulses due to distention of the vaginal vault and perineum are carried by the pudendal nerves, composed of lower sacral fibers (S2–4).

Well conducted obstetric analgesia, in addition to relieving pain and anxiety, may benefit the mother. For instance, in animal studies, pain has been shown to result in maternal hypertension and reduced uterine blood flow.⁴⁰ During the first and second stages of labor, epidural analgesia blunts the increases in maternal cardiac output, heart rate, and blood pressure that occur with painful uterine contractions and “bearing-down” efforts.⁴¹ In reducing maternal secretion of catecholamines, epidural analgesia may convert a previously dysfunctional labor pattern to normal.⁴² Maternal analgesia may also benefit the fetus by eliminating maternal hyperventilation, which often leads to a reduced fetal arterial oxygen tension because of a leftward shift of the maternal oxygen–hemoglobin dissociation curve.⁴³

The most frequently chosen methods for relieving the pain of parturition are psychoprophylaxis, systemic medication, and regional analgesia. Inhalational analgesia, conventional spinal analgesia, and paracervical blockade are less commonly used. General anesthesia is rarely necessary but may be indicated for uterine relaxation in some complicated deliveries.

Psychoprophylaxis

The philosophy of prepared childbirth maintains that lack of knowledge, misinformation, fear, and anxiety can heighten a patient's response to pain and consequently increase the need for analgesics. Although there is no question that an informed patient is better equipped for the stresses of parturition, few women are able to withstand labor without some pharmacologic analgesia.⁴⁴ The most popular method of prepared childbirth is that introduced by Lamaze. It provides an educational program on the physiology of parturition and attempts to diminish cortical pain perception by encouraging responses such as specific patterns of breathing and focused attention on a fixed object.⁴⁵ However, labors do vary in length and intensity; thus, it is realistic to encourage the mother in the Lamaze method while recognizing individual variations in pain tolerance and need for pain relief. Of course, medication should not be withheld if required. Neonatal outcome appears to be similar for women who deliver infants solely with the Lamaze technique and for women who receive appropriate supplementary analgesia.

Systemic Medication

The advantages of systemic analgesics include ease of administration and patient acceptability. However, the drug, dose, time, and method of administration must be chosen carefully to avoid maternal or neonatal depression. Drugs used for systemic analgesia are opioids, tranquilizers, and occasionally ketamine.

Opioids

Meperidine is the most commonly used systemic analgesic and is reasonably effective in ameliorating pain during the first stage of labor. It can be administered by iv injection (effective analgesia in 5–10 minutes) or intramuscularly im (im; peak effect in 40–50 minutes). The major side effects are a high incidence of nausea and vomiting, dose-related depression of ventilation, orthostatic hypotension, and the potential for neonatal depression. Meperidine may cause transient alterations of the fetal heart rate, such as decreased beat-to-beat variability and tachycardia. Among other factors, the risk of neonatal depression is related to the interval from the last drug injection to delivery.⁴⁶ The placental transfer of an active metabolite, normeperidine, which has a long elimination half-life in the neonate (62 hours), has also been implicated in contributing to neonatal depression and subtle neonatal neurobehavioral dysfunction.⁴⁶

Experience with the newer synthetic opioids, such as fentanyl and alfentanil, has been limited. Although they are potent, their use during labor is restricted by their short duration of action. For example, a single iv injection of fentanyl, up to $1 \mu\text{g} \cdot \text{kg}^{-1}$, results in prompt pain relief without severe neonatal depression.⁴⁷ These drugs offer an advantage when analgesia of rapid onset but short duration is necessary (e.g., with forceps application). For more prolonged analgesia, fentanyl can be administered with patient-controlled delivery devices.⁴⁸ Remifentanyl is a new opioid that is rapidly metabolized by serum and tissue cholinesterases, and consequently, has a short (3-minute), context-sensitive half-time.⁴⁹ In one study, Apgar and neurobehavioral scores were good in neonates whose mothers were given an intravenous infusion of remifentanyl, $0.1 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, during cesarean delivery under epidural anesthesia.⁵⁰ Unfortunately, there are no studies of the use of remifentanyl for labor analgesia. Opioid agonists–antagonists, such as butorphanol and nalbuphine, have also been used for obstetric analgesia. These drugs have the proposed benefits of a lower incidence of nausea, vomiting, and dysphoria, as well as a “ceiling effect” on depression of ventilation. However, studies for the most part have not demonstrated a clear advantage over meperidine during parturition.⁵¹ Butorphanol is probably most popular; unlike meperidine, it is biotransformed into inactive metabolites and has a ceiling effect on depression of ventilation in doses exceeding 2 mg. A potential disadvantage is a high incidence of maternal sedation. The recommended dose is 1–2 mg by iv or im injection. Nalbuphine, 10 mg iv or im, is an alternative to butorphanol.

Naloxone, a pure opioid antagonist, should not be administered to the mother shortly before delivery to prevent neonatal ventilatory depression because it reverses maternal analgesia at a time when it is most needed and, in some instances, has caused maternal pulmonary edema and even cardiac arrest. If necessary, the drug should be given directly to the newborn im ($0.1 \text{ mg} \cdot \text{kg}^{-1}$).

Ketamine

Ketamine is a potent analgesic. However, it may also induce unacceptable amnesia that may interfere with the mother's recollection of the birth. Nonetheless, ketamine is a useful adjuvant to incomplete regional analgesia during vaginal delivery or for obstetric manipulations. In low doses ($0.2\text{--}0.4 \text{ mg} \cdot \text{kg}^{-1}$), ketamine provides adequate analgesia without causing neonatal depression.

Regional Analgesia

Regional techniques provide excellent analgesia with minimal depressant effects in mother and fetus. The regional techniques most commonly used in obstetric anesthesia include central neuraxial blocks (spinal, epidural, and combined spinal–epidural), paracervical and pudendal blocks, and, less frequently, lumbar sympathetic blocks (LSB). Hypotension resulting from sympathectomy is the most frequent complication that occurs with central neuraxial blockade. Therefore, maternal blood pressure must be monitored at regular intervals, typically every 2–5 minutes for approximately 15–20 minutes after the initiation of the block and at routine intervals thereafter. The use of regional analgesia may be contraindicated in the presence of severe coagulopathy, acute hypovolemia, or infection at the site of needle insertion. Chorioamnionitis itself, without frank sepsis, is not a contraindication to central neuraxial blockade in obstetrics.

Epidural Analgesia

Epidural analgesia may be used for pain relief during labor, vaginal delivery, and for anesthesia during cesarean delivery, if required. Effective analgesia during the first stage of labor may be achieved by blocking the T10–L1 dermatomes with low concentrations of local anesthetic. For the second stage of labor and delivery, because of pain due to vaginal distention and perineal pressure, the block should be extended to include the S2–4 segments.

Because of ethical considerations and methodologic difficulties, it is difficult to design clinical studies to examine the effects of epidural analgesia on the progress of labor and mode of delivery. In general, the first stage of labor is not prolonged by epidural analgesia, provided aortocaval compression is avoided.^{52,53,54,55} and ⁵⁶ There

has been concern that early initiation of epidural analgesia during the latent phase of labor (2–4 cm cervical dilation) in nulliparous women may result in a higher incidence of dystocia and cesarean delivery.^{54,55,56 and 57} However, this has largely been dispelled by several large, randomized, prospective studies. Chestnut *et al*^{62,53} demonstrated that there was no significant difference in the incidence of cesarean delivery between nulliparous women having epidural analgesia initiated during the latent phase (<14 cm dilation) compared with control group whose analgesia was initiated during the active phase. Similarly, other investigators have demonstrated that epidural analgesia was not associated with an increased incidence of cesarean delivery compared with patient-controlled iv analgesia in nulliparous women.^{55,56} However, a prolongation of the second stage of labor has been reported in nulliparous women, possibly owing to a decrease in expulsive forces or malposition of the vertex.^{52,53,54,55,56 and 57} Thus, with use of epidural analgesia, the American College of Obstetricians and Gynecologists have redefined an abnormally prolonged second stage of labor as greater than 3 hours in nulliparous and 2 hours in multiparous women.⁵⁸ Prolongation of the second stage may be minimized by the use of an ultradilute local anesthetic solution in combination with opioid.⁵⁹ Long-acting amides such as bupivacaine, ropivacaine, or levobupivacaine are most frequently used because they produce excellent sensory analgesia while sparing motor function, particularly at the low concentrations used for epidural analgesia. Analgesia for the first stage of labor may be achieved with 5–10 ml of bupivacaine, ropivacaine, or levobupivacaine (0.125–0.25%), followed by a continuous infusion (8–12 ml · h⁻¹) of 0.0625% bupivacaine or levobupivacaine, or 0.1% ropivacaine. Addition of fentanyl 1–2 µg · ml⁻¹ or sufentanil 0.3–0.5 µg · ml⁻¹ is often required. During the delivery, the sacral dermatomes may be blocked with 10 ml of 0.5% bupivacaine, 1% lidocaine, or, if a rapid effect is required, 2% chloroprocaine, in the semirecumbent position.

There is controversy regarding the need for a test dose when using an ultradilute solution of local anesthetic.^{60,61} Because catheter aspiration is not always diagnostic, some authors believe that a test dose should be administered to improve detection of an intrathecally or intravascularly placed catheter (see [Lumbar Epidural Anesthesia](#) for cesarean section).

Patient-controlled epidural analgesia (PCEA) is a safe and effective alternative to conventional bolus or infusion techniques.⁶² Maternal satisfaction is excellent and demands on anesthesia manpower reduced. Analgesia is initially achieved with bolus doses of local anesthetic. Once the mother is comfortable, PCEA may then be started with a maintenance infusion (4–8 ml · h⁻¹) of local anesthetic (bupivacaine, levobupivacaine, ropivacaine, 0.0625–0.125%), with or without opioid (fentanyl 1–2 µg · ml⁻¹, sufentanil 0.3–0.5 µg · ml⁻¹). The patient-controlled analgesia pump may be programmed to deliver an epidural bolus of 4 ml with a lockout period of 10 minutes between doses.⁶²

The caudal approach may result in a faster onset of perineal analgesia and therefore, when an imminent vaginal delivery is anticipated, may be preferable to the lumbar epidural approach. However, caudal analgesia is no longer popular because of occasionally painful needle placement, a high failure rate, potential contamination at the injection site, and risks of accidental fetal injection. Before caudal injection, a digital rectal examination must be performed to exclude needle placement in the fetal presenting part.³⁶ Low spinal “saddle block” has virtually eliminated the need for caudal anesthesia in modern practice.

Spinal Analgesia

A single subarachnoid injection for labor analgesia has the advantages of a reliable and rapid onset of neural blockade. However, repeated intrathecal injections may be required for a long labor, thus increasing the risk of postdural puncture headache (PDPH). In addition, the motor block may be uncomfortable for some parturients and may prolong the second stage of labor. Spinal anesthesia is a safe and effective alternative to general anesthesia for instrumental delivery.

Microcatheters were introduced for continuous spinal anesthesia in the 1980s. They were subsequently withdrawn when found to be associated with neurologic deficits, possibly related to maldistribution of local anesthetic in the cauda equina region.⁶³ Fortunately, in a recent multi-institutional study, there were no cases of neurologic complaints after the use of 28-gauge microcatheters for continuous spinal analgesia in laboring women.⁶⁴

Combined Spinal–Epidural Analgesia

Combined spinal–epidural analgesia (CSE) is an ideal analgesic technique for use during labor. CSE combines the rapid, reliable onset of profound analgesia resulting from spinal injection with the flexibility and longer duration of epidural techniques. After identification of the epidural space using a conventional (or specialized) needle, a longer (127-mm), pencil-point spinal needle is advanced into the subarachnoid space through the epidural needle. After intrathecal injection, the spinal needle is removed and an epidural catheter is inserted. Intrathecal injection of fentanyl 10–25 µg or sufentanil 5–10 µg, alone or more commonly in combination with 1 ml of isobaric bupivacaine 0.25%, produces profound analgesia lasting for 90–120 minutes with minimal motor block.⁶⁵ Although opioid alone may suffice for the early latent phase, addition of bupivacaine is usually necessary for satisfactory analgesia during advanced labor. An epidural infusion of bupivacaine 0.03–0.0625% with added opioid may be started within 10 minutes of spinal injection. Alternatively, the epidural component may be activated when necessary. Women with hemodynamic stability and preserved motor function who do not require continuous fetal monitoring may ambulate with assistance.^{66,67} Before ambulation, women should be observed for 30 minutes after intrathecal or epidural drug administration to assess maternal and fetal well-being.

The most common side effects of intrathecal opioids are pruritus, nausea, vomiting, and urinary retention. Rostral spread resulting in delayed respiratory depression is rare with fentanyl and sufentanil, and usually occurs within 30 minutes of injection.⁶⁸ Transient nonreassuring fetal heart rate patterns may occur because of uterine hyperstimulation, presumably as a result of a rapid decrease in maternal catecholamines, or because of hypotension after sympatholysis.⁶⁹ A preliminary study by O’Gorman *et al*⁷⁰ suggests that fetal bradycardia may occur in the absence of uterine hyperstimulation or hypotension and is unrelated to uteroplacental insufficiency. The incidence of fetal heart rate abnormalities may be greater in multiparous women with rapidly progressing, painful labors.⁷¹ Most studies have demonstrated that the incidence of emergency cesarean delivery is no greater after CSE than after conventional epidural analgesia.^{72,73}

Postdural puncture headache is always a risk after intrathecal injection. However, it has been demonstrated that the incidence of cephalalgia is no greater with CSE compared with standard epidural analgesia.⁷⁴

Unintentional intrathecal catheter placement through the dural puncture site is also extremely rare after use of a 26-gauge spinal needle for CSE.⁷⁴ The potential exists for epidurally administered drug to leak into the subarachnoid space after dural puncture, particularly if large volumes of drug are rapidly injected. Indeed, epidural drug requirements are approximately 30% less with CSE than with standard lumbar epidural techniques.⁷⁵

Paracervical Block

Although paracervical block effectively relieves pain during the first stage of labor, the technique has fallen out of favor because it was associated with a high incidence of fetal asphyxia and poor neonatal outcome, particularly with the use of bupivacaine. This may be related to uterine artery constriction or increased uterine tone.⁷⁶ The technique is basically simple and involves a submucosal injection of local anesthetic at the vaginal fornix, near the neural fibers innervating the uterus.

Paravertebral Lumbar Sympathetic Block

Paravertebral LSB is a reasonable alternative when contraindications exist to central neuraxial techniques. LSB interrupts the painful transmission of cervical and uterine impulses during the first stage of labor.⁷⁷ Although there is less risk of fetal bradycardia with LSB compared with paracervical blockade, technical difficulties associated with the performance of the block and risks of intravascular injection have decreased its use in standard practice.

Pudendal Nerve Block

The pudendal nerves, derived from the lower sacral nerve roots (S2–4), supply the vaginal vault, perineum, rectum, and parts of the bladder. The nerves are easily anesthetized transvaginally where they loop around the ischial spines. Ten milliliters of local anesthetic deposited behind each sacrospinous ligament can provide adequate anesthesia for outlet forceps delivery and episiotomy repair.

Inhalation Analgesia

Inhalation analgesia is easily administered and although it does not relieve pain completely, it may make uterine contractions more tolerable. During delivery, a combination of inhalation analgesia with a pudendal block or infiltration of the perineum with a local anesthetic may be satisfactory. A particular advantage of inhalation analgesia is that the desired level of analgesia can be easily and rapidly titrated. However, a major disadvantage of inhalational analgesia is the need for a waste gas scavenging system.

Inhalation anesthetic agents can be self-administered by the patient under supervision. A nitrous oxide inhaler is commercially available for self-administration. The system must be able to deliver a precise concentration of agent over a wide range of inspiratory flow rates. The parturient is instructed to breathe deeply from the

inhaler when she detects the onset of uterine contraction, so that analgesia is established at its peak. Nitrous oxide, 50% by volume, is the most commonly used inhalation agent for analgesia during labor. However, the analgesia provided by intermittently self-administered 50% nitrous oxide alone has been shown to be equivalent to that of a placebo.⁷⁸

General Anesthesia

General anesthesia is rarely used for vaginal delivery, and precautions against gastric aspiration must always be observed. It may be required when time constraints prevent induction of regional anesthesia. Potent inhalation drugs (1.5–2.0 MAC for short periods) can provide uterine relaxation for obstetric maneuvers such as second twin delivery, breech presentation, or postpartum manual removal of a retained placenta. In all cases, preoxygenation and rapid iv induction of anesthesia with the use of cricoid pressure and placement of a cuffed endotracheal tube are required. High inspiratory flows ensure quick delivery of the drug. The depth of anesthesia must be monitored to avoid maternal hemodynamic instability. Immediately after the obstetric manipulation is completed, the potent inhalational agent should be discontinued or reduced to prevent uterine atony and hemorrhage. An intravenous infusion of oxytocin 10–20 units should be commenced to promote uterine contraction. The endotracheal tube should not be removed until the woman is awake and airway reflexes have returned. In current practice, intravenous nitroglycerin (50–500 µg) has replaced the need for general anesthesia for uterine relaxation.^{79,80}

ANESTHESIA FOR CESAREAN SECTION

Despite efforts to promote vaginal birth after previous cesarean delivery, the frequency of cesarean section has remained elevated. The most common indications include failure to progress, nonreassuring fetal status, cephalopelvic disproportion, malpresentation, prematurity, and prior uterine surgery involving the corpus. The choice of anesthesia should depend on the urgency of the procedure, in addition to the condition of the mother and fetus. After a comprehensive discussion of the risks and benefits of all anesthesia options, the mother's wishes should be considered.

Regional Anesthesia

A 1992 survey of obstetric anesthesia practices in the United States revealed that most patients undergoing cesarean section do so under spinal or epidural anesthesia.⁸¹ Regional techniques have several advantages: they lessen the risk of gastric aspiration, avoid the use of depressant anesthetic drugs, and allow the mother to remain awake during delivery. It has also been suggested that operative blood loss is less with regional than general anesthesia. In elective cesarean sections, the duration of antepartum anesthesia does not affect neonatal outcome provided that there is no protracted aortocaval compression or hypotension.⁸² The risk of hypotension is greater than during vaginal delivery because the block must extend to at least the T4 dermatome. In this regard, epidural anesthesia is advantageous because of its slower onset and controllability. Proper positioning and prehydration with at least 10–20 ml · kg⁻¹ of a crystalloid solution is recommended.⁸³ If hypotension occurs despite these measures, left uterine displacement should be increased, the rate of iv infusion augmented, and iv ephedrine 10–15 mg administered incrementally.

Spinal Anesthesia

Subarachnoid block is probably the most commonly administered regional anesthetic for cesarean delivery because of its speed of onset and reliability. It has become an alternative to general anesthesia for emergency cesarean section.⁸⁴ Hyperbaric solutions of lidocaine 5%, tetracaine 1.0%, or bupivacaine 0.75% are available for spinal use. The dosages and duration of action of these local anesthetics are listed in Table 42-2. Using 0.75% hyperbaric bupivacaine, Norris⁸⁵ has shown that it is not necessary to adjust the dose of drug based on the patient's height. Hemodynamic monitoring during cesarean section should be similar to that used for other surgical procedures. Before delivery, oxygen should be routinely administered to optimize fetal oxygenation.

| | Lidocaine 5% in 7.5% Dextrose | Tetracaine 1% in Equal Volume of 10% Dextrose | Bupivacaine 0.75% in 0.25% Dextrose |
|---|----------------------------------|---|--|
| Dosage (mg) according to height (cm) | | | |
| 150–160 | 65 | 8 | 8 |
| 160–182 | 70 | 9 | 10 |
| 182 and taller | 75 | 10 | 12 |
| Onset of action (min) | 1–3 | 3–5 | 2–4 |
| Duration of action (min) | 45–75 | 120–180 | 120–180 |

Table 42-2. LOCAL ANESTHETICS COMMONLY USED FOR CESAREAN SECTION WITH SUBARACHNOID BLOCK

Despite an adequate dermatomal level for surgery, women may experience varying degrees of visceral discomfort, particularly during exteriorization of the uterus and traction on abdominal viscera. Improved perioperative analgesia can be provided by the addition of fentanyl 6.25 µg or 0.1 mg of preservative-free morphine to the local anesthetic solution.⁸⁶ Nausea and vomiting may be alleviated by the administration of droperidol or metoclopramide. Maternal sedation should be avoided if possible.

Lumbar Epidural Anesthesia

In contrast to spinal anesthesia, epidural anesthesia is associated with a slower onset of action and a larger drug requirement to establish an adequate sensory block. The advantages are a reduced risk of PDPH and the ability to titrate the local anesthetic through the epidural catheter. To avoid inadvertent intrathecal or intravascular injection, correct placement of the epidural catheter is essential. This is especially a concern when administering the large doses of local anesthetic required for cesarean delivery.

Aspiration of the epidural catheter for blood or cerebrospinal fluid is not reliable for detection of catheter misplacement. Thus, administration of a test dose has become popular. A small dose of local anesthetic, lidocaine 45 mg or bupivacaine 5 mg, produces a readily identifiable sensory and motor block if injected intrathecally. Addition of epinephrine (15 µg) with careful hemodynamic monitoring may signal intravascular injection when followed by a transient increase in heart rate and blood pressure. However, the use of an epinephrine test dose is controversial because false-positive results do occur in the presence of uterine contractions. In addition, epinephrine may reduce uteroplacental perfusion. Electrocardiography and application of a peak-to-peak heart rate criterion may improve detection.⁸⁷ Use of isoproterenol may be preferable to epinephrine because in the event of intravascular injection, tachycardia is reliably achieved without affecting uteroplacental blood flow,⁸⁸ but, before its use in clinical practice, safety and efficacy studies must be performed. Rapid injection of 1 ml of air with simultaneous precordial Doppler monitoring appears to be a reliable indicator of intravascular catheter placement.⁸⁹ A negative test, although reassuring, does not eliminate the need for fractional administration of local anesthetic.

The most commonly used agents are 2-chloroprocaine 3%, bupivacaine 0.5%, and lidocaine 2% with epinephrine 1:200,000. Adequate anesthesia is usually achieved with 15–25 ml of the solution, given in divided doses. The patient should be monitored as with spinal anesthesia. Because of its extremely high rate of metabolism in maternal and fetal plasma, 2-chloroprocaine provides a rapid-onset, reliable block with minimal risk of systemic toxicity.²⁶ It is the local anesthetic of choice in the presence of fetal acidosis and when a pre-existing epidural block is to be rapidly extended for an urgent cesarean section.⁸⁴ Transient neurologic deficits after massive inadvertent intrathecal administration of the drug have occurred with the formulation containing a relatively high concentration of sodium bisulfite, at a low pH.⁹⁰ In a new formulation of 2-chloroprocaine (Nesacaine-MPF), ethylene diaminetetra-acetic acid (EDTA) has been substituted for sodium bisulfite and, to date, no new cases of neurologic deficit have been reported. However, severe spasmodic back pain has been described after epidural injection of large volumes of Nesacaine-MPF in surgical patients, but not in parturients.⁹¹ This complication has been attributed to EDTA-induced leaching of calcium from paravertebral muscles. The most recent formulation of 2-chloroprocaine contains no additives and is packaged in an amber vial to prevent oxidation. Bupivacaine 0.5% provides profound anesthesia for cesarean section of slower onset but longer duration of action. Considerable attention has been focused on the drug since it was reported that unintentional intravascular injection could result not only in convulsions but in almost simultaneous cardiac arrest, with patients often refractory to resuscitation.⁹² The greater cardiotoxicity of bupivacaine (and etidocaine) compared with other amide local anesthetics has been well established.⁹³ Lidocaine has an onset and duration intermediate to those of 2-chloroprocaine and bupivacaine. The need to include epinephrine in the local anesthetic solution to ensure adequate lumbosacral anesthesia limits the use of lidocaine in the setting of maternal hypertension and uteroplacental insufficiency.

Prolonged postoperative pain relief can be provided by epidural administration of an opioid, such as morphine 4 mg. PCEA is another option. Delayed respiratory depression may occur, particularly with the use of morphine, and hence the patient must be monitored carefully in the postoperative period.

General Anesthesia

General anesthesia may be necessary when contraindications exist to regional anesthesia or when time precludes central neuraxial blockade. General anesthesia with a potent halogenated agent may also be useful in situations where uterine relaxation will facilitate delivery, as with breech presentation, transverse lie, or in women with multiple gestation, who often do not tolerate regional blocks owing to dyspnea and supine hypotension syndrome. General anesthesia should be used cautiously in women with asthma, upper respiratory tract infection, obesity, or a history of difficult tracheal intubation. Preoperative airway evaluation is particularly important in pregnant women because inability to intubate the trachea and provide effective ventilation is the leading cause of maternal death related to anesthesia.⁸¹ If airway difficulties are anticipated, a regional anesthetic technique should be considered, or an awake tracheal intubation performed. Premedication is usually not necessary, except for administration of 15–30 ml of a nonparticulate antacid within 30 minutes of induction of anesthesia. The patient should be positioned with a wedge in place to prevent aortocaval compression. Routine monitoring should be the same as with regional anesthetic techniques, and comply with national standards.

To minimize the risk of hypoxemia during induction, denitrogenation for 3–5 minutes with a tight-fitting mask is essential. In an emergency, four deep breaths with 100% oxygen suffices. A “defasciculating” dose of a nondepolarizing muscle relaxant is not necessary. Rapid-sequence induction is performed with thiopental ($4 \text{ mg} \cdot \text{kg}^{-1}$), ketamine (up to $1 \text{ mg} \cdot \text{kg}^{-1}$), or a combination of thiopental ($2\text{--}3 \text{ mg} \cdot \text{kg}^{-1}$) and ketamine ($0.5 \text{ mg} \cdot \text{kg}^{-1}$), followed by succinylcholine ($1\text{--}1.5 \text{ mg} \cdot \text{kg}^{-1}$) to facilitate intubation. Cricoid pressure is applied by a trained assistant until the airway is properly secured with a cuffed endotracheal tube. If there is difficulty in securing the airway, cricoid pressure should be maintained throughout and the mother ventilated with 100% oxygen before a subsequent attempt at tracheal intubation is made. It is safer to permit the mother to awaken and to reassess the method of induction than to persist with traumatic efforts at tracheal intubation, which may result in loss of the airway because of edema and bleeding (Fig. 42-6). Once placement of the endotracheal tube is confirmed, with capnography and auscultation, the obstetrician may proceed with incision. In the predelivery interval, anesthesia is maintained with a 50:50 mixture of nitrous oxide in oxygen and 0.5 MAC of a potent agent. Severe maternal hyperventilation should be avoided because it may reduce uterine blood flow. A few minutes before delivery is anticipated, the concentration of the potent agent may be increased temporarily to 2 MAC, when uterine relaxation is desired to facilitate delivery.

Figure 42-6. Management of the difficult airway in pregnancy with special reference to the presence or absence of fetal distress. When mask ventilation is not possible, the clinician is referred to the American Society of Anesthesiologists (ASA) algorithm for the emergency airway management found in [Chapter 23](#). (Adapted with permission from Reisner LS, Benumof JL, Cooper SD. The difficult airway: Risk, prophylaxis, and management. p 607. In Chestnut DH (ed): *Obstetric Anesthesia: Principles and Practice*, p 607. St. Louis, Mosby, 1999.)

The newborn's condition after cesarean section with general anesthesia is comparable with that seen with regional techniques.⁹⁴ The uterine incision-to-delivery interval seems to be more important to neonatal outcome than the induction of anesthesia-to-delivery interval. Lower Apgar scores at 1 minute and acidosis were reported in cases in which the uterine incision-to-delivery time interval exceeded 180 seconds, whereas anesthesia for up to 30 minutes before delivery appears to have no adverse effects on the infant.⁹⁵ In contrast, with use of nitrous oxide 70–75% in oxygen, neonatal depression has been reported to occur within approximately 10 minutes of anesthesia. Increasing the FiO_2 to 50% has the additional benefit of increasing the fetal PaO_2 .⁹⁶

After delivery of the infant, 20 units of oxytocin should be added to the infusion and anesthesia is deepened with an opioid or benzodiazepine, as necessary. At the end of the procedure, the mother's trachea is extubated once she is awake and extubation criteria have been met. The usual blood loss at a cesarean section is 750–1000 ml, and transfusion is rarely necessary.

ANESTHETIC COMPLICATIONS

Maternal Mortality

A study of anesthesia-related deaths in the United States between 1979 and 1990 revealed that the case fatality rate with general anesthesia was 16.7 times greater than that with regional anesthesia. Most anesthesia-related deaths were a result of cardiac arrest due to hypoxemia when difficulties securing the airway were encountered.⁸¹ Pregnancy-induced anatomic and physiologic changes, such as reduced FRC, increased oxygen consumption, and oropharyngeal edema, may expose the patient to serious risks of desaturation during periods of apnea and hypoventilation (see [Physiologic Changes of Pregnancy](#)).

Pulmonary Aspiration

The risk of inhalation of gastric contents is increased in pregnant women, as discussed previously, particularly if difficulty is encountered establishing the airway. Measures to decrease the risks of aspiration include comprehensive airway evaluation, prophylactic administration of nonparticulate antacids, and preferred use of regional anesthesia. Occasionally, general anesthesia may be unavoidable in obstetric anesthesia practice, and therefore awake intubation may be indicated in women in whom airway difficulties are anticipated.

Hypotension

Regional anesthesia is commonly associated with hypotension, which is related to the degree and rapidity of local anesthetic-induced sympatholysis. Thus, more hemodynamic stability is usually observed with epidural anesthesia, where careful titration of local anesthetic may be performed.

In addition, the risk of hypotension is lower in women who are in labor compared with nonlaboring women.⁹⁷ Maternal prehydration with $10\text{--}20 \text{ ml} \cdot \text{kg}^{-1}$ of lactated Ringer's solution before initiation of regional anesthesia, and avoidance of aortocaval compression after induction, may decrease the incidence of hypotension. It has been demonstrated that for effective prevention of hypotension, the blood volume increase from preloading must be sufficient to result in a significant increase in cardiac output.⁹⁸ This was possible only with the administration of hetastarch, 0.5–1 liter.⁹⁸ Nonetheless, controversy exists regarding the efficacy of volume loading in the prevention of hypotension.^{99,100} If hypotension does occur despite prehydration, therapeutic measures include increased displacement of the uterus, rapid infusion of iv fluids, titration of iv ephedrine (5–10 mg), oxygen administration, and placement of the patient in the Trendelenburg position. In the presence of maternal tachycardia, phenylephrine 25–50 μg may be substituted for ephedrine, in women with normal uteroplacental function. Continued vigilance and active management of hypotension can prevent serious sequelae in both mother or neonate.^{97,101}

Total Spinal Anesthesia

High or total spinal anesthesia is a rare complication of intrathecal injection, and occurs after excessive cephalad spread of local anesthetic in the subarachnoid space. Unintentional intrathecal administration of epidural medication as a result of dural puncture or catheter migration may also result in this complication. Left uterine displacement, placement in the Trendelenburg position, and continued fluid and vasopressor administration may be necessary to achieve hemodynamic stability. Rapid control of the airway is essential and endotracheal intubation may be necessary to ensure oxygenation without aspiration.

Local Anesthetic–Induced Seizures

Unintended intravascular injection or drug accumulation after repeated epidural injection can result in high serum levels of local anesthetic. Rapid absorption of local anesthetic from highly vascular sites of injection may also occur after paracervical and pudendal blocks.

Resuscitation equipment should always be available when any major nerve block is undertaken. Intravenous access, airway equipment, emergency drugs, and suction equipment should be immediately accessible. To avoid systemic toxicity of local anesthetic agents, strict adherence to recommended dosages and avoidance of unintentional intravascular injection are essential.

Despite these precautions, life-threatening convulsions and, more rarely, cardiovascular collapse may occur. Seizure activity should be treated with iv thiopental 50–100 mg or diazepam 5–10 mg; larger doses may enhance local anesthetic-induced myocardial depression. The maternal airway should be secured and oxygenation maintained. If cardiovascular collapse does occur, cesarean delivery may be required to relieve aortocaval compression and to ensure the efficiency of cardiac massage.¹⁰²

Postdural Puncture Headache

By virtue of age and sex, pregnant women are at a higher risk for developing PDPH. In addition, after delivery, the reduced epidural pressure increases the risk of cerebrospinal fluid leakage through the dural opening.

The frequency of PDPH development is related to the diameter of the dural puncture, ranging from in excess of 70% after use of 16-gauge needles to less than 1% with the smaller 25- or 26-gauge spinal needles. The incidence of cephalgia is reduced with the use of atraumatic pencil-point needles (Whitacre or Sprotte), which are thought to separate the dural fibers, compared with the diamond-shaped (Quincke) cutting needles. Conservative treatment is indicated in the presence of mild to moderate discomfort, and includes bed rest, hydration, and simple analgesics. Caffeine (500 mg iv or 300 mg orally) and theophylline have also been used in treatment of PDPH.^{103,104} and ¹⁰⁵ Severe headache that does not respond to conservative measures is best treated with autologous blood patch. Using an aseptic technique, 10–15 ml of the patient's blood is injected into the epidural space close to the site of dural puncture. This procedure may be repeated as necessary and is associated with excellent success rates. If an epidural catheter is in place after delivery, 15–20 ml of autologous blood may be injected through the catheter before removal. This may decrease the risk of a headache developing.¹⁰⁶

Nerve Injury

Neurologic sequelae of central neuraxial blockade, although rare, have been reported. Pressure exerted by a needle or catheter on spinal nerve roots produces immediate pain and necessitates repositioning. Infections such as epidural abscess or meningitis are very rare and may be a manifestation of systemic sepsis. Epidural hematoma can also occur, usually in association with coagulation defects. Nerve root irritation may have a protracted recovery, lasting weeks or months. Peripheral nerve injury as a result of instrumentation, lithotomy position, or compression by the fetal head may occur even in the absence of neuraxial technique.

MANAGEMENT OF HIGH-RISK PARTURIENTS

Pregnancy and parturition are considered “high risk” when accompanied by conditions unfavorable to the well-being of the mother or fetus, or both. Maternal problems may be related to pregnancy, such as pre-eclampsia–eclampsia and other hypertensive disorders of pregnancy, or antepartum hemorrhage resulting from placenta previa or abruptio placentae. Diabetes mellitus; cardiac, chronic renal, neurologic, or sickle cell disease; and asthma, obesity, and drug abuse are not related to pregnancy but often are affected by it. Prematurity (gestation of less than 37 weeks), postmaturity (42 weeks or longer), intrauterine growth retardation, and multiple gestation are fetal conditions associated with risk. During labor and delivery, fetal malpresentation (breech, transverse lie), placental abruption, compression of the umbilical cord (prolapse, nuchal cord), precipitous labor, or intrauterine infection (prolonged rupture of membranes) may increase the risk to the mother or the fetus.

In general, the anesthetic management of the high-risk parturient is based on the same maternal and fetal considerations as the management of healthy mothers and fetuses. These include maintenance of maternal cardiovascular function and oxygenation, maintenance and possibly improvement of uteroplacental blood flow, and creation of optimal conditions for a painless, atraumatic delivery of an infant without significant drug effects. However, there is less room for error because many of these functions may be compromised before the induction of anesthesia. For example, significant acidosis is prone to develop in fetuses of diabetic mothers when delivered by cesarean section with spinal anesthesia complicated by even brief maternal hypotension.¹¹ Because the high-risk parturient may have received a variety of drugs, anesthesiologists must be familiar with potential interactions between these drugs and the anesthetic drugs they plan to administer.

Pre-eclampsia–Eclampsia

Hypertensive disorders, which occur in approximately 7% of all late pregnancies, are among the major causes of maternal mortality, accounting for approximately one fifth of maternal deaths, and have been estimated to result in 30,000 neonatal deaths and stillbirths per year in the United States alone. Pre-eclampsia is diagnosed on the basis of development of hypertension with proteinuria or edema, or both. The added appearance of convulsions makes for the diagnosis of eclampsia. Pre-eclampsia–eclampsia is a disease unique to human pregnancy, occurring predominantly in young nulliparas. Symptoms usually appear after the 20th week of gestation, occasionally earlier than that if in association with a hydatidiform mole. Thus, the condition requires the presence of a trophoblast but not a fetus.

The origin of pre-eclampsia–eclampsia is unknown. One theory invokes immunologic rejection of fetal tissues by the mother, which causes a placental vasculitis and ischemia. This theory explains why the disease is more common among nulliparas (no previous exposure to a trophoblast) and in conditions associated with an abnormally large mass of trophoblastic tissues, as in hydatidiform mole, multiple pregnancy, diabetes, and Rh incompatibility. Various studies have demonstrated an abnormal maternal immune responsiveness in pre-eclampsia. Placental ischemia results in a release of uterine renin and an increase in angiotensin activity (Fig. 42-7). This would lead to a widespread arteriolar vasoconstriction, causing hypertension, tissue hypoxia, and endothelial damage. Adherence of platelets at sites of endothelial damage would result in coagulopathies, occasionally in disseminated intravascular coagulation. Enhanced angiotensin-mediated aldosterone secretion would lead to an increased sodium reabsorption and edema. Proteinuria, another symptom of pre-eclampsia, may also be attributed to placental ischemia, which would lead to local tissue degeneration and a release of thromboplastin with subsequent deposition of fibrin in constricted glomerular vessels and increased permeability to albumin and other plasma proteins. Furthermore, there is thought to be a decreased production of prostaglandin E, a potent vasodilator secreted in the trophoblast, which normally would balance the hypertensive effects of the renin–angiotensin system.

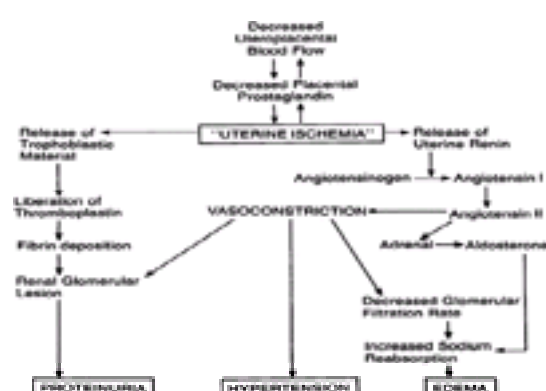

Figure 42-7. Proposed scheme of pathophysiologic changes in toxemia of pregnancy. (Reprinted with permission from Speroff L: Toxemia of pregnancy: Mechanism and therapeutic management. *Am J Cardiol* 32:582, 1973.)

Many of the symptoms associated with pre-eclampsia, including placental ischemia, systemic vasoconstriction, and increased platelet aggregation, may result from an imbalance between the placental production of prostacyclin and thromboxane (Fig. 42-8). During normal pregnancy the placenta produces equivalent quantities of these prostaglandins, whereas in pre-eclamptic pregnancy, there is seven times more thromboxane than prostacyclin.¹⁰⁷ According to the latest theory, endothelial cell injury is central to the development of pre-eclampsia.¹⁰⁸ This injury occurs as a result of reduced placental perfusion leading to a production and release of substances (possibly lipid peroxidases) causing endothelial cell injury. Abnormal endothelial cell function contributes to an increase in peripheral resistance and other abnormalities

noted in pre-eclampsia through a release of fibronectin, endothelin, and other substances.

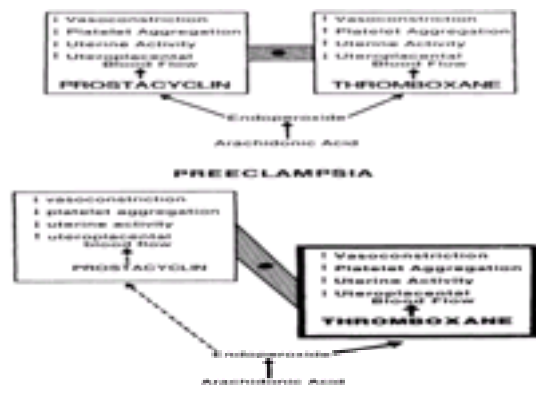

Figure 42-8. Comparison of the balance in the biologic actions of prostacyclin and thromboxane in normal pregnancy with the imbalance of increased thromboxane and decreased prostacyclin in pre-eclamptic pregnancy. (Reprinted with permission from Walsh SW: Preeclampsia: An imbalance in placental prostacyclin and thromboxane production. *Am J Obstet Gynecol* 152:335, 1985.)

Pre-eclampsia is classified as severe if it is associated with any of the following:

1. Systolic blood pressure of 160 mm Hg
2. Diastolic blood pressure of 110 mm Hg
3. Proteinuria of $5 \text{ g} \cdot 24 \text{ h}^{-1}$
4. Oliguria ($400 \text{ ml} \cdot 24 \text{ h}^{-1}$)
5. Cerebral or visual disturbances
6. Pulmonary edema or cyanosis
7. Epigastric pain
8. Intrauterine growth retardation

In severe pre-eclampsia–eclampsia, all major organ systems are affected because of widespread vasospasm. Global cerebral blood flow is not diminished, but focal hypoperfusion cannot be ruled out. Indeed, postmortem examination has revealed hemorrhagic necrosis in the proximity of thrombosed precapillaries, suggesting intense vasoconstriction. Edema and small foci of degeneration have been attributed to hypoxia. Petechial hemorrhages are common after the onset of convulsions. Symptoms related to the above changes include headache, vertigo, cortical blindness, hyper-reflexia, and convulsions. The extent of blood pressure elevation correlates poorly with the incidence of seizures, which are commonly generalized. Fifty percent of pre-eclamptic and 75% of eclamptic women have abnormal electroencephalograms consisting of diffuse slowing in the form of theta and delta waves. Cerebral hemorrhage and edema are the leading causes of death in pre-eclampsia–eclampsia, together accounting for approximately 50% of deaths.

In the eyes, intense arteriolar constriction may result in blurred vision, even temporary blindness. Heart failure may occur in severe cases as a result of peripheral vasoconstriction and increased blood viscosity secondary to hemoconcentration. Changes described in autopsy specimens include left ventricular hypertrophy, subendocardial hemorrhages, cloudy swelling, and fatty and hyaline degeneration.

Decreased blood supply to the liver may lead to periportal necrosis of variable extent and severity. Subcapsular hemorrhages account for the epigastric pain encountered in severe cases. Rarely, there is rupture of the overstretched liver capsule and massive hemorrhage into the abdominal cavity. Hepatic function tests show elevated plasma levels of aspartate aminotransferase, lactate dehydrogenase, and alkaline phosphatase, whereas bilirubin is unaltered.

In the kidneys, there is swelling of glomerular endothelial cells and deposition of fibrin, leading to a constriction of the capillary lumina. Renal blood flow and glomerular filtration rate decrease, resulting in reduced uric acid clearance and, in severe cases, reduced clearance of urea and creatinine. As already stated, oliguria and proteinuria are among the characteristic symptoms of severe pre-eclampsia. The severity of renal involvement is reflected in the degree of proteinuria, which may reach nephrotic levels of $10\text{--}15 \text{ g} \cdot 24 \text{ h}^{-1}$.

A mild degree of pulmonary ventilation–perfusion imbalance has been reported in severe cases. It is not believed to be clinically important because the arterial oxygen tension was within normal limits. In contrast, airway edema, which may also occur in severe pre-eclampsia, is of great concern because it may lead to respiratory embarrassment and difficulty in tracheal intubation. Pulmonary edema is commonly found at autopsy. It may result from heart failure, circulatory overload, or aspiration of gastric contents during convulsions.

In the placenta, a reduction in intervillous blood flow may result from vasoconstriction or the development of occlusive lesions in decidual arteries, despite the elevated maternal blood pressure. Histologic examination of the placenta often reveals nodular ischemia and varying stages of infarction. Necrosis of the supporting tissues may lead to a rupture of fetal cotyledonary vessels and hemorrhage. If the hemorrhage is extensive, it may extend retroplacentally, initiating the process of abruption. Reduced placental blood flow leads to chronic fetal hypoxia and malnutrition. The risks of intrauterine growth retardation, premature birth, and perinatal death are substantially higher than in normal pregnancies and correlate with the severity of pre-eclampsia.

Although pre-eclampsia is accompanied by exaggerated retention of water and sodium, the shift of fluid and proteins from the intravascular into the extravascular compartment may result in hypovolemia, hypoproteinemia, and hemoconcentration. This phenomenon may be further aggravated by proteinuria. The risk of uteroplacental hypoperfusion and poor fetal outcome correlates with the degree of maternal plasma and protein depletion. The mean plasma volume in women with pre-eclampsia was found to be 9% less than normal, and in those with severe disease it was as much as 30–40% below normal.¹⁰⁹ The inverse relationship between the intravascular volume and the severity of hypertension was confirmed with measurements of central venous pressure (CVP; Fig. 42-9). Patients with a diastolic pressure of 110 mm Hg may have a CVP as low as $- \text{cm H}_2\text{O}$ and may require careful hydration to increase the CVP to a normal range. A significant reduction in maternal plasma volume may precede the clinical appearance of pre-eclampsia in previously normotensive patients.

Figure 42-9. Initial central venous pressure measurements (three or more recordings of maternal diastolic pressure) and intravenous volume replacement required to attain the range of 6–8 $\text{cm H}_2\text{O}$ in five groups of women with pre-eclampsia classified according to the severity of the disease (by diastolic BP). LR = lactated Ringer's solution. (Reprinted with permission from Joyce TH III, Debnath KS, Baker EA: Preeclampsia: Relationship of CVP and epidural analgesia. *Anesthesiology* 51:S297, 1979.)

Hemodynamic changes in pre-eclampsia may vary with the progression of the disease, whether patients are in labor or have received therapy. Earlier studies, using pulmonary artery flow-directed catheters, suggested that patients with severe pre-eclampsia were in a hyperdynamic state. However, these investigations were

performed when patients were in labor or in the postpartum period, after treatment had been instituted. More recently, hemodynamic data were obtained in 10 pre-eclamptic and 4 healthy pregnant women near term who were not in labor¹¹⁰ (Table 42-3). In the pre-eclamptic women, measurements were made before treatment, after volume expansion, and, finally, after vasodilation was achieved with a continuous iv infusion of dihydralazine. Initial measurements revealed a low pulmonary capillary wedge pressure, a low cardiac index, a high systemic vascular resistance, and an increased heart rate, indicating the existence of a low-output state in untreated pre-eclamptic women. Volume expansion resulted in a significant increase in pulmonary capillary wedge pressure and cardiac index, whereas the systemic vascular resistance and maternal heart rate decreased. The mean arterial pressure was significantly reduced, mainly because of a decrease in systolic pressure. Subsequent infusion of dihydralazine did not alter the capillary wedge pressure but led to an additional increase in cardiac index and a decrease in systemic vascular resistance. These data indicate that careful volume expansion may improve maternal tissue perfusion in severe pre-eclampsia.

| Variable | Pre-eclamptic Patients (n = 10) | | | | Control Subjects (n = 4) |
|--|---------------------------------|------------------------|--------------------|-------|--------------------------|
| | Initial | After Volume Expansion | After Vasodilation | p† | |
| Diastolic blood pressure (mm Hg) | 88 (85-120) | 82 (80-120) | 85 (82-100) | <0.05 | 77 (74-80) |
| Mean arterial pressure (mm Hg) | 82 (75-106) | 78 (80-104) | 81 (82-104) | <0.05 | 85 (84-106) |
| Heart rate (beats min ⁻¹) | 88 (85-120) | 80 (80-110) | 82 (82-100) | NS | 84 (79-88) |
| Pulmonary capillary wedge pressure (mm Hg) | 11 (7-15) | 17 (7-21) | 18 (17-24) | NS | 19 (17-22) |
| Systemic vascular resistance (dyne cm ⁻² min ⁻¹ m ²) | 160 (140-200) | 120 (105-140) | 147 (132-162) | <0.05 | 86 (85-102) |
| Stroke volume (ml min ⁻¹ m ²) | 2.75 (1.97-4.10) | 3.77 (3.24-4.05) | 4.48 (2.94-5.00) | <0.05 | 4.5 (3.9-4.9) |

NS = not significant. Wilcoxon signed-rank test (two-tailed).

Table 42-3. HEMODYNAMIC VARIABLES (MEAN AND RANGE) IN PRE-ECLAMPTIC PATIENTS AND CONTROL SUBJECTS

Simultaneous determinations of CVP and pulmonary capillary wedge pressure were obtained in another group of 18 patients with severe pre-eclampsia.¹¹¹ In approximately half of the cases, there was a linear relation between the two modalities, but even in these women it was difficult to predict the pulmonary capillary wedge pressure from the CVP because of wide interindividual variations.

Adherence of platelets at sites of endothelial damage may result in consumption coagulopathy, which develops in approximately 20% of patients with pre-eclampsia. Thrombocytopenia is the most frequent finding. It is usually mild, with the platelet count in the range of 100,000–150,000 per mm³. Elevated levels of fibrin degradation products are found less frequently, and plasma fibrinogen concentrations remain normal unless there is a placental abruption. Prolongation of prothrombin and partial thromboplastin times indicates consumption of procoagulants. Bleeding time, which was found to be prolonged in approximately 25% of patients with normal platelet counts, is no longer considered a reliable test of clotting.¹¹² The HELLP syndrome is a particular form of severe pre-eclampsia characterized by hemolysis, elevated liver enzymes, and thrombocytopenia. In contrast to pre-eclampsia, elevations in blood pressure and proteinuria may be mild.

General Management

Because the origin of pre-eclampsia–eclampsia is not known, management is symptomatic. The goals are to prevent or control convulsions, improve organ perfusion, normalize blood pressure, and correct clotting abnormalities. Delivery is indicated in refractory cases or if the pregnancy is close to term. In severe cases, aggressive management should continue for at least 24–48 hours after delivery.

The mainstay of anticonvulsant therapy in the United States is magnesium sulfate. Although its efficacy in preventing seizures has been well substantiated, its mechanism of action remains controversial. The patient usually receives an iv loading dose of 4 g in a 20% solution, administered over 5 minutes. Therapeutic blood levels are maintained by continuous infusion of 1–2 g · h⁻¹. In addition to its anticonvulsant properties, by causing mild peripheral arterial vasodilation, magnesium sulfate may affect the maternal hemodynamic state. Magnesium ions cross the placenta readily and may lead to fetal and neonatal hypermagnesemia. There is poor correlation between magnesium concentrations in the umbilical cord blood and the incidence of low Apgar scores and depression of ventilation at birth, which are more likely due to fetal asphyxia and prematurity.

Magnesium potentiates the duration and intensity of action of depolarizing and nondepolarizing muscle relaxants by decreasing the amount of acetylcholine liberated from the motor nerve terminals, diminishing the sensitivity of the endplate to acetylcholine, and depressing the excitability of the skeletal muscle membrane. The aim of fluid therapy is to increase the CVP and pulmonary capillary wedge pressure to the normal range (4–6 cm H₂O and 5–10 mm Hg, respectively) and to increase the urine output to 1 ml · kg⁻¹ · hr⁻¹. As already mentioned, this has been shown to improve the cardiac index and, interestingly, to decrease the mean systemic arterial pressure as well as systemic vascular resistance.¹¹⁰ Care must be taken to avoid fluid overload. In all cases, careful monitoring of arterial pressure, urine output, and specific gravity should be started as soon as possible. In severe cases, invasive central pressure monitoring may be required.¹¹¹ A pulmonary artery catheter is preferred in patients with pulmonary edema, refractory oliguria, or unexpectedly high CVP (6 mm Hg).¹¹¹ Monitoring should be carried out in the postpartum period as well, preferably in the recovery room or intensive care setting. In patients with blood clotting abnormalities, the risk of inadvertent puncture of the carotid artery associated with internal jugular cannulation may be averted by inserting the line in the basilic or external jugular vein.

Antihypertensive therapy in pre-eclampsia is used to lessen the risk of cerebral hemorrhage in the mother while maintaining, even improving, tissue perfusion. Plasma volume expansion combined with vasodilation fulfills these goals.¹¹⁰ Hydralazine is the most commonly used vasodilator in pre-eclampsia because it increases uteroplacental and renal blood flows. It can be administered orally, im, or iv. Nitroprusside, a potent vasodilator of resistance and capacitance vessels, with an immediate but evanescent action, is useful in preventing dangerous elevations in systemic and pulmonary artery blood pressure during laryngoscopy and intubation and is ideal for treatment of hypertensive emergencies. Its infusion can be decreased gradually in the interim as a longer-acting agent, such as hydralazine, begins to take effect. Infusion rates of nitroprusside less than 5–10 mg · kg⁻¹ · min⁻¹, depending on the length of administration, can be maintained without undue risk of cyanide toxicity to the mother and fetus. Trimethaphan, a ganglionic blocking agent, is particularly useful in hypertensive emergencies when cerebral edema and increased intracranial pressure are of particular concern because it does not cause vasodilation in the brain. Other agents used to control maternal blood pressure in pre-eclampsia include α-methyldopa and nitroglycerin. Labetalol, a nonselective β blocker with some α₁-blocking effects, is now frequently used.^{111,112}

Consumption coagulopathy may require corrective measures such as infusion of fresh whole blood, platelet concentrates, fresh frozen plasma, and cryoprecipitate. The administration of conduction anesthesia is contraindicated in patients with severe coagulopathy because of the increased risk of an epidural hematoma, leading to permanent neurologic damage.

Anesthetic Management

Epidural anesthesia (or CSE) for labor and delivery should no longer be considered contraindicated, provided there is no severe clotting abnormality or plasma volume deficit.¹¹³ In volume-repleted patients positioned with left uterine displacement, epidural anesthesia does not cause an unacceptable reduction in blood pressure and leads to a significant improvement in placental perfusion.¹¹⁴ With the use of radioactive xenon, it was shown that the intervillous blood flow increased by approximately 75% after the induction of epidural analgesia (10 ml of bupivacaine 0.25%).¹¹⁵ The total maternal body clearance of amide local anesthetics is prolonged in pre-eclampsia, and repeated administration of these drugs can lead to higher blood concentrations than in normotensive patients.¹¹⁶

For cesarean section, the sensory level of regional anesthesia must extend to T3–4, making adequate fluid therapy and left uterine displacement even more vital. Epidural anesthesia has been preferred to spinal anesthesia in pre-eclamptic women because of its slower onset of action and controllability. The rapid onset of spinal anesthesia may be associated with hypotension, particularly in a volume-depleted patient. However, in two recent studies, the incidence of hypotension, perioperative fluid and ephedrine administration, and neonatal conditions were found to be similar in pre-eclamptic women who received either epidural or spinal anesthesia for cesarean delivery.^{117,118} There is an increased sensitivity to vasopressors in pre-eclampsia; therefore, lower doses of ephedrine are usually required to correct hypotension.

General anesthesia in pre-eclamptic patients has its particular hazards. Rapid-sequence induction of anesthesia and intubation of the trachea necessary to avoid aspiration are occasionally difficult because a swollen tongue, epiglottitis, or pharynx distorts the anatomy. In patients with impaired coagulation, laryngoscopy and intubation of the trachea may provoke profuse bleeding. Marked systemic and pulmonary hypertension occurring at intubation and extubation enhance the risk of cerebral hemorrhage and pulmonary edema (Fig. 42-10). However, these hemodynamic changes can be minimized with appropriate antihypertensive therapy, such as administration of a trimethaphan or nitroprusside infusion. The use of ketamine and ergot alkaloids should be avoided. As already mentioned, magnesium sulfate may

prolong the effects of all muscle relaxants through its actions on the myoneural junction. Therefore, relaxants should be administered with caution (using a nerve stimulator) to avoid overdosage. General anesthesia may be necessary in acute emergencies, such as abruptio placentae, and in patients who do not meet the criteria for epidural anesthesia.

Figure 42-10. Mean and SE of mean arterial pressure (MAP), mean pulmonary artery pressure (PAP), and pulmonary wedge pressure (PWP) in patients with severe pre-eclampsia receiving thiopental and nitrous oxide (40%) with 0.5% halothane anesthesia for cesarean section. Antepartum Hemorrhage

Antepartum hemorrhage occurs most commonly in association with placenta previa (abnormal implantation on the lower uterine segment, and partial to total occlusion of the internal cervical os) and abruptio placentae. Placenta previa occurs in 0.1–1.0% of all pregnancies, resulting in up to a 0.9% incidence of maternal and a 17–26% incidence of perinatal mortality. It may be associated with abnormal fetal presentation, such as transverse lie or breech. Placenta previa should be suspected whenever a patient presents with painless, bright red vaginal bleeding, usually after the seventh month of pregnancy. The diagnosis is confirmed by ultrasonography. If the bleeding is not profuse and the fetus is immature, obstetric management is conservative to prolong pregnancy. In severe cases, or if the fetus is mature at the onset of symptoms, prompt delivery is indicated, usually by cesarean section. An emergency hysterectomy may be required because of severe hemorrhage, even after delivery of the placenta, because of uterine atony. The risk of severe hemorrhage after attempted removal of a placenta previa is greatly increased in patients who have undergone prior uterine surgery, including cesarean section. This is due to a higher incidence of placenta accreta, which results from the penetration of myometrium by placental villi. After one previous cesarean delivery, placenta accreta was reported to occur in 20–25% of patients with placenta previa, and after four or more prior cesarean sections, the incidence is greater than 67%.¹¹⁹

Abruptio placentae occurs in 0.2–2.4% of pregnant women, usually in the final 10 weeks of gestation and in association with hypertensive diseases. Complications include Couvelaire uterus (when extravasated blood dissects between the myometrial fibers), renal failure, disseminated intravascular coagulation, and anterior pituitary necrosis (Sheehan's syndrome). The maternal mortality rate is high (1.8–11.0%), and the perinatal mortality rate is even higher, in excess of 50%. The diagnosis of abruptio placentae is based on the presence of uterine tenderness and hypertonus and vaginal bleeding of dark, clotted blood. Bleeding may be concealed if the placental margins have remained attached to the uterine wall. If the blood loss is severe (>2 l), there may be changes in the maternal blood pressure and pulse rate indicative of hypovolemia. Fetal movements may increase during acute hypoxia or decrease if hypoxia is gradual. Fetal bradycardia and death may ensue. Management of milder cases of abruptio includes artificial rupture of amniotic membranes and oxytocin augmentation of labor, if required. In the presence of fetal distress, an emergency cesarean section should be performed.

The anesthesiologist is involved in maternal resuscitation and provision of anesthesia. This may include the establishment of invasive monitoring (an arterial and a central venous catheter are usually adequate) and blood volume replacement, preferably through 14- or 16-gauge cannulae. To correct clotting abnormalities, blood components such as fresh frozen plasma, cryoprecipitate, and platelet concentrates may be required. The anesthesiologist also performs the traditional role of providing appropriate anesthesia for a cesarean section or, occasionally, a hysterectomy. Epidural anesthesia should be considered, but general anesthesia is indicated in the presence of uncontrolled hemorrhage and coagulation abnormalities.¹²⁰ As usual, it should be preceded by adequate denitrogenation. In hypovolemic patients, induction may be accomplished with ketamine iv, 0.5–1.0 mg · kg⁻¹. In all obstetric patients, proper precautions should be taken to prevent aspiration of gastric contents. These include the administration of a clear antacid and rapid-sequence induction of anesthesia with application of cricoid pressure until tracheal intubation.

Heart Disease

Heart disease during pregnancy occurs in 0.4–4.1% of patients and is the leading nonobstetric cause of maternal mortality, with a mortality rate ranging from 0.4% among patients in Class I or II of the New York Heart Association's functional classification to 6.8% among those in Classes III and IV. The following lesions pose the greatest risk for the mother: pulmonary hypertension, particularly with Eisenmenger's syndrome; mitral stenosis with atrial fibrillation; tetralogy of Fallot; Marfan's syndrome; and coarctation of the aorta. Cardiac decompensation and death occur most commonly at the time of maximum hemodynamic stress, that is, in the third trimester of pregnancy, during labor and delivery, and particularly during the immediate postpartum period. During labor, cardiac output increases above antepartum levels. Between contractions this increase is approximately 15% in the early first stage, approximately 30% during the late first stage, approximately 45% during the second stage, and, after delivery, 30–50%.⁴¹ With each uterine contraction, approximately 200 ml of blood is squeezed out of the uterus into the central circulation. Consequently, stroke volume, cardiac output, and left ventricular work increase, and each contraction consistently increases cardiac output by 10–25% above that of uterine diastole. The greatest change occurs immediately after delivery of the placenta, when cardiac output increases to an average of 80% above prepartum values, and in some patients it may increase by as much as 150%. These changes in cardiac output can be reduced by administration of regional anesthesia. In patients managed with continuous caudal anesthesia, cardiac output increased only 24% above prepartum control values during the second stage and 59% immediately postpartum.⁴¹

Until 1960, rheumatic fever was responsible for almost 90% of the heart disease encountered in pregnant women. Since that time, with improved medical care and surgical techniques, more patients with congenital disease survive to reach childbearing age. Simultaneously, better living conditions and antibiotic treatment have reduced the incidence of rheumatic heart disease, and the ratio of rheumatic to congenital heart disease among parturients has declined to 3:1.

Rheumatic Heart Disease

Mitral stenosis is the sole or predominant valvular lesion in most parturients with rheumatic heart disease. The primary defect is obstruction to diastolic blood flow from the left atrium to the left ventricle. This becomes hemodynamically significant when the valve orifice is diminished or the rate of blood flow through the constricted orifice is increased sufficiently to raise left atrial pressure and, consequently, pressure in the pulmonary veins and capillaries.

The physiologic changes of pregnancy usually aggravate the problems of mitral stenosis. An increased pulse rate necessitates a higher diastolic flow rate across the mitral orifice to maintain cardiac output. The flow rate is also augmented by the increased cardiac output that pregnancy requires. In the presence of significant mitral stenosis, these increases in flow rate can be accomplished only by an increase in left atrial and pulmonary venous pressure. The increased blood volume in the lungs that occurs during pregnancy may also contribute to the distention of pulmonary capillaries. Atrial fibrillation may occur in the presence of an enlarged left atrium, leading to pulmonary edema with an associated maternal mortality rate as high as 17%. Cardioversion should be undertaken if drug therapy does not decrease ventricular rate. Mitral commissurotomy may be necessary because of symptoms of congestive heart failure or, less frequently, because of hemoptysis or emboli. When performed in the second or early third trimester, closed as well as open commissurotomies have been well tolerated by the mother and were accompanied by fetal survival rates in excess of 80%. Fortunately, 90% of pregnant women with mitral stenosis are in functional Classes I and II. These patients usually tolerate childbearing well. The relatively small number in functional Classes III and IV account for most maternal cardiac deaths.

Other valvular diseases, namely mitral regurgitation, aortic stenosis, or regurgitation, are much less frequent in pregnant cardiac patients. Together they account for 10–35% of all cases. Pure mitral regurgitation is rarely a problem. Properly managed patients can have repeated pregnancies without serious complications. Similarly, pure aortic insufficiency rarely causes disability in the absence of bacterial endocarditis. Aortic stenosis is frequently associated with aortic insufficiency and mitral stenosis. Myocardial failure secondary to pure aortic stenosis is rare in patients of childbearing age because symptoms develop in most patients when they are in their fifth or sixth decades. Left ventricular hypertrophy and a relatively fixed stroke volume develop in those with significant aortic stenosis. These changes reduce their tolerance to decreases in systemic vascular resistance, bradycardia, and decreased venous return (and left ventricular filling).

Continuous epidural block offers particular advantages to the pregnant cardiac patient. It not only eliminates pain and tachycardia throughout labor and delivery but prevents the progressive increase in cardiac output and stroke volume that normally occurs in parturition.⁴¹ It also abolishes the bearing-down reflex. CSE may be expected to produce the same salutary effects. In view of these advantages, continuous lumbar epidural and CSE techniques are recommended for most pregnant women with rheumatic valvular diseases, whether they are to have vaginal or cesarean section deliveries, with the exception of those with severe symptomatic aortic stenosis. In patients with this condition, even transient episodes of hypotension may cause serious coronary hypoperfusion, arrhythmias, and even cardiac arrest. However, use of a pulmonary artery catheter, careful titration of anesthetic dose, and the use of phenylephrine for changes in blood pressure may permit the use of regional anesthesia in selected patients. Intrathecal opioids have been used in an attempt to provide adequate obstetric analgesia during labor without the risk of hypotension. Morphine, 0.5–1.0 mg, or fentanyl, 10–20 µg, alone or in combination, relieves the pain of uterine contractions. Pudendal block is needed for delivery. Should general anesthesia be deemed necessary for cesarean section, the standard thiopental–nitrous oxide–halogenated anesthetic–muscle relaxant technique is recommended. In cases of severe mitral stenosis, etomidate, 0.2–0.3 mg · kg⁻¹, or a slower induction with halothane or iv fentanyl is preferred. The benefit of high-dose narcotic induction should be weighed against the risk of transient neonatal depression. In patients with severe aortic stenosis and evidence of left ventricular compromise, halogenated agents should be avoided.

Congenital Heart Diseases

Patent ductus arteriosus, atrial septal defect, and ventricular septal defect are the more common congenital cardiovascular abnormalities. In all these conditions, anomalous communicating channels exist between the cardiac chambers or the great vessels. Normally, pressures on the left side of the circulation are higher than those on the right and there is a left-to-right shunt. Late in the natural history of these diseases, pulmonary hypertension may develop, causing a reversal of the shunt (Eisenmenger's syndrome). Patients with Eisenmenger's syndrome rarely live beyond the age of 40 years. Pregnancy is poorly tolerated because the gestational decrease in systemic vascular resistance in the presence of fixed pulmonary vascular resistance results in a significant increase in the right-to-left shunt. Changes in systemic and pulmonary pressures are also likely to occur with the aortocaval compression near the end of pregnancy, hypotension caused by epidural or spinal anesthesia, and bearing-down efforts of parturition. Severe shunt disturbances induced by these changes may lead to further cyanosis, even death.

Tetralogy of Fallot is the most common cyanotic congenital heart defect. It consists of an interventricular septal defect, pulmonary stenosis, displacement of the aortic orifice so that it overlies the ventricular septal defect, and right ventricular hypertrophy. The pulmonary stenosis leads to increases in right ventricular systolic pressure with dilation and hypertrophy of that chamber. Blood from the right ventricle is shunted through the septal defect, and the overriding aorta receives venous blood from this source and oxygenated blood from the left ventricle. Reduced arterial oxygenation leads to cyanosis, polycythemia, and clubbing. Symptoms develop in patients during the first few months of life, with their severity related to the degree of the pulmonic stenosis. However, the introduction of cardiac surgery has increased the number of patients surviving to childbearing age.

Anesthesia for parturients with cyanotic heart disease should provide effective pain relief while avoiding hypotension, struggling, or coughing, and eliminating bearing-down efforts, all of which could increase the right-to-left shunt. For labor, intrathecal opioids rather than conventional epidural anesthesia can be administered. Light planes of general anesthesia are usually well tolerated for cesarean section.

PRETERM DELIVERY

Preterm labor and delivery present a significant challenge to the anesthesiologist because the mother and the infant may be at risk. The definition of prematurity was altered to distinguish between the preterm infant, born before the 37th week of gestation is completed, and the small-for-gestational-age infant, who may be born at term but whose weight is more than 2 standard deviations below the mean. Although preterm deliveries occur in 8–10% of all births, they account for approximately 80% of early neonatal deaths. In general, the mortality and morbidity rates are higher among preterm infants than among small-for-gestational-age infants of comparable weight. Severe problems, including respiratory distress syndrome, intracranial hemorrhage, hypoglycemia, hypocalcemia, and hyperbilirubinemia, are prone to develop in preterm infants. Fortunately, with improved neonatal intensive care, severe, lasting impairment, such as cerebral palsy, mental retardation, or chronic lung disease, has become infrequent among the survivors.

Obstetricians frequently try to inhibit preterm labor to enhance fetal lung maturity. Delaying delivery by even 24–48 hours may be beneficial if glucocorticoids are administered to the mother. Various agents have been used to suppress uterine activity (tocolysis), including ethanol, magnesium sulfate, prostaglandin inhibitors, b-sympathomimetics, and calcium channel blockers. b-Adrenergic drugs, such as ritodrine and terbutaline, are the most commonly used tocolytics. These agents are initially administered by an iv infusion at the rate of 0.05–0.1 mg · min⁻¹ for ritodrine and 0.01 mg · min⁻¹ for terbutaline. Their predominant effect is b₂ receptor stimulation, resulting in myometrial inhibition, vasodilation, and bronchodilation. Numerous maternal complications have been reported: hypotension, hypokalemia, hyperglycemia, myocardial ischemia, pulmonary edema, and death.¹²¹ Complications also may occur because of interactions with anesthetic drugs and techniques. With the use of regional anesthesia, peripheral vasodilation caused by b-adrenergic stimulation increases the risk of hypotension. Acute prehydration must be managed carefully to avoid pulmonary edema. General anesthesia may be associated with increased risks of hemodynamic instability in the presence of pre-existing tachycardia, hypotension, and hypokalemia. Caution should be exercised with use of halothane (cardiac dysrhythmias), atropine, and pancuronium (tachycardia). In nonemergent situations, delay of anesthesia by at least 3 hours from the cessation of tocolysis allows b-mimetic effects to dissipate. Potassium supplementation is usually not necessary because the intracellular potassium concentration is normal despite a reduction in serum concentrations.

It has become axiomatic that the premature infant is more vulnerable than the term newborn to the effects of drugs used in obstetric analgesia and anesthesia. However, there have been few systematic studies to determine the maternal and fetal pharmacokinetics and dynamics of drugs throughout gestation. There are several postulated causes of enhanced drug sensitivity in the preterm newborn: less protein available for drug binding; higher levels of bilirubin, which may compete with the drug for protein binding; greater drug access to the central nervous system because of a poorly developed blood–brain barrier; greater total body water and lower fat content; and a decreased ability to metabolize and excrete drugs. However, these deficiencies of the preterm infant should not be as serious as we have been led to believe. Although the serum albumin and a₁-acid glycoprotein concentrations are lower in the preterm fetus, this would primarily affect drugs that are highly bound to these proteins. However, most drugs used in anesthesia exhibit only low to moderate degrees of binding in the fetal serum: approximately 50% for etidocaine and bupivacaine, 25% for lidocaine, 52% for meperidine, and 75% for thiopental.

The placenta efficiently eliminates fetal bilirubin. Thus, the hyperbilirubinemia of prematurity normally occurs in the postpartum period. With the exception of diazepam, bilirubin does not compete with anesthetic drugs because most are bound to other serum proteins (e.g., meperidine and local anesthetics to a₁-acid glycoproteins). It seems likely that the human blood–brain barrier develops substantially in early gestation. Thus, factors such as tissue affinity changes may account for differences between immature and mature animals in brain uptake of highly lipid-soluble drugs.

Greater total body water in the preterm fetus results in a greater volume of distribution for drugs. Thus, to achieve equal blood concentrations, the immature fetus must receive a greater amount of drug transplacentally than the mature fetus. A study of age-related toxicity of lidocaine in sheep showed that the greater the volume of distribution, the greater the dose required to achieve toxic blood concentrations of the drug.³⁷ Decreased ability to metabolize or excrete drugs, associated with prematurity, is certainly not a universal phenomenon. In a study comparing the pharmacokinetics of lidocaine in preterm newborns and adults, plasma clearance was similar in both groups.³⁵ Neonates excreted much more unchanged lidocaine than did adults. Similarly, although meperidine metabolism is more limited in the neonate than in the adult, urinary excretion of the unchanged drug is greater in the neonate.

Another factor is gestational changes in maternal serum albumin and a₁-acid glycoprotein concentrations, which tend to decrease. Serial determinations of protein binding of diazepam, phenytoin, and valproic acid in maternal serum, performed in early (8–16 weeks), middle (17–32 weeks), and late pregnancy, showed a progressive increase in the unbound fraction of these drugs.¹²² This increases drug availability for placental transfer. Placental permeability itself increases as pregnancy progresses because of the increased area and decreased thickness of tissue barriers.³⁰

In a largely ignored, prospective study of more than 1000 premature labors, during which mothers received meperidine alone or with scopolamine, medication had no effect on the perinatal death rate, the incidence of respiratory distress syndrome, Apgar scores, the need for resuscitation, and the incidence of severe neurologic defects within 1 year.¹²³

Therefore, it appears that in selection of the anesthetic drugs and techniques for delivery of a preterm infant, concerns regarding drug effects on the newborn are far less important than prevention of asphyxia and trauma to the fetus. For labor and vaginal delivery, well conducted epidural anesthesia is advantageous in providing good perineal relaxation. The anesthesiologist should ascertain that the fetus is neither hypoxic nor acidotic before induction of epidural blockade. Asphyxia results in a redistribution of fetal cardiac output, which increases oxygen delivery to vital organs such as the brain, heart, and adrenals. These changes in the preterm fetus may be better preserved with bupivacaine or chlorprocaine than with lidocaine.^{124,125} Preterm infants with breech presentation are usually delivered by cesarean section. General anesthesia with uterine relaxation, provided by a halogenated drug, facilitates delivery of the aftercoming head. If regional anesthesia is used, nitroglycerin should be available for uterine relaxation.

FETAL AND MATERNAL MONITORING

The development of biophysical and biochemical monitoring of the fetus during labor and delivery has had a tremendous impact on obstetric practice since the early 1970s. Monitoring procedures are now performed routinely, and it is important that the anesthesiologist understand the basic principles of the technology, as well as the interpretation of results, because they relate to both mother and fetus.

During the same period, there has been an explosion in monitoring technology in the fields of anesthesiology and intensive care. The mother with serious medical problems requiring intensive care or the one whose infant is delivered in an operating room under an anesthesiologist's care is subject to the same standards of monitoring as any other surgical patient. It is generally agreed that the use of intensive peripartum monitoring is appropriate in a high-risk pregnancy. In contrast, patients with routine labor are frequently observed in the same way that patients were many generations ago (*i.e.*, with intermittent blood pressure readings). With the growing sophistication of electronic devices, and specifically the science of telemetry, we can look forward to better surveillance of both mother and fetus without the loss of maternal freedom and activity that monitoring currently entails.

Biophysical Monitoring

A fetal monitor is a two-channel recorder of fetal heart rate and uterine activity. In the direct system, the fetal ECG is obtained from an electrode attached to the presenting part. Intrauterine pressure is measured continuously with a transducer connected to a saline-filled catheter that is inserted transcervically. Direct monitoring is quantitative but requires rupture of the membranes and a cervical dilation of at least 1.5 cm. In addition, the presenting part must dip into the true pelvis. Indirect fetal monitoring uses data obtained from transducers secured to the mother's abdomen with adjustable straps. Ultrasound cardiography is the most commonly used indirect method of obtaining fetal heart rate signals. Uterine activity is monitored with a tocodynamometer triggered by the changing shape of the uterus during the contraction. Indirect monitoring is mostly qualitative. Its advantage is that it can be applied without rupture of membranes, even before the onset of labor.

The following variables are considered when fetal well-being is determined: baseline heart rate, beat-to-beat variability, periodic patterns, and uterine activity. The baseline fetal heart rate is measured between contractions and ranges between 120–160 beats \cdot min⁻¹ in the normal fetus. An acceleration of fetal heart rate in response to fetal stimulation, such as during vaginal examination or fetal capillary blood sampling, is a reassuring sign that the fetus is not acidotic. Persistently elevated rates may be associated with chronic fetal distress, maternal fever, or administration of drugs such as ephedrine and atropine. Abnormally low rates may be encountered in fetuses with congenital heart block or as a late occurrence during the course of fetal hypoxia and acidosis.

The baseline fetal heart rate variability, which is normally present, reflects the beat-to-beat adjustments of the parasympathetic and sympathetic nervous systems to a variety of internal and external stimuli. Fetal central nervous system depression by asphyxia may decrease baseline variability. Therefore, a smooth fetal heart rate tracing may be an ominous finding. Studies comparing beat-to-beat variability with fetal acid–base analysis indicate a good correlation between the two parameters.¹²⁶ However, drugs can also decrease fetal heart rate variability by depressing mechanisms in the central nervous system that integrate cardiac control (tranquilizers, opioids, barbiturates, anesthetics) or by blocking the transmission of control impulses to the cardiac pacemaker (atropine). In contrast, ephedrine administration may increase beat-to-beat variability.¹²⁷

Periodic fetal heart rate patterns consist of decelerations or accelerations of relatively brief duration in association with uterine contractions (Fig. 42-11). There are three major forms of fetal heart rate deceleration: early, late, and variable. Early decelerations are U-shaped, with the heart rate usually not decreasing to less than 100 beats \cdot min⁻¹. The fetal heart begins to slow with the onset of the contraction, the low point coincides with the peak of the contraction, and the rate usually returns to the baseline as the uterus relaxes. This type of deceleration has been attributed to fetal head compression, leading to increased vagal tone. It is not ameliorated by increasing fetal oxygenation but is blocked by atropine administration. Early decelerations are transitory and well tolerated by the fetus because there is no systemic hypoxemia or acidosis.¹²⁸

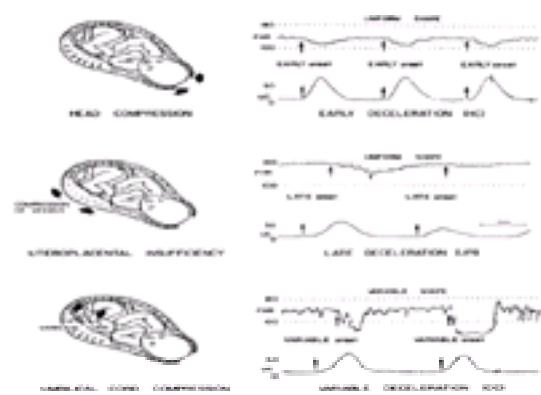

Figure 42-11. Classification and mechanism of fetal heart rate patterns. (Reprinted with permission from Hon EH: An Introduction to Fetal Heart Rate Monitoring, p 29. New Haven, Connecticut, Hart Press, 1969.)

Late decelerations are also U-shaped. They begin 20–30 seconds or more after the onset of uterine contraction, and the low point of the deceleration occurs well after the peak of the contraction. Myocardial ischemia resulting from uteroplacental insufficiency is believed to cause this pattern. The pattern of late deceleration can be corrected by improving fetal oxygenation, which may be accomplished with oxygen administration to the mother, correction of maternal hypotension, or aortocaval compression, or by taking measures that decrease uterine activity. If this pattern is repetitive, continuous, and progressive in severity, there is a significant correlation with fetal acidosis, and delivery may be required.¹²⁸

Variable decelerations, which result from umbilical cord compression, are the most common periodic patterns observed in the intrapartum period. They are variable in shape and onset, with the rate usually decreasing to less than 100 beats \cdot min⁻¹. Although the initial fetal heart rate changes are of reflex origin, if the cord compressions are frequent or prolonged, fetal asphyxia may result in direct myocardial depression.¹²⁸

Cervical dilation and descent of the presenting part during the first stage of labor result primarily from uterine contractions. During the active phase, contractions should occur every 2–3 minutes, with peak intrauterine pressures of 50–80 mm Hg and resting pressures of 5–20 mm Hg. Uterine activity may be abnormally elevated in association with abruptio placentae or the injudicious use of oxytocics. Tetanic uterine contractions have been reported after the use of methoxamine, a pure α -adrenergic agonist. In the first and second trimesters of pregnancy, increased uterine tone may be induced with ketamine in doses greater than 1.1 mg \cdot kg⁻¹. At term, ketamine does not appear to have this effect.¹²⁹

Poor uterine contractility may result from overdistention (polyhydramnios, multiple pregnancy) or maintenance of the supine position. During early labor, administration of opioids, sedatives, or regional anesthesia may delay the onset of the active phase by diminishing uterine activity. However, regional anesthesia instituted during the active phase has no untoward effects on uterine activity as long as hypotension and the supine position are avoided. The addition of epinephrine to a local anesthetic solution may have a dose-related inhibitory effect on uterine activity.

Biochemical Monitoring

Before labor, the normal fetus is neither hypoxic nor acidotic. During labor, many events, including uterine contractions, cord compression, aortocaval compression, and maternal hypotension from any cause, may decrease uteroplacental blood flow sufficiently to produce fetal hypoxia and acidosis. Acidosis associated with short-term placental hypoperfusion primarily results from carbon dioxide accumulation (respiratory acidosis). In prolonged asphyxia, hypercarbia is accompanied by metabolic acidosis resulting from anaerobic metabolism. Thus, fetal acid–base indices, such as P_{CO₂} and base deficit, usually reflect the degree and duration of asphyxia.

Assessment of acid–base status of the fetus became possible in the early 1960s, with the development of a fetal capillary blood-sampling technique. Blood is usually obtained from the scalp but may also be sampled from the breech. It is collected into a heparinized glass capillary tube, and pH, P_{CO₂}, PO₂, and base deficit are determined immediately with an appropriate electrode system adapted to the small sample size.

This technique has been validated in animal and clinical studies. It has been shown in fetal monkeys that the blood values obtained from the scalp are closely correlated with those in simultaneously obtained samples from the carotid artery and jugular vein.¹³⁰ A fetal capillary blood pH of 7.25 is the lowest limit of normal. A pH below 7.20 indicates fetal acidosis, and values between 7.20 and 7.24 are considered preacidotic. The last predelivery fetal pH correlated with the Apgar score at 1 or 2 minutes after birth.^{131,132} Ninety-two percent of infants scored 7 or better when the pH was above 7.25. With the pH below 7.16, 80% of infants scored 6 or less.¹³¹ In general, when the pH is normal immediately before delivery, it can be assumed that the infant will be in good condition. However, there is a small incidence of false-positive and false-negative results. In one study, normal pH was associated with low Apgar scores (false-positive results) in approximately 10% of cases¹³² (Fig. 42-12). In approximately 8% of cases (false-negative results), a vigorous infant was born despite a low capillary scalp pH. The major factors contributing to false-positive outcomes are administration of sedative drugs or anesthetics, infection, airway obstruction, and congenital anomalies. False-negative outcomes are usually associated with maternal acidosis, which may occur after prolonged labor, excessive muscular activity, or inadequate fluid and caloric intakes. Obtaining a maternal sample (arterial or free-flowing venous blood) for the evaluation of the acid-base status helps identify this group. If fetal acidosis is of maternal origin, the mother's blood shows a large base deficit value, and the difference between the fetal and maternal base deficit values (DBD) is small. In contrast, fetal acidosis resulting from prolonged asphyxia is reflected in a large fetal but a normal maternal base deficit value; consequently, the difference in base deficit values is large. Fetal acidosis of maternal origin can be treated by correcting the maternal acid-base imbalance.

Figure 42-12. Fetal pH as an index of infant's condition at birth in 355 patients during labor. Segment A: depressed infants with normal pH; segment B: vigorous infants with normal pH; segment C: depressed infants with low pH; segment D: vigorous infants with low pH. Complications

There are data correlating direct fetal monitoring with maternal infection.¹³³ However, conclusions from these reports are tenuous because most of the affected patients had prolonged rupture of membranes. A less frequent complication of internal monitoring is uterine perforation. The firm plastic cannula used to introduce the intra-amniotic pressure catheter has been implicated. Fetal complications related to scalp electrodes are ecchymoses, lacerations, leakage of cerebrospinal fluid, osteomyelitis of the skull, sepsis, scalp abscesses, and a case of meningitis with ventriculitis and hydrocephalus. The overall incidence of these complications is unknown. Scalp abscess is the most commonly reported.

Scalp capillary blood sampling can also lead to fetal complications. The two major ones are hemorrhage and abscess formation. Bleeding from the sampling site is usually self-limited, but massive hemorrhage resulting in severe anemia and, rarely, neonatal death has been reported. Prenatal and postnatal bleeding from a sampling incision may be the first manifestation of a severe fetal coagulation disorder.

The costs and benefits of fetal monitoring are still being questioned. There is a conflict between the desire for a "natural" childbirth experience and the physician's concern for maternal and fetal safety. It is generally agreed that the use of intensive intrapartum monitoring is appropriate in high-risk pregnancies. Debate continues concerning the benefits of these methods to low-risk fetuses. A large, randomized, controlled trial comparing continuous electronic fetal monitoring with traditional intermittent auscultation of the fetal heart (with an option to measure fetal scalp capillary blood pH) showed that neonatal seizures and abnormal neurologic signs occurred twice as frequently in the group with intermittent auscultation. In addition, the study showed no difference in the cesarean section rate between the two groups.¹³⁴

NEWBORN RESUSCITATION IN THE DELIVERY ROOM

Of the approximately 3.5 million infants born in the United States each year, 6% require resuscitation in the delivery room. Among those weighing 1500 g or less, the incidence is approximately 80%. The following factors may contribute to depression of the newborn: drugs used in labor or during delivery, including anesthetic agents; trauma of precipitate labor and operative obstetrics; and birth asphyxia (*i.e.*, hypoxia and hypercapnia with acidosis).

Fetal Asphyxia

Fetal asphyxia, the best-studied cause of neonatal depression, usually develops as a result of interference with maternal or fetal perfusion of the placenta. As stated previously, the normal fetus is neither hypoxic nor acidotic before labor. Experimental data have revealed that transplacental gradients for pH and P_{CO_2} are approximately 0.05 pH units and 5 mm Hg, respectively. Although oxygen tension is low, oxygen saturation is relatively high (80–85%) by virtue of the shift to the left of the fetal oxyhemoglobin dissociation curve.

During labor, uterine contractions decrease the blood flow through the intervillous space of the placenta or may stop it completely. On the fetal side, cord compression occurs during the final stages of approximately one third of vaginal deliveries. Thus, mild degrees of hypoxia and acidosis occur even during normal labor and delivery, and play an important role in initiation of ventilation. On average, healthy, vigorous infants (at birth) have an oxygen saturation of 21%, a pH of 7.24, and a P_{CO_2} of 56 mm Hg.

Severe fetal asphyxia occasionally develops as a result of fetal and maternal complications such as a tight nuchal cord, prolapsed cord, premature separation of the placenta, uterine hyperactivity, or maternal hypotension. During asphyxia, changes in blood gases and hydrogen ion concentration are rapid. The decrease in pH results from accumulation of carbon dioxide and end products of anaerobic glycolysis. After oxygen stores are exhausted, the ability of fetal brain and myocardium to derive energy from anaerobic metabolism is essential for survival. However, anaerobic glycolysis is pH dependent, and its rate is greatly diminished when the pH decreases below 7.0. Other untoward effects of severe hypoxia and acidosis include depression of the myocardium resulting from a decrease in its responsiveness to catecholamines; a shift to the right of the fetal oxyhemoglobin dissociation curve, resulting in reduced oxygen-carrying capacity; and an increase in pulmonary vascular resistance, which plays an important role during circulatory readjustment after birth.

Ventilatory and cardiovascular responses to controlled experimental asphyxia have been investigated extensively in newborn monkeys (Fig. 42-13). During the initial phase of asphyxia, the unanesthetized animal exhibits respiratory efforts that increase in depth and frequency for up to 3 minutes. This period, called primary hyperpnea, is followed by primary apnea, which lasts for approximately 1 minute. Rhythmic gasping then begins and is maintained at a fairly constant rate of approximately 6 gasps \cdot min^{-1} for 4–5 minutes. Thereafter, the gasps become weaker and slower. Their cessation at approximately 8.5 minutes after the onset of asphyxia marks the beginning of secondary apnea. Administration of opioids and systemic anesthetic agents to the mother can abolish the period of primary hyperpnea and prolong primary apnea.

Figure 42-13. Schematic diagram of changes in rhesus monkeys during asphyxia and with resuscitation by positive-pressure ventilation. Brain damage was assessed by histologic examination some weeks or months later. (Reprinted with permission from Dawes GS: Foetal and Neonatal Physiology: A Comparative Study of the Changes at Birth, p 149. Chicago, Year Book Medical Publishers, 1968.)

There is a linear relationship between the duration of asphyxia and the onset of gasping and rhythmic spontaneous breathing. In the newborn monkey, for each minute of asphyxia beyond the last gasp, 2 additional minutes of artificial ventilation is required before gasping begins again and 4 minutes before rhythmic breathing is established.¹³⁵ This indicates that the longer artificial ventilation of the lungs is delayed during secondary apnea, the longer it will take to resuscitate the infant. Furthermore, in the newborn monkey, prolongation of asphyxia for 4 minutes beyond the last gasp is accompanied by extensive damage to brain stem nuclei, whereas animals resuscitated before the last gasp show little or no brain damage. Thus, a relatively short delay in resuscitation can have serious sequelae.

Neonatal Adaptations at Birth

During this period, and through the early hours and days of life, many morphologic and functional changes take place, with the cardiovascular and ventilatory systems undergoing the most dramatic alterations. In the normal newborn, two events occur almost simultaneously, and within seconds of delivery: the arrest of umbilical circulation through the placenta and expansion of the lungs. These events change the fetal circulation toward the adult type. Survival of the neonate depends primarily on prompt expansion of the lungs and establishment of effective ventilation.

The onset of ventilation and expansion of the lungs opens up the pulmonary vascular bed, resulting in decreased resistance and a significant increase in pulmonary blood flow. Pulmonary vascular resistance decreases as oxygen tension increases and carbon dioxide levels decrease. As soon as pulmonary perfusion increases, the foramen ovale, which constitutes a communication between the inferior vena cava and the left atrium, undergoes functional closure because of pressure changes across the valve of the foramen (see Fig. 42-4). Cessation of the umbilical circulation reduces pressure in the inferior vena cava and right atrium, whereas the increase in pulmonary blood flow increases venous return and pressure in the left atrium. The ductus arteriosus does not constrict abruptly or completely after birth; functional closure may take hours, even days. Thus, shunting still occurs in the neonatal period, its direction depending on relative resistances in the pulmonary and systemic vascular beds. The smooth muscle of the ductus arteriosus constricts in response to increased oxygen tension in the newborn's blood. Catecholamines, which exist in increased concentrations in the newborn, particularly during the first 3 hours of life, also constrict the ductus arteriosus. In contrast, prostaglandins PGI₂ and PGE₂, produced by the wall of the ductus arteriosus, relax the ductal smooth muscle. Administration of prostaglandin synthesis inhibitors to fetal animals promotes constriction of the ductus arteriosus.

Cardiac output and its distribution also increase; left ventricular output increases ~150–400 ml · kg⁻¹ · min⁻¹, whereas right ventricular output increases less significantly. Cardiac output changes closely parallel the increase in oxygen consumption. The redistribution of cardiac output also leads to increases in myocardial, renal, and gastrointestinal blood flow and decreases in cerebral, adrenal, and carotid flow.

During fetal life, respiratory gas exchange takes place through the placenta. Delivery of the infant's trunk relieves the thoracic compression that occurs as the infant passes through the birth canal, and the thorax and the lungs expand. Most infants initiate respiratory efforts a few seconds after birth. After the first inspiration, a cry usually results as the infant exhales against a partially closed glottis, thus increasing intrathoracic pressure significantly. Negative pressures in excess of 40 cm H₂O bring about the initial entry of air into fluid-filled alveoli. In the mature, normal neonate, the lungs expand almost completely after the first few breaths, and the pressure–volume changes achieved with each respiration resemble those of the adult. After lung expansion, the FRC approximates 70 ml in the term newborn and changes little over the first 6 days of life. The tidal volume varies between 10 and 30 ml, the breathing frequency ranges from 30–60 breaths · min⁻¹, and minute ventilation exceeds 500 ml. After delivery and prompt lung expansion, reoxygenation is rapid, but it takes 2 or 3 hours to achieve a relatively normal acid–base balance, primarily by pulmonary excretion of carbon dioxide. By 24 hours, the healthy neonate has reached the same acid–base state as that of the mother before labor.

Resuscitation

The delivery room must be prepared for adequate and prompt treatment of severe neonatal depression at birth. All members of the delivery room team should be trained in resuscitation methods because both mother and infant may encounter difficulty simultaneously. Every piece of apparatus necessary for emergency resuscitation should be checked carefully before delivery (Table 42-4). An overview of resuscitation in the delivery room is provided in Figure 42-14.

Initial Treatment and Evaluation of All Infants

Immediately after delivery, the infant should be held head down while the cord is clamped and cut. The infant should then be placed supine under a radiant heat source, with the head kept low with a slight lateral tilt, and the skin should be dried promptly. A nurse or assistant should listen to the heart beat immediately, indicating the rate by finger movement. If help is not available, the rate can be detected from pulsation of the umbilical cord. At the same time, the resuscitator should aspirate the mouth, pharynx, and nose with a catheter. This suction should be brief, not exceeding 30 seconds. Slapping the infant's soles lightly or rubbing its back frequently aids in initiating a deep breath or cry. The initial appraisal of the newborn should start from the moment of birth, with particular attention paid to the first few breaths and the evenness and ease of respiration. Most infants are vigorous and cough or cry within seconds of delivery. Their heart rate is above $100 \text{ beats} \cdot \text{min}^{-1}$. The administration of free-flowing oxygen rapidly improves their oxygenation and decreases pulmonary vascular resistance. Mildly to moderately depressed infants constitute the largest group requiring some form of resuscitation at birth. These infants are pale or cyanotic, have not established sustained respiration even at 1 minute after delivery, and may be nearly flaccid. However, their heart rate is usually above $100 \text{ beats} \cdot \text{min}^{-1}$. The severely depressed infant is flaccid, unresponsive, and pale, and may often have a heart rate below $100 \text{ beats} \cdot \text{min}^{-1}$. The scoring system introduced by Apgar is a useful method of clinically evaluating the infant, particularly at 1 and 5 minutes after delivery (Table 42-5).

| Sign | 0 | 1 | 2 |
|---------------------|-------------|--|--|
| Heart rate | Absent | $<100 \text{ beats} \cdot \text{min}^{-1}$ | $>100 \text{ beats} \cdot \text{min}^{-1}$ |
| Respiratory effort | Absent | Slow, irregular | Good, crying |
| Muscle tone | Limp | Some flexion of extremities | Active motion |
| Reflex irritability | No response | Grimace | Cough, sneeze, or cry |
| Color | Pale, blue | Body pink, extremities blue | Completely pink |

Table 42-5. APGAR SCORES

Treatment of Moderately Depressed Infants

If initial resuscitative methods, including rubbing the back or slapping the feet once or twice, have produced no response, that is, the infant is apneic or its heart rate remains below $100 \text{ beats} \cdot \text{min}^{-1}$, positive-pressure ventilation by bag and mask should be instituted at a rate of $40 \text{ breaths} \cdot \text{min}^{-1}$. The initial breath may require pressures of 30–40 cm H₂O. Subsequently, the inflation pressures should be reduced to 15–20 cm H₂O in an infant with normal lungs. A small plastic oropharyngeal airway may be needed to maintain patency of the upper airway. If after 15–30 seconds of ventilation the heart rate is below $60 \text{ beats} \cdot \text{min}^{-1}$, or maintained between 60 and $80 \text{ beats} \cdot \text{min}^{-1}$, chest compressions should be initiated.

Treatment of Severely Depressed Infants

Ventilation should be established without delay. The glottis should be inspected immediately with the laryngoscope. If meconium or thick meconium-stained mucus has been aspirated into the trachea, it must be suctioned out at once through an endotracheal tube before the lungs are inflated. It is usually possible to accomplish this within 1–2 minutes of delivery. Severely depressed infants may require 3–8 minutes of artificial ventilation before a spontaneous gasp is taken. The endotracheal tube can be removed as soon as quiet and sustained respiration is established.

Use of Cardiac Massage

If the blood pressure or heart rate is unduly low at the beginning of resuscitation, positive-pressure ventilation is unlikely to be successful unless cardiac massage is used. The technique preferred by the authors consists of intermittent compression of the lower third of the sternum 120 times per minute with the index and middle fingers. During chest compressions, positive-pressure ventilation with 100% oxygen should be performed at a rate of 40–60 per minute. Cardiac massage and ventilation should be maintained until the heart rate exceeds $100 \text{ beats} \cdot \text{min}^{-1}$.

Rapid Correction of Acidosis

In clinical practice, severe acidosis ($\text{pH} < 7.0$ or a base deficit $> 15 \text{ mEq} \cdot \text{l}^{-1}$) should be corrected promptly to improve pulmonary perfusion and oxygenation. For that purpose, a 3.5- or 5.0-French catheter should be inserted, under sterile conditions, into the umbilical vein and advanced until the tip of the catheter is just below the skin level. A solution of sodium bicarbonate, $0.5 \text{ mEq} \cdot \text{ml}^{-1}$ (4.2%), is then infused over at least 2 minutes, up to a total dose of $2 \text{ mEq} \cdot \text{ml}^{-1}$ (Fig. 42-15). Adequate pulmonary ventilation should be ensured during the infusion.

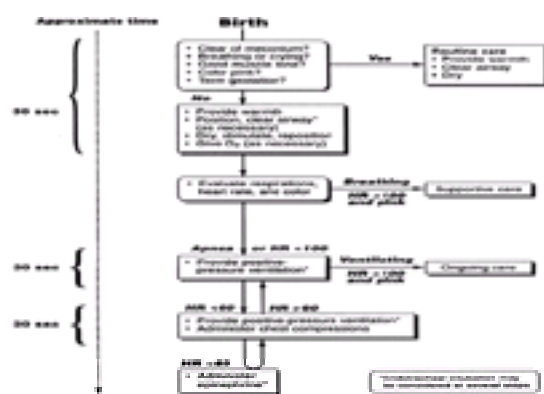

Figure 42-15. Algorithm for resuscitation of the newly born heart.

Other Drugs and Fluids

If it is believed that persistent depression has resulted from maternal opioid medication, naloxone should be given after adequate ventilation has been established (Table 42-6). The recommended dose of $0.1 \text{ mg} \cdot \text{kg}^{-1}$ may be injected iv, im, subcutaneously, or by endotracheal tube. The initial dose may be repeated as needed. Naloxone should be avoided in infants born to opioid-addicted mothers so as not to precipitate acute withdrawal. A severely asphyxiated newborn might require cardiotoxic drugs during early resuscitation. Epinephrine should be used to treat asystole or persistent bradycardia despite adequate ventilation and external cardiac massage. A dose of $0.1\text{--}0.3 \text{ ml} \cdot \text{kg}^{-1}$ of a 1:10,000 solution should be injected iv or by endotracheal tube, and repeated every 5 minutes if necessary.

| Drug or Volume Expansion | Concentration to Administer | Preparation (Based on Recommended Concentration) | Dose | Route |
|--------------------------|---|---|----------------------------|---|
| Epinephrine | 1:1000 | 2 ml in a syringe Catheter (1 with ventral side) 2 pins IT | 0.1-0.2 ml/kg ^a | iv or IT Grossly empty |
| Volume expansion | Whole blood 75% albumin solution Normal saline Lactated Ringer's solution (LR) | 40 ml to be given by syringe or in bag | 20 ml/kg ^b | Given over 5-10 min |
| Sodium bicarbonate | 8.4% solution (150 mEq/L) | 20 ml in a syringe or in bag (10 ml per 100 ml) | 2 ml/kg ^c | iv Given slowly over at least 2 min (2 ml/kg ^c over 10-15 min) iv, 10-15 min IT Grossly empty |
| Normal saline | 0.9% solution (154 mEq/L) | 2 ml in a syringe | 10 ml/kg ^d | iv, 10-15 min IT Grossly empty |

iv = intravenous; IT = intratracheal; iv = intratracheal; iv = subcutaneous.

Table 42-6. THERAPEUTIC GUIDELINES FOR NEONATAL RESUSCITATION

Hypovolemia frequently follows severe birth asphyxia because a greater than normal portion of fetal blood remains in the placenta. The infant appears pale and has low arterial pressure, tachycardia, and tachypnea. Acute blood volume expansion may be accomplished with the iv administration of the following solutions over 5–10 minutes: O negative blood, cross-matched with the mother's blood, 10 ml · kg⁻¹; 5% albumin, 10 ml · kg⁻¹; and normal saline or lactated Ringer's solution, 10 ml · kg⁻¹.

Diagnostic Procedures

After the neonate is successfully resuscitated and stabilized, several diagnostic procedures are indicated. To rule out choanal atresia, each nostril should be obstructed. Because newborns must breathe through their noses, occlusion of the nostril on the patent side causes respiratory obstruction. To rule out esophageal atresia, a suction catheter is inserted into the stomach. Gastric contents are aspirated; volume in excess of 12 ml after vaginal delivery and 20 ml after cesarean section may result from an abnormality of the upper gastrointestinal tract.

ANESTHESIA FOR NONOBSTETRIC SURGERY IN THE PREGNANT WOMAN

Approximately 1.6–2.2% of pregnant women undergo surgery for reasons unrelated to parturition.^{136,137} Apart from trauma, the most common emergencies are abdominal, involving torsion or rupture of an ovarian cyst and acute appendicitis, but breast tumors are not uncommon, as are serious conditions such as intracranial aneurysms, cardiac valvular disease, and pheochromocytoma. Surgery to correct an incompetent cervix with Shirodkar or McDonald sutures is more related to the pregnancy itself.

When the necessity for surgery arises, anesthetic considerations are related to the alterations in maternal physiologic condition with advancing pregnancy, the teratogenicity of anesthetic drugs, the indirect effects of anesthesia on uteroplacental blood flow, and the potential for abortion or premature delivery. The risks must be balanced to provide the most favorable outcome for mother and child.

Four major studies have attempted to relate surgery and anesthesia during human pregnancy to fetal outcome as determined by anomalies, premature labor, or intrauterine death.^{136,137,138,139} and ¹⁴⁰ Although they failed to correlate surgery and anesthetic exposure with congenital anomalies, all of them demonstrated an increased incidence of fetal death, particularly after operations during the first trimester. No particular anesthetic agent or technique was implicated, and it seemed that the condition that necessitated surgery was the most relevant factor, with fetal mortality greatest after pelvic surgery or procedures performed for obstetric indications (*i.e.*, cervical incompetence).

Two studies deserve mention. A review was taken of the entire population of the province of Manitoba, Canada, between the years 1971 and 1978.¹³⁹ State health insurance records were used to identify approximately 2500 pregnant women who had undergone surgery during this period. Each patient was matched with a woman of similar age, living in the same area, with a pregnancy-related condition but no surgical intervention. As in earlier studies, there was no increase in the incidence of congenital anomalies in the offspring of mothers who had had surgery. However, there was an increased risk of spontaneous abortion in women who had received general anesthesia during the first or second trimesters, which was most evident after gynecologic operations. Few of the surgical group had had procedures to treat cervical incompetence, suggesting that factors other than the obstetric condition itself might be important. The results also might have been influenced by the fact that a small number of gynecologic procedures were performed with anesthesia other than general, so that the effect of the surgical site alone could not be distinguished. The authors emphasized a multiplicity of factors other than choice of anesthetic agent (*e.g.*, diagnostic radiologic procedures, antibiotics, analgesics, infection, decreased uterine perfusion, and stress) that might have been responsible for the increased risk of abortion.

The largest study to date regarding reproductive outcome after surgery during pregnancy is a Swedish registry review covering the years 1973–1981.¹⁴⁰ During this period, there were a total of 720,000 births, 5405 of them after anesthesia and surgery during pregnancy. The results of this study are reassuring in that there was no increased incidence of congenital anomalies or stillbirths among infants exposed *in utero* to maternal surgery and anesthesia. However, in this group there was an increased frequency of very low and low birth weights, and of deaths within 168 hours after delivery. The reasons for this are unclear and are not related to any specific type of operation. The authors postulated that the maternal illness itself may have been a major contributor to adverse neonatal outcome.

Studies of the effects of chronic exposure to subanesthetic concentrations of inhalation agents on pregnancy offer a different approach to the question of outcome. Evidence originates from animal studies and from epidemiologic surveys performed on operating room personnel and their offspring. A nationwide survey conducted by the American Society of Anesthesiologists found a higher incidence of cancer among female anesthesia personnel as well as increased rates of abortion and congenital abnormalities in their infants.¹⁴¹ Furthermore, the last of these misfortunes also applied, although to a lesser degree, to unexposed wives of male operating room personnel. The results of these studies have been disputed because of possible statistical inaccuracies and inappropriate choices of control groups. Another survey conducted among dentists and their female assistants compared the incidence of spontaneous abortions and congenital abnormalities among those exposed to inhalation anesthetics and those using only local anesthetics in their daily practices.¹⁴² A significant increase in these complications occurred among assistants and wives of dentists exposed to inhalation drugs. Because of the controversy surrounding this issue, the American Society of Anesthesiologists commissioned an independent review by a team of epidemiologists.¹⁴³ This group found the data from most of the surveys to be flawed for a variety of reasons. These included responder bias, inappropriate control groups, failure to document exposure levels or verify medical data, and inability to ascertain which of the many environmental factors present in operating rooms might be blamed. The group concluded that, although exposed women appeared to have an increased risk of abortion (and, to a much lesser extent, congenital anomalies), the increase was small enough to be accounted for by bias and uncontrolled variables. Some of these problems are absent in two subsequent studies in which questionnaire information was matched with information obtained from medical records or registries of abortions, births, and congenital malformations.^{144,145} Neither of these studies found significant deviations from expected rates of threatened abortion in exposed women. In addition, no differences in birth weight distribution, perinatal mortality, or congenital malformations in the infants of exposed and nonexposed women were detected.¹⁴⁵ The authors point out that their results do not indicate that there is no reproductive hazard relating to working in operating rooms; effects that might have been missed include very early abortions not requiring hospitalization, congenital abnormalities not apparent at birth, and infertility.

Direct Effects of Anesthetic Agents on Embryo and Fetus

The idea that surgical anesthesia, although deemed necessary for the patient, might have detrimental effects on the growth and development of the human fetus has led to a great deal of investigation, both *in vitro* and in experimental animals. These studies present difficulties in interpretation because the concentrations of anesthetic and the duration of exposure are frequently far in excess of what is clinically used and because most of the studies were performed in lower animals.

Animals exposed to toxic substances and anesthetics show a dose-related response, the first change being decreased fertility and increased fetal death. With increasing dose, the number of surviving fetuses with anomalies begins to increase, with the peak incidence occurring at a dose that causes a 50% incidence of fetal death.¹⁴⁶ The teratogenic effects between species and also within the same species vary significantly. The developmental stage is crucial, with dramatic sensitivity to exposure at certain times and little or no effect at a later time.¹⁴⁶ The period of organogenesis is most critical. In humans, it corresponds to the 15th–56th days of gestation.

Many congenital malfunctions show a pattern of multifactorial inheritance. In this mode, maldevelopment may result from a combination of factors in one person, such as hereditary predisposition, sensitivity to a given drug, and exposure at a vulnerable time in development. There are numerous other factors contributing to the potential teratogenicity of anesthesia. The cytotoxicity of anesthetic agents is closely associated with biodegradation, which, in turn, is influenced by oxygenation and hepatic blood flow. Thus, the complications associated with anesthesia, such as maternal hypoxia, hypotension, administration of vasopressors, hypercarbia,

hypocarbica, and electrolyte disturbances, may possibly be a greater cause for concern as regards teratogenesis than the use of the agents themselves.¹⁴⁷ Hypoxia is certainly a well documented teratogen in the incubating chick embryo.¹⁴⁸ The role of maternal carbohydrate metabolism on embryonic development is also important. For example, the effects of 48 hours of fasting and administration of insulin to pregnant rats have included a large number of skeletal deformities.¹⁴⁹

Experimental evidence on exposure to specific drugs and agents is highlighted briefly, with the consideration that it is difficult to extrapolate laboratory data to the clinical situation in humans. Very large numbers of patients must be exposed to a suspected teratogen before its safety can be ascertained. Complicating factors include the frequency of maternal exposure to a multiplicity of drugs; the difficulty in separating the effects of the underlying disease process and surgical treatment from those of the drug administered; differing degrees of risk with stage of gestation; and the variety, rather than the consistency, of anomalies that appear in association with one agent. Of the premedicants, anticholinergics have not been found to be teratogenic, whereas tranquilizers and sedatives such as phenothiazines and barbiturates produce anomalies in some species.¹⁵⁰ Several reports have described a specific relationship between diazepam and oral clefts, but another study has not confirmed this.^{151,152} Intravenous agents such as thiopental, methohexital, and ketamine in doses normally used in the operating room have not been associated with birth defects. Only one study has shown musculoskeletal deformities involving the joints after infusion of a muscle relaxant (*d*-tubocurarine) in the chick embryo between the 7th and 15th day of incubation.¹⁵³ Local anesthetics have not been shown to be teratogenic in animals or humans.¹⁴⁷ Halogenated inhalation drugs have produced conflicting results. Pregnant rats exposed to halothane 0.8% for 12 hours at various times during gestation have increased incidences of anomalous skeletal development and fetal death.¹⁵⁴ Other investigators have failed to show teratogenic effects of halothane in rats, rabbits, and mice exposed to subanesthetic concentrations for brief periods. Subanesthetic concentrations of enflurane do not appear to be teratogenic. However, mice exposed to 1% enflurane for 4 h · day⁻¹ on days 6–15 of gestation showed an increased incidence of cleft palates and minor skeletal and visceral abnormalities.¹⁵⁵ In a subsequent study by the same authors, teratogenic changes after exposure to 0.6% isoflurane in mice were similar to those found with enflurane, but the incidence of cleft palate was six times more frequent (12 vs. 1.9%).¹⁵⁶ Cleft palate readily develops in mice, and its occurrence as an isolated finding suggests that this might be a species-specific response. To clarify the results from earlier studies, rats were exposed to 0.75 MAC halothane, isoflurane, or enflurane; 0.55 MAC nitrous oxide; or a known teratogen, retinoic acid, for two 6-hour periods at three different stages of pregnancy.¹⁵⁷ No major morphologic abnormalities occurred in any of the anesthetic-exposed groups.

Nitrous oxide has been the most extensively investigated agent since the 1955 observation that leukopenia developed in patients with tetanus after they inhaled nitrous oxide for several days. Numerous studies have demonstrated significant effects on fetal growth, skeletal development, and death rate in both pregnant rats and incubating chicks exposed to concentrations of between 50 and 80%, for periods ranging from hours to days.¹⁵⁸ The question arises whether adverse effects at such high doses resulted from the anesthetic itself or from the accompanying physiologic derangements.

Although the mechanism of the teratogenic effect of nitrous oxide has not been determined, it may be related to the inhibitory effect of the agent on methionine synthetase activity and vitamin B₁₂. A dose-dependent decrease in both maternal and fetal methionine synthetase activity occurred in pregnant rats receiving 10 or 50% nitrous oxide for periods ranging from 60–240 minutes.¹⁵⁹ It is possible that failure of this enzyme to convert homocysteine to the essential amino acid methionine may lead to abnormalities of myelination of nerve fibers (Fig. 42-16). Furthermore, inhibition of methionine synthesis results in decreased thymidine production, which in turn can lead to decreased DNA synthesis and inhibition of cell division. Because there is evidence that nitrous oxide adversely affects methionine synthetase activity, it has been recommended that it not be administered to pregnant women in the first two trimesters.^{160,161} However, a more recent human study demonstrated no significant changes in plasma methionine concentrations after anesthesia with 60–70% nitrous oxide for up to 4 hours.¹⁶² Two other reviews of exposure to this agent, this time for cervical cerclage procedures, showed no effects on fetal outcome.^{163,164} Further, in the already mentioned Swedish birth registry study, nitrous oxide was administered to almost all of 2929 patients receiving general anesthesia without adverse fetal consequences.¹⁴⁰ In rats, the teratogenic effects of nitrous oxide could be prevented by the concomitant administration of isoflurane or halothane.¹⁶⁵ It is controversial whether pretreatment with folic acid, the concentration of which is reduced when methionine synthetase is inhibited, affords protection against the effects of nitrous oxide.¹⁶⁵ Because a single exposure to anesthetic agents seems unlikely to result in fetal abnormality, the selection of agent should be based on specific surgical requirements.

Indirect Effects of Agents and Techniques

The adequacy of the uteroplacental circulation, so vital to the well-being of the fetus, is easily affected by drugs and anesthetic procedures. As discussed previously, perfusion of the intervillous space of the placenta may be diminished consequent on maternal systemic hypotension, which in turn may result from the use of epidural or spinal anesthesia, from aortocaval compression with the patient in the supine position, or from hemorrhage. Similarly, increased uterine activity may result in reduced placental perfusion. Thus, the use of α -adrenergic drugs to correct maternal hypotension and anesthetics such as ketamine (in doses above 1 mg · kg⁻¹) may produce increased uterine tone sufficient to endanger the fetus. Severe hyperventilation of the mother may also reduce uterine blood flow. Finally, it has been shown in experimental animals that epinephrine or norepinephrine infusion results in decreased uterine blood flow and deterioration of fetal condition. Maternal pain and apprehension may similarly affect the fetus.¹⁶⁶

Practical Suggestions

It is generally agreed that only emergency surgery should be performed during pregnancy, particularly in the first trimester. The possibility of pregnancy should be considered in all female surgical patients of reproductive age. Based on the maternal and fetal hazards already described, the following approach to anesthesia seems indicated:

1. The patient's apprehension should be allayed as much as possible by personal reassurance during the preanesthetic visit and by adequate sedation and premedication.
2. Pain should be relieved whenever present.
3. An antacid, 15–30 ml, should be administered within half an hour before induction of anesthesia. Ranitidine and metoclopramide may be useful.
4. Beginning in the second trimester, uterine displacement must be maintained at all times.
5. Hypotension related to spinal or epidural anesthesia should be prevented as much as possible by rapid iv infusion of crystalloid solution before induction. If the mother becomes hypotensive, ephedrine should be promptly administered iv.
6. General anesthesia should be preceded by careful denitrogenation.
7. The risk of aspiration should be minimized by application of cricoid pressure and rapid tracheal intubation with a cuffed tube.
8. To reduce fetal hazard, particularly during the first trimester, it appears preferable to choose drugs with a long history of safety; these drugs include thiopental, morphine, meperidine, muscle relaxants, and low concentrations of nitrous oxide.
9. Avoid maternal hyperventilation and monitor end-expiratory P_aCO₂ or arterial blood gases.
10. Fetal heart rate should be monitored continuously throughout surgery and anesthesia, provided that placement of the transducer does not encroach on the surgical field¹⁶⁷ (this becomes technically feasible from the 16th week of pregnancy). Uterine tone may also be monitored with an external tocodynamometer if the uterus reaches the umbilicus or above.
11. Monitoring of uterine activity should be continued after operation, and tocolytic agents may be required.
12. Special procedures such as hypothermia and induced hypotension might be necessary to facilitate surgery, despite the potential fetal hazard. It is reassuring to know that there was successful fetal outcome after both procedures for intracranial operations.^{168,169} There are numerous reports of cardiopulmonary bypass being performed during pregnancy, with generally good maternal and fetal results.^{170,171}

PHYSIOLOGY OF THE INFANT AND THE TRANSITION PERIOD

The first year of life is characterized by an almost miraculous growth in size and maturity. The body weight alone changes by a factor of 3, and there is no other period in extrauterine life when changes occur so rapidly. Before birth, fetal growth and development depend on the genetic composition of the fetus, the mother's placental function, and potential exposure to chemicals or infectious agents that can affect mother, fetus, or both. The journey down the birth canal (or through the abdominal wall)—called the most dangerous trip in a person's life—ends the fetal period, and the newborn must adapt to extrauterine life. This change from fetal to extrauterine life is called the period of transition or adaptation.

The newborn infant is an infant in the first 24 hours of life. This chapter focuses on the neonatal period, which is defined as the first 30 days of extrauterine life and includes the newborn period.

The most significant part of transition occurs in the first 24–72 hours after birth. All systems of the body change during transition, but the most important to the anesthesiologist are the circulatory, pulmonary, hepatic, and renal systems. The circulatory and pulmonary systems are so interdependent that they are discussed together.

Transition of the Cardiopulmonary System

Fetal Circulation

Fetal circulation is characterized by the presence of three main shunts (Fig. 43-1A). These shunts are the placenta, foramen ovale, and ductus arteriosus. The relatively low pressure in the left atrium and the high pressure in the right atrium result in the foramen ovale being open. The pulmonary vascular bed has a high vascular resistance because the alveoli are relatively closed and filled with fluid and the blood vessels are compressed. In addition, the low partial pressure of oxygen in arterial blood (PaO_2) and pH increase pulmonary vascular resistance. However, the ductus arteriosus represents a low-resistance system because it is dilated secondary to a low PaO_2 . Therefore, the blood that leaves the right ventricle by the pulmonary artery is shunted preferentially (90%) through the ductus arteriosus and down the descending aorta, whereas only 10% of the output of the right ventricle flows through the pulmonary artery into the pulmonary vascular bed. The pulmonary vascular bed requires only enough blood flow to ensure growth and development of the pulmonary tissue, including surfactant production.

Figure 43-1. (A) Schematic representation of the fetal circulation. Oxygenated blood leaves the placenta in the umbilical vein (vessel without stippling). Umbilical vein blood joins blood from the viscera (represented here by the kidney, gut, and skin) in the inferior vena cava. Approximately half of the inferior vena cava flow passes through the foramen ovale to the left atrium, where it mixes with a small amount of pulmonary venous blood, and this relatively well oxygenated blood (light stippling) supplies the heart and brain by way of the ascending aorta. The other half of the inferior vena cava stream mixes with superior vena cava blood and enters the right

ventricle (blood in the right atrium and ventricle has little oxygen, which is denoted by *heavy stippling*). Because the pulmonary arterioles are constricted, most of the blood in the main pulmonary artery flows through the ductus arteriosus (DA), so that the descending aorta's blood has less oxygen (*heavy stippling*) than does blood in the ascending aorta (*light stippling*). (B) Schematic representation of the circulation in the normal newborn. After expansion of the lungs and ligation of the umbilical cord, pulmonary blood flow and left atrial and systemic arterial pressures increase. When left atrial pressure exceeds right atrial pressure, the foramen ovale closes so that all the inferior and superior vena cava blood leaves the right atrium, enters the right ventricle, and is pumped through the pulmonary artery toward the lung. With the increase in systemic arterial pressure and decrease in pulmonary artery pressure, flow through the ductus arteriosus becomes left-to-right and the ductus constricts and closes. The course of circulation is the same as in the adult. (Reprinted with permission from Phipps R: Delivery room management of the newborn. In Avery GB [ed]: Neonatology, Pathophysiology and Management of the Newborn, p 184. Philadelphia, JB Lippincott, 1981.)

The placenta oxygenates the blood, which then courses up the inferior vena cava into the right atrium. The right atrium is divided by a structure called the crista dividens, so that this relatively well oxygenated blood is shunted from the right atrium through the foramen ovale into the left atrium, thereby bypassing the right ventricle and the pulmonary vascular bed. This blood, the best oxygenated in the fetus, progresses from the left atrium to the left ventricle and out the ascending aorta to provide oxygenation for the brain and upper extremities. Blood returns from the upper body to the right heart by the superior vena cava, where it is directed by the crista dividens into the right ventricle, from which it is then pumped out the pulmonary artery.

Clamping of the umbilical cord and initiation of ventilation produce enormous circulatory changes in the newborn (Fig. 43-1B). The transition of the alveoli from a fluid-filled to an air-filled state results in a reduced compression of the pulmonary alveolar capillaries with a reduction in pulmonary vascular resistance; there is a rapid reduction in the first several hours of life. However, it takes 3–4 days for the pulmonary vascular resistance to decrease to the eventual level that it will achieve during the neonatal period. Nitric oxide is an integral part of the reduction in pulmonary vascular resistance; its clinical use is discussed later in the chapter. The initial moderate decrease in pulmonary vascular resistance is accompanied by constriction of the ductus arteriosus secondary to oxygenation. This results in an increase in pulmonary blood flow and an increase in left atrial pressure, so that the foramen ovale functionally closes. Closure of these two neonatal shunts (*i.e.*, the ductus arteriosus and the foramen ovale) is initially only a functional closure. Both shunts usually close permanently in the first several months of life. However, an autopsy study of normal hearts has demonstrated a 30% incidence of patent foramen ovale during the first 30 years of life and a 20% incidence for people 30 years of age and older.¹

Incidence of Patent Ductus Arteriosus in the Premature Infant

A study by Reller *et al*² demonstrated that a patent ductus arteriosus (PDA) on or beyond the fourth day of life is abnormal regardless of gestational age. Prematurity, unless complicated by acute asphyxia or the respiratory distress syndrome, is not a risk factor for persistent PDA. In their study, 95% of premature infants, regardless of gestational age, had closure of the ductus by day 4. The incidence of a PDA in premature infants with the respiratory distress syndrome without a history of birth asphyxia was 11%, a percentage that is somewhat less than is commonly assumed.

Persistent Pulmonary Hypertension

The major transition of the circulatory system occurs over the first 24 hours of life. Figure 43-2 illustrates the correlation of the mean pulmonary artery pressure with age during the first 3 days of life. The pulmonary circulation is extremely sensitive to oxygen, pH, and nitric oxide. Hypoxia and acidosis, along with inflammatory mediators, may cause pulmonary artery pressure either to persist at a high level, or, after initially decreasing, to increase to pathologic levels. The result is termed *persistent pulmonary hypertension* (PPH). The pathophysiologic characteristics of pulmonary hypertension comprise a spectrum, ranging from normal pulmonary vasculature to abnormal pulmonary vasculature that is characterized by extension of smooth muscle into the distal respiratory units (Fig. 43-3). There are all degrees in between. Vasoconstriction of the muscle in the blood vessels of the pulmonary vascular bed results in pulmonary hypertension with a right-to-left shunt through the foramen ovale or the ductus arteriosus (Fig. 43-4).

Figure 43-2. Correlation of mean pulmonary arterial pressure with age in 85 normal-term infants studied during the first 3 days of life. (Reprinted with permission from Emmanouilides GC, Moss AJ, Duffie ER, Adams FH: Pulmonary arterial pressure changes in human newborn infants from birth to 3 days of age. *J Pediatr* 65:327, 1964.)

Figure 43-3. Diagram of muscle extension along pulmonary arterial branches (*shaded bars*). In the normal newborn, virtually no intra-acinar artery is muscular. In 9 of 10 infants with meconium aspiration and persistent pulmonary hypertension (PPH), muscle extended into the most peripheral arteries; the infant with meconium aspiration without PPH (case 11) had normal intra-acinar arteries. (Reprinted with permission from Murphy JD, Vawter GF, Reid LM: Pulmonary vascular disease in fetal meconium aspiration. *J Pediatr* 104:758, 1984.)

Figure 43-4. Schematic representation of the circulation in an asphyxiated newborn with incomplete expansion of the lungs. Pulmonary vascular resistance is high,

pulmonary blood flow is low (note the small caliber of the pulmonary vein), and flow through the ductus arteriosus is high. With little pulmonary venous flow, left atrial pressure decreases below right atrial pressure, the foramen ovale opens, and vena cava blood flows through the foramen into the left atrium. This partially venous blood flows to the brain by the ascending aorta. The descending aorta blood that flows to the viscera has less oxygen than that of the ascending aorta (*heavy stippling*) because of the right-to-left flow through the ductus arteriosus. The circulation is the same in the fetus except that there is no oxygenated blood in the inferior vena cava from the umbilical vein. (Reprinted with permission from Phibbs R: Delivery room management of the newborn. In Avery GB [ed]: Neonatology, Pathophysiology and Management of the Newborn, p 184. Philadelphia, JB Lippincott, 1981.)

Persistent pulmonary hypertension is a syndrome that may be primary with no recognized etiology, or it may be secondary to meconium aspiration, sepsis, pneumonia, respiratory distress, and congenital diaphragmatic hernia (CDH). Currently, the basic treatment depends on the degree of respiratory failure and the response to therapy. The goals of therapy are to achieve a PaO₂ between 50 and 70 and a PaCO₂ between 40 and 60 cm H₂O. Problems of PPH or hypoxic respiratory failure involve not only preterm but term infants. There have been major changes in therapy in the 1990s with the introduction of surfactant, high-frequency ventilation, inhaled nitric oxide, and extracorporeal membrane oxygenation (ECMO). The technique and degree of intervention depend on the response to supportive care. Surfactant and various ventilatory techniques are used as the first-line treatment. These techniques include intermittent mandatory ventilation, assist control ventilation, and proportional assist ventilation.^{3,4} and ⁵ Studies with proportional assist ventilation demonstrate that gas exchange can be maintained with smaller transpulmonary pressure changes, which may reduce the incidence of chronic lung disease in low-birth-weight infants.⁵

A number of reports have discussed the use of ECMO.^{4,6,7} The therapy is aimed at resting the infant's lungs while providing adequate oxygenation for survival and lung repair. It is hoped that the rested lung can recover its function by repairing the pulmonary parenchyma and restructuring the pulmonary vascular bed. The lung is ventilated with low pressures, namely, 20 cm H₂O pressure with 5 cm H₂O of positive end-expiratory pressure (PEEP) and an FIO₂ of 0.21 to 0.3. As the infant's pulmonary function improves, evidenced by increasing PaO₂ levels, the ECMO is reduced accordingly. This is an extremely expensive and high-risk technique that requires an experienced and talented team. The vascular shunt is performed through either a venovenous or a venoarterial circuit. Heparin must be administered to the infants, and this may increase the chance of intracranial bleeding. The use of ECMO therapy has increased tremendously in the past several years; however, there is a definite associated morbidity and mortality rate.^{8,9} Many infants with respiratory failure who are candidates for ECMO have been successfully treated with nitric oxide, and ECMO has been avoided.

Meconium Aspiration

Interference with the normal maternal placental circulation in the third trimester may cause chronic fetal hypoxia. Fetal hypoxia can result in an increase in the amount of muscle in the blood vessels of the distal respiratory units.¹⁰ Figure 43-3 illustrates the muscle increase found in blood vessels of a series of 11 infants who died of PPH.¹¹ Chronic fetal hypoxia leads to the passage of meconium *in utero*. The fetus breathes *in utero* so that the meconium enters the pulmonary system. It is thought that the meconium *per se* does not cause the extension of the muscle of the pulmonary vascular system but that such muscle extension along pulmonary arterial branches is due to fetal hypoxia. Meconium aspiration can be a marker of chronic fetal hypoxia in the third trimester. This condition is different from the meconium aspiration that occurs during delivery. This meconium at birth is thick and tenacious and mechanically obstructs the tracheobronchial system. Meconium aspiration syndrome leads to varying degrees of respiratory failure, which can be fatal in spite of all treatment modalities.

Until relatively recently, tracheal intubation and suctioning were recommended for all infants with frank meconium aspiration or meconium staining (approximately 10% of newborns). Now a more conservative approach should be used because routine intubation may cause unnecessary respiratory complications.^{8,9,12} Routine oropharyngeal suctioning is recommended immediately at the time of delivery, but tracheal intubation and suctioning should be performed selectively, depending on the condition of the infant. Infants with a high Apgar score (*i.e.*, 7–9) need no additional airway management. Infants with a low Apgar score or who are clinically obstructed with meconium should have the appropriate resuscitative measures taken.

Transition of the Pulmonary System

The pulmonary system transition occurs more quickly than the circulatory system transition. The primary event of the pulmonary system transition is the initiation of ventilation, which changes the alveoli from a fluid-filled to an air-filled state. During the first 5–10 minutes of extrauterine life, normal ventilatory volumes develop and a normal tidal ventilation is established. The initial negative intrathoracic pressures that the newborn generates are often in the range of 40–60 cm H₂O. By 10–20 minutes of life, the newborn has achieved its near-normal functional residual capacity (FRC) and the blood gases are well stabilized. Table 43-1 lists the normal blood gases for the various periods of life. A recent study in preterm infants older than 26 weeks' gestational age demonstrated that a single dose of dexamethasone given within 2 hours of delivery resulted in lower ventilator settings and a higher mean blood pressure during the first week of life.¹³ In addition, fewer infants in this group received indomethacin to treat a PDA.

| Subject | Age | Po ₂ (mm Hg) | Pco ₂ (mm Hg) | pH |
|------------------------------|--------------|----------------------------|-----------------------------|------|
| Fetus (term) | Before labor | 25 | 40 | 7.37 |
| Fetus (term) | End of labor | 10–20 | 55 | 7.25 |
| Newborn (term) | 10 min | 50 | 48 | 7.20 |
| Newborn (term) | 1 hr | 70 | 35 | 7.35 |
| Newborn (term) | 1 wk | 75 | 35 | 7.40 |
| Newborn (preterm, 1500 g) | 1 wk | 60 | 38 | 7.37 |

Table 43-1. NORMAL BLOOD GAS VALUES IN THE NEWBORN

Transition and Maturation of the Renal System

The fetal kidneys and the fetal lungs have certain similarities. During the fetal period, both have a relatively low blood flow compared with that during the newborn and neonatal periods because both organs need only enough blood flow for growth and development. The maternal placenta removes fetal waste material. The major function of the fetal kidneys is the production of urine, which contributes to the formation of amniotic fluid, which is important for the normal development of the fetal lung and acts as a shock absorber for the fetus. The fetal kidney is characterized by a low renal blood flow (RBF) and glomerular filtration rate (GFR).¹⁴ There are four major reasons for the low RBF and GFR: low systemic arterial pressure, high renal vascular resistance, low permeability of the glomerular capillaries, and the small size and number of glomeruli. The low systemic arterial pressure and high vascular resistance are the two characteristics that are similar to those found in the fetal lung. This results in a low RBF, which in turn results in a low GFR. Transition changes the first two factors: the systemic arterial pressure increases and the renal vascular resistance decreases. Again, this is similar to what occurs in the lung. The other two factors are changed through maturation. The limited ability of the newborn's kidney to concentrate or dilute urine results from the low GFR at birth. However, during the first 3–4 days, the circulatory changes increase RBF and GFR and improve the neonate's ability to concentrate and dilute the urine. The maturation continues, and by the time the normal full-term infant is 1 month of age, the kidneys are approximately 70% mature. This is sufficient renal function to handle almost any contingency.

The neonatal kidney does have certain limitations. The renin–angiotensin–aldosterone system is the primary compensatory system for the reabsorption of sodium and water to compensate for the loss of plasma, blood, gastrointestinal tract fluid, and third-space fluid. Although the neonate has a normal renin–angiotensin–aldosterone system, the neonatal kidney cannot completely conserve sodium, even with a severe sodium deficit. Aldosterone facilitates the reabsorption of sodium in the distal tubule. The immature tubular cells cannot completely reabsorb sodium under the stimulus of aldosterone, so that the neonate continues to excrete sodium in the urine even in the presence of a severe sodium deficit. For this reason, the neonate is considered an “obligate sodium loser.” In the mature state, the distal tubule can reabsorb essentially all of the sodium, so that the urine has less than 5–10 mEq of sodium per liter of urine. In the neonate, this number may be as high as 20–25 mEq of sodium per liter of urine.

Fluid and Electrolyte Therapy in the Neonate

The inability of the neonatal distal tubule to respond fully to aldosterone results in the obligatory sodium loss in the urine. Therefore, intravenous (iv) fluids in the neonate must contain sodium. Most operations on neonates involve loss of blood and extracellular fluid, which must be replaced with a fluid of similar electrolyte content (*i.e.*, a balanced salt solution: lactated Ringer's, Plasmalyte).

The other problems of the neonate are those of appropriate glucose administration. Infants of diabetic mothers and those small for gestational age have particular problems with hypoglycemia. These infants need to have their blood glucose values monitored until stable. Neonates scheduled for surgery who have been receiving hyperalimentation fluids or supplementary glucose must continue to receive that fluid during surgery or must have their glucose levels monitored because of concerns of hypoglycemia. This concern must be balanced against the potential augmentation of ischemic injury by the administration of glucose, which may result in glycemia. One issue of glucose metabolism is what constitutes hypoglycemia.¹⁵ There is no consensus on this issue. The anesthesiologist and neonatologist have very different problems in this area. For the neonatologist, the issue is not one or two episodes of hypoglycemia, but the recurrent problem of hypoglycemia over a period of days, which has been demonstrated to result in brain damage. The anesthesiologist is faced with a different picture, in which the issues are whether the glucose-containing solution may be interrupted or, conversely, if a bolus of the solution should be administered along with various medications that may be required during the anesthetic. For this reason, the balanced salt solution used for replacement therapy during surgery should either be administered through a separate iv line or as close to the iv port as possible. If there is any question about the glucose level, it should be checked during surgery.

Premature infants and neonates must receive full-strength balanced salt solution for the replacement of third-space and blood losses during the perioperative period.¹⁰ There is a misconception that these infants cannot tolerate the salt load; therefore, they are often given hypotonic fluids. It is not unusual to see premature infants with postoperative sodium values of 125–130 mEq · l⁻¹. Alone, these levels may not be a major problem, but when added to the residual effects of muscle relaxants and antibiotics in a sick infant, they may result in depression of neuromuscular function.

Atrial Natriuretic Factor

There has been interest in the role of atrial natriuretic factor (ANF, a peptide) in sodium homeostasis of the infant. ANF is released from the atria and reduces sodium overload in the body. ANF affects renal function by altering renal hemodynamics and increasing urinary sodium and water excretion; it also increases the GFR, which results in a significant natriuresis without an alteration in total RBF. In addition, ANF opposes the renin system. The renin–angiotensin–aldosterone system is a tightly controlled system that immediately activates when there is a challenge to arterial blood pressure as well as a deficit of sodium. Sometimes this system overshoots and the patient acquires an excessive sodium load.

ANATOMIC AND MATURATIONAL FACTORS OF NEONATES AND THEIR CLINICAL SIGNIFICANCE

The anatomic and maturational factors unique to the neonate have far-reaching clinical implications (Fig. 43-5). Neonates are obligate nose breathers; therefore, anything that obstructs the nares compromises the neonate's ability to breathe. For this reason, choanal atresia is a life-threatening surgical problem for the infant. The large tongue occupies relatively more space in the infant's airway and makes it difficult to conduct a laryngoscopic examination and intubate the infant's trachea. In the normal adult, the glottis is at the level of C5. In the full-term infant, the glottis is at the level of C4, and in the premature infant it is at the level of C3. The combination of a large tongue and a relatively high glottis means that on laryngoscopic examination it is more difficult to establish a line of vision between the mouth and larynx: there is relatively more tissue in less distance. Therefore, the infant's larynx appears to be anterior. When combined with the anterior-slanting vocal cords, the result is a more difficult laryngoscopic examination and intubation. Application of cricoid pressure by the anesthesiologist or an assistant improves visualization of the neonate's larynx. If the anesthesiologist's hand is large enough, cricoid pressure can be applied with the little finger (Fig. 43-6). This is more effective than having an assistant apply pressure because the anesthesiologist can determine the best position for intubation.

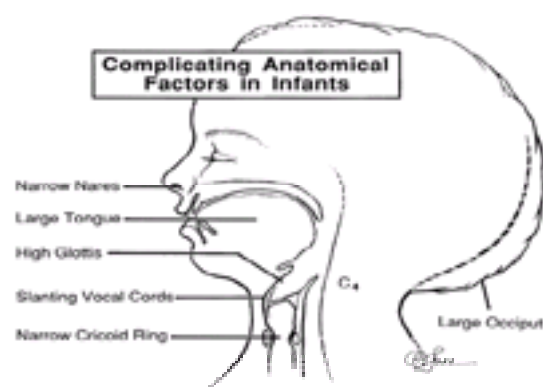

Figure 43-5. Complicating anatomic factors in infants. (Modified with permission from Smith RM: Anesthesia for Infants and Children, 4th ed. St. Louis, CV Mosby, 1980.)

Figure 43-6. Cricoid pressure applied with little finger. (Reprinted with permission from Physiology and surgery of the infant. In Berry FA [ed]: Anesthetic Management of Difficult and Routine Pediatric Patients, p 129. New York, Churchill Livingstone, 1990.)

A narrow cricoid ring is significant because it means that the narrowest portion of the neonate's airway is not the vocal cords but the cricoid ring. In the mature state, the airway from the vocal cords down the trachea is of equal dimensions (Fig. 43-7), and if the endotracheal tube passes comfortably through the vocal cords, it will not be tight within the cricoid cartilage. However, the neonate's laryngeal structures resemble a funnel; even though the endotracheal tube may pass through the vocal cords, which are at the midpoint of the funnel, the endotracheal tube may be tight within the cricoid ring. This tight fit may cause temporary or permanent damage to the cricoid cartilage, resulting in short- or long-term airway difficulties. The infant has a large occiput so that the head flexes forward onto the chest when the infant is lying supine with its head in the midline (Fig. 43-8A). Extreme extension can also obstruct the airway, so that a mid-position of the head with slight extension is preferred for airway maintenance. This is accomplished by placing a small roll at the base of the neck and shoulders (see Fig. 43-8B).

Figure 43-7. Configuration of the adult (A) versus the infant larynx (B). The adult larynx has a cylindrical shape. The infant larynx is funnel shaped because of the narrow, undeveloped cricoid cartilage. (Reprinted with permission from The pediatric airway. In Ryan JF, Todres ID, Cote CJ *et al* [eds]: A Practice of Anesthesia for Infants and Children, 2nd ed., p 61. Orlando, Florida, Grune & Stratton, 1992.)

Figure 43-8. (A) Pad placed under occiput in an attempt to achieve a “sniffing” position obstructs the infant’s airway. (B) Pad is placed under infant’s neck to improve the airway patency and for laryngoscopic examination.

Anatomic and Physiologic Factors of the Pulmonary System

Anatomically and physiologically, the neonate’s pulmonary system differs in at least four respects from that of the adult: a high oxygen consumption, high closing volumes, a high ratio of minute ventilation to FRC, and pliable ribs. The oxygen consumption of the infant is $7-9 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, whereas in the adult it is $3 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Therefore, varying degrees of airway obstruction have more impact on oxygen delivery and reserve in the neonate, infant, and child than in adults.

The high closing volumes of the neonate’s lungs are within the lower range of the normal tidal volume (Fig. 43-9). Closing volumes are the lung volumes at which alveoli close, resulting in the shunting of blood by a closed alveolus. If an infant experiences mild laryngospasm and a reduction in lung volume, the high closing volume contributes to shunting of blood and rapid desaturation. When a high oxygen consumption is combined with a high closing volume in the presence of laryngospasm, the rapidity with which desaturation occurs is breathtaking not only for the infant but also for the anesthesiologist. When coughing and breath-holding occur with an endotracheal tube in place, the situation is not much different because there is an inability to ventilate the alveoli. Positive pressure ventilates the large airways, but there is no oxygen delivery to the closed alveoli. Therefore, even though an endotracheal tube may be in the appropriate anatomic location, severe desaturation can occur in infants who are lightly anesthetized and are coughing on the endotracheal tube. At times, because of inability to oxygenate the infant, it might be incorrectly believed that the endotracheal tube has come out of the trachea. The high intrathoracic pressure along with hypoxia, which increases pulmonary vascular resistance, may well cause right-to-left shunting either through the ductus arteriosus or through the foramen ovale. Management of the patient in this situation entails deepening the anesthesia or paralysis. This can be done with either small iv doses of succinylcholine, $0.5 \text{ mg} \cdot \text{kg}^{-1}$, or iv lidocaine, $1.5 \text{ mg} \cdot \text{kg}^{-1}$. Caution must be taken not to exceed this dose of lidocaine in the neonate.

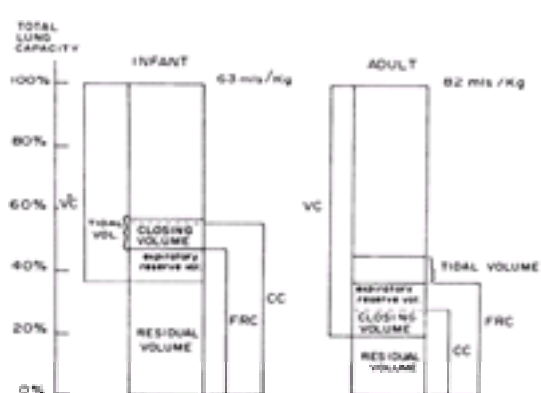

Figure 43-9. Static lung volumes of infants and adults. (Reprinted with permission from Smith CA, Nelson NM: Physiology of the Newborn Infant, 4th ed. Springfield, Illinois, Charles C Thomas, 1976.)

The third unique pulmonary feature of the neonate is the high ratio of minute ventilation to FRC, which is similar to that of the term pregnant woman but occurs for different reasons. The pregnant woman has a reduction in FRC because of elevation of the diaphragm by the uterus. The neonate has an increased alveolar ventilation because of the need to increase oxygen delivery secondary to the high oxygen consumption. Table 43-2 compares the normal respiratory values for newborns and adults.

| Parameter | Infant | Adult |
|---|---------|-------|
| Respiratory frequency | 30-50 | 12-16 |
| Tidal volume ($\text{ml} \cdot \text{kg}^{-1}$) | 7 | 7 |
| Dead space ($\text{ml} \cdot \text{kg}^{-1}$) | 2-2.5 | 2.2 |
| Alveolar ventilation ($\text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) | 100-150 | 60 |
| Functional residual capacity ($\text{ml} \cdot \text{kg}^{-1}$) | 27-30 | 30 |
| Oxygen consumption ($\text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) | 7-9 | 3 |

Table 43-2. COMPARISON OF NORMAL RESPIRATORY VALUES IN INFANTS AND ADULTS

The tidal ventilation for an infant is the same, in milliliters per kilogram, as for the adult; therefore, with an oxygen consumption that is three times greater, the respiratory rate must be three times greater, which results in an alveolar ventilation that is three times greater. Consequently, the ratio of minute ventilation to FRC is 5:1 in the neonate, whereas in adults it is 1.5:1. The clinical implication of the high ratio of minute ventilation to FRC is that there is a much more rapid induction of inhalational anesthesia, as well as more rapid awakening. The more rapid induction of anesthesia also results from a higher percentage of the neonate's body weight consisting of vessel-rich tissues. [Figure 43-10](#) compares the predicted versus observed ratio of end-tidal to inspired halothane in infants and adults. The practical implication of the data is that clinicians who use the adult curve and the usual overpressure of halothane for induction will find the neonate more rapidly induced and perhaps at risk for an overdose of anesthetic (see [Uptake and Distribution of Anesthetic Agents](#)).

Figure 43-10. Predicted versus observed ratio of end-tidal to inspired halothane (FE/FI) in infants and adults. Predicted FE/FI values are those generated by a computer program of anesthetic uptake and distribution. In infants, the minute ventilation averaged 1.9 l; in adults, 6.9 l. The inspired fraction of halothane was 0.5% in both cases. (Reprinted with permission from Brandom BW, Brandom RB, Cook DR: Uptake of halothane in infants. *Anesth Analg* 62:404, 1983.)

The fourth anatomic difference of the neonate is a pliable rib cage. When increased minute ventilation is needed, which requires an increase in respiratory frequency or tidal volume, the pliable ribs of the neonate are a disadvantage. The neonate's diaphragm is the major ventilatory muscle. To increase oxygen delivery by either an increase in frequency or excursion, the contraction of the diaphragm results in greater negative intrathoracic pressures. In mature people with a fixed rib cage, this results in an increase in air movement. However, with a pliable rib cage, the resulting increase in negative intrathoracic pressure results in retractions of ribs as well as retraction in the subcostal and supraclavicular area. This results in less efficient ventilation and a high energy price for the effort involved. This is one of the reasons why neonates are susceptible to fatigue with airway obstruction, pneumonia, and any other condition that results in interference with pulmonary function; another reason is the immaturity of the muscles.

Maturation of Respiratory Muscles

There are two types of muscles: Type 1, slow-twitch, high-oxidative muscles, which are necessary for sustained muscle activity; and Type 2, fast-twitch, low-oxidative muscles, which have an immediate but short activity.¹⁶ The development of Type 1 muscles is necessary for sustained ventilatory activity. The premature infant has 10% Type 1 and the newborn 25% Type 1 muscles in the diaphragm, which is the primary muscle for ventilation. The infant's diaphragm achieves maturity of Type 1 muscles at approximately 8 months of age. At that point, he or she has approximately 55% Type 1 muscles. The intercostal muscles are the other ventilatory muscles. The premature infant has 20% Type 1 intercostal muscles and the newborn, 46%. The age of maturity for these muscles is 2 months, when Type 1 muscles comprise 65% of the total.

Maturation of the Cardiovascular System

Heart and Sympathetic Nervous System

The ability of the neonate's immature cardiovascular system to respond to stress is limited by the relatively low contractile mass per gram of cardiac tissue, which results in a limited ability to increase myocardial contractility as well as a reduction in ventricular compliance.¹⁷ The clinical implication of this limited stretchability or compliance of the ventricle means that, although there may be some ability to increase stroke volume, it is extremely limited. Therefore, any increase in cardiac output must be accomplished by an increase in heart rate. For this reason, the infant is said to be rate dependent for its cardiac output. Thus, any slowing of the heart rate is reflected in a reduction in cardiac output. This is why bradycardia has such serious consequences for the infant. Hypoxia is a major cause of bradycardia in the neonate. Even in the absence of stress, the neonatal heart has limited ability to increase cardiac output compared with the mature heart ([Fig. 43-11](#)). The resting cardiac output of the immature heart is very close to the maximal cardiac output, so there is a limited reserve. The mature heart can increase cardiac output by 300%, whereas the immature heart can only increase cardiac output by 30–40%.

Figure 43-11. Schema of reduced cardiac reserve in fetal and newborn animal hearts compared with adult hearts. (A) In the newborn infant, resting cardiac muscle performance is close to a peak of ventricular function because of limitations in diastolic, systolic, and heart rate reserve. (B) Similarly, pump reserve early in life is limited by these factors as well as by much higher resting cardiac output relative to body weight, compared with that in adults. (Reprinted with permission from Friedman WF, George BL: Treatment of congestive heart failure by altering loading conditions of the heart. *J Pediatr* 106:700, 1985.)

In summary, the neonatal heart has some significant limitations. The resting cardiac output is much higher relative to body weight than in the adult. The neonatal heart is less able to handle a volume or pressure change. Stimulation of the myocardium produces a limited increase in contractility and cardiac output. The sympathetic nervous system, which usually provides the important chronotropic and inotropic support to the mature circulation during stress, is severely limited in the neonate because of immaturity.

Baroreponse

Neonates have immature baroreceptors. The baroreceptor is responsible for the reflex tachycardia that occurs in response to hypotension. Therefore, the immaturity of this reflex would limit the neonate's ability to compensate for hypotension. In addition, the baroreponse of the neonate is more depressed than that of the adult at the same level of anesthesia.

ANESTHESIA FOR THE NEONATE

Anticholinergic Drugs

There is controversy about the need for premedication with anticholinergics. However, two special concerns in the neonate and immature infant distinguish them from

the more mature infant and child: an active vagal reflex and secretions. Because of these concerns, many anesthesiologists routinely administer anticholinergics either before or during surgery to infants younger than 6 months of age. We administer anticholinergics only for specific indications (*i.e.*, reactive airway disease or excessive secretions).

One of the major indications for anticholinergics is to reduce secretions. The management of the combination of a difficult infant airway and excessive secretions can be simplified by reducing secretions. The dose of atropine in the neonate is $0.02 \text{ mg} \cdot \text{kg}^{-1}$; for glycopyrrolate it is $0.01 \text{ mg} \cdot \text{kg}^{-1}$.

Tracheal Intubation

One of the frequently asked questions about the anesthetic management of neonates is whether tracheal intubation is routinely needed or if the airway and ventilation can be managed with the laryngeal mask airway. The answer to this question depends on the skill of the anesthesiologist and the surgical procedure, but in most clinical situations, the neonate should be intubated because of various anatomic and physiologic considerations. If the anesthesiologist is skilled and the surgery is short, intubation may not be necessary and a laryngeal mask airway can be used. This is a clinical judgment that must be determined individually by each anesthesiologist and in each situation. Another question is whether to control the ventilation of all neonates. If the overall condition of the neonate is healthy and the procedure is short, then spontaneous ventilation is certainly acceptable. However, if the neonate is debilitated, has had a relatively long-standing illness, has circulatory instability, and requires muscle relaxation for the surgery, then intraoperative controlled ventilation of the lungs is certainly indicated.

Opinion on whether to perform awake tracheal intubation in the neonate has changed in the last several years. There is concern that awake tracheal intubation causes hypertension and that the hypertension can rupture the fragile intracerebral vessels, particularly in premature infants. There are times when awake tracheal intubation would seem to be the technique of choice, such as in neonates who are critically ill and need resuscitation. Neonates who are persistently vomiting should have an awake tracheal intubation if at all possible. An awake tracheal intubation can be accomplished with topical anesthesia of the oropharynx and lidocaine, $1.5 \text{ mg} \cdot \text{kg}^{-1}$ iv, to blunt the response to the intubation. If problems of a full stomach and the resulting concern for aspiration are not present, the current trend is to perform tracheal intubation after the induction of anesthesia (see [Anesthetic Management of the Neonate](#)).

The question of extubation of the trachea is considerably easier to answer. The awake state is associated with control of the airway reflexes. Partially anesthetized infants are susceptible to laryngospasm and its associated apnea. Laryngospasm, apnea, and a high oxygen consumption are a devastating combination. Therefore, the trachea should be extubated when the neonate is awake. An awake neonate opens his or her eyes, grasps the endotracheal tube, and cries. Crying cannot be heard because of the endotracheal tube but can be readily visualized. Any of these findings indicates that the infant is ready for extubation. If there is any doubt, however, the neonate should remain intubated until the clinician feels comfortable that the neonate can be extubated.

Does the Neonate Need Anesthesia?

There was some question in past years about whether the premature infant needed anesthesia for surgery. However, the neonate and premature infant should be considered as any other patient who needs anesthesia.¹⁸ The selection of anesthetic techniques for the neonate is based on the same criteria as for any patient, while recognizing the pharmacokinetic and pharmacodynamic differences.

Impact of Surgical Requirements on Anesthetic Technique

Blood loss and muscle relaxation are two areas of concern for the surgeon and anesthesiologist. Parents and health care workers also are concerned about the transmission of acquired immunodeficiency syndrome and hepatitis through transfusion of blood and blood products. The use of blood and blood products should be minimized whenever possible. One way to minimize blood replacement is to minimize blood loss. This can be achieved through the control of blood pressure by the various anesthetics and muscle relaxants. The anesthetic techniques used can be directed toward preventing hypertension, which often occurs with the use of nitrous oxide or an opioid plus muscle relaxant, by inducing controlled normovolemic hypotension. Therefore, it is extremely important for the anesthesiologist and surgeon to discuss the impact of blood pressure on the surgical procedure, as well as the potential for loss of blood. Blood replacement is indicated if the neonate has demonstrated circulatory instability and considerable blood loss is anticipated. However, if the neonate is basically healthy, and the anticipated blood loss is 25–30% of the blood volume, and the final hemoglobin is in the range of $8\text{--}9 \text{ g} \cdot \text{dL}^{-1}$, then blood transfusion probably can be avoided. The anesthesiologist can tailor the anesthetic to control the blood pressure and thereby reduce blood loss. This requires an appreciation of the cardiovascular effects of anesthetics and muscle relaxants.

Cardiovascular Effects of Muscle Relaxants

Although *d*-tubocurarine does trigger a dose-related histamine release that causes peripheral vasodilation, the incremental administration of *d*-tubocurarine minimizes, if not eliminates, any effect on the blood pressure. Pancuronium has vagolytic and sympathomimetic actions that cause tachycardia and an increase in blood pressure¹⁹ (Table 43-3). If a neonate is moribund or in shock or there is concern about the volume status, then pancuronium may well be the muscle relaxant of choice. However, in a relatively normal neonate with a normal blood pressure and normal blood volume, the use of pancuronium may result in hypertension, which has the potential to increase blood loss. In such an infant, cisatracurium or rocuronium would be a more logical choice of muscle relaxant. Atracurium and rocuronium have certain advantages over vecuronium in the infant younger than 1 year of age because vecuronium is metabolized by the liver. The duration of action of vecuronium is approximately twice that observed in older children because of liver immaturity, and it would be similar to pancuronium in its length of action. If a long-acting nondepolarizing muscle relaxant were desired, vecuronium would have advantages in a child with a normal blood pressure, blood volume, and cardiovascular system.²⁰ The length of action of cisatracurium and rocuronium in the neonate is similar to that in the older infant or child. The infant's neuromuscular junction is more sensitive to muscle relaxants, and the infant has a larger volume of distribution because of a large extracellular fluid volume. These two effects tend to balance each other, so that, roughly speaking, the dose of a nondepolarizing muscle relaxant for an infant is similar to that for a child on a milligram per kilogram basis. The major difference in neonates is the great variability in response to the nondepolarizing muscle relaxants, so that dose–response effects must be carefully observed to avoid either overdose or underdose. A neuromuscular stimulator is a very useful monitor in infants as well as in older children and adults.

| Drug | Mechanism of Action on Circulation | Circulatory Changes |
|-------------|---|---|
| Curare | Histamine release | Slow administration—minimal Rapid administration—20–30% decrease in blood pressure |
| Atracurium | Histamine release | Rapid administration, high dose—20% decrease in blood pressure |
| Mivacurium | None | Minimal change |
| Vecuronium | None | No change |
| Pancuronium | Vagal blockade, indirect adrenergic stimulation | Increased pulse and blood pressure |

Table 43-3. CARDIOVASCULAR EFFECTS OF MUSCLE RELAXANTS

There is some increase in succinylcholine requirement in the infant compared with the older child.²¹ The intramuscular dose of succinylcholine is $4 \text{ mg} \cdot \text{kg}^{-1}$ in the infant. The iv dose of succinylcholine in the infant and child is $2 \text{ mg} \cdot \text{kg}^{-1}$. The recent succinylcholine controversy has called into question the use of succinylcholine in male children younger than 8 years of age.²² The reports of hyperkalemia with cardiac arrest in such children with unrecognized muscular dystrophy has led some clinicians to take the position that succinylcholine should not be used routinely for this group of patients. The occurrence of this problem is somewhere in the range of 1 in 250,000 anesthetics, with a mortality rate of 50%. However, succinylcholine is still recommended in rapid-sequence situations, a potentially difficult airway, or if there are airway emergencies with a developing desaturation. The anesthesiologist must know how to recognize and treat hyperkalemia;²³ hyperkalemia can be recognized by peaked T waves. However, the clinician may not see this particular electrocardiographic change because it occurs 2–3 minutes after drug administration, when the anesthesiologist is attending to the airway. The hyperkalemia interferes with conduction, leading to a bradycardia and, if severe enough, cardiac arrest. If the heart rate slows, then the drug of first choice is calcium $10\text{--}15 \text{ mg} \cdot \text{kg}^{-1}$ in a diluted solution. However, if the circulation is unstable with severe bradycardia and hypotension or cardiac arrest, the drug of first choice is epinephrine $5\text{--}10 \mu\text{g} \cdot \text{kg}^{-1}$. One of the actions of epinephrine is to stimulate the sodium–potassium pump and cause the potassium to re-enter the cell, thereby reducing the serum level. If there is no response at this dose level, it should be increased incrementally until there is a response. Magnesium has been described as a treatment for hyperkalemia because it also antagonizes the effects of hyperkalemia, as does calcium.²⁴ The use of sodium bicarbonate to treat any metabolic acidosis that may occur with arrest is also thought to be useful because alkalosis decreases hyperkalemia. At the same time, the

patient should be hyperventilated to reduce the CO₂, thereby encouraging a respiratory alkalosis.

In the emergency airway situation, the clinician should not wait to use succinylcholine until the patient becomes severely desaturated and bradycardic. When it is evident that a neonate is obstructed by laryngospasm or any other reason and no progress is made in ventilation, then either intramuscular succinylcholine (4–5 mg · kg⁻¹) if there is no iv, or an iv dose of 1–2 mg · kg⁻¹ is given. When succinylcholine is used on an elective basis for a rapid-sequence induction or for any other reason, then curare in a dose of 0.05 mg · kg⁻¹ should be administered 2–3 minutes before the administration of succinylcholine. The curare reduces the degree and length of the hyperkalemia that is associated with up-regulation of the neuromuscular junction.

Cisatracurium and rocuronium appear to be the drugs of choice among the intermediate-acting, nondepolarizing muscle relaxants. The dose of rocuronium is 0.3–0.4 mg · kg⁻¹. If a larger dose of rocuronium is used to avoid using succinylcholine, then these doses cause rocuronium to be a relatively long-acting muscle relaxant, and this needs to be kept in mind. Cisatracurium does not have a prolonged effect in the neonate. Its metabolism is by Hofmann elimination, ester hydrolysis, and the liver and kidney. The recommended dose is 0.4–0.6 mg · kg⁻¹. The use of nondepolarizing muscle relaxants should be guided by monitoring of neuromuscular function with a nerve stimulator. There is some controversy about the routine reversal of nondepolarizing muscle relaxants if a nerve stimulator indicates only a 75–80% return of function. One opinion is that if the usual time for the spontaneous reversal of neuromuscular function has been exceeded by a factor of two, and if neuromuscular function is determined to be normal as judged clinically and by the nerve stimulator, there is no need for reversal. The other opinion is that, regardless of time, there is relatively little risk in administering neuromuscular reversal drugs. We do not favor routine reversal of muscle relaxants.

Reversal of Nondepolarizing Neuromuscular Blocking Agents

Edrophonium in a dose of 1 mg · kg⁻¹ achieves a 90% reversal of a neuromuscular block in 2 minutes, whereas neostigmine in a dose of 0.06 mg · kg⁻¹ requires 10 minutes for a 90% reversal of neuromuscular block. This difference in time to peak effect allows the anesthesiologist to decide which agent is needed. A word of caution: when edrophonium is used to reverse neuromuscular blockade, the effect is so rapid that atropine should be administered before the edrophonium; and there some believe that atropine is superior to glycopyrrolate for this reversal. The dose of atropine is 0.01–0.02 mg · kg⁻¹. Neostigmine is a suitable alternative for reversal of nondepolarizing muscle relaxants in neonates. The muscarinic effects of neostigmine can be blocked with atropine or glycopyrrolate (0.01 mg · kg⁻¹), and the drugs can be given concurrently. The two advantages of edrophonium over neostigmine are a more rapid reversal and fewer muscarinic side effects.

Cardiovascular Effects of the Anesthetic Drugs

Opioids are mild vasodilators but have little direct effect on cardiac function. Cholinergic side effects may decrease the heart rate. If the neonate is hypovolemic, the administration of opioids may decrease blood pressure. However, if the infant is adequately volume resuscitated, the administration of opioids should have little effect on the blood pressure.^{25,26} Ketamine has unique cardiovascular effects.²⁷ Its action is centrally mediated through the sympathetic nervous system, and it can cause a release of norepinephrine. Ketamine *in vitro* has negative inotropic effects. However, on balance, ketamine can override the depressant effects on the myocardium and overall results in support of the cardiovascular system. Therefore, ketamine is a useful agent for the infant who has an unstable cardiovascular system or in whom there is some question about volume repletion. The iv induction dose of ketamine is 1–2 mg · kg⁻¹ in titrated doses, followed by 0.5–1 mg · kg⁻¹ every 15–30 minutes.

Nitrous oxide usually is considered a reasonably benign anesthetic drug from the standpoint of the cardiovascular system. However, in adult patients, when nitrous oxide is combined with opioids, the cardiac index and arterial pressure decrease because of myocardial depression.²⁷ Nitrous oxide has mild depressant effects on systemic hemodynamics in sedated infants, similar to those reported in adults, but does not produce the elevations in pulmonary artery pressure and pulmonary vascular resistance that are seen in adults. Therefore, it appears that nitrous oxide is a reasonable drug in neonates if there is no concern for expanding gas pockets within the body (*i.e.*, pneumoencephalos, intestinal obstruction, pneumothorax) and no need for a high F_{IO₂} to maintain saturation.

All of the volatile anesthetics affect the cardiovascular system. Halothane has little effect on peripheral vascular resistance; therefore, the decrease in blood pressure that accompanies the administration of halothane results from myocardial depression. However, isoflurane, desflurane, and sevoflurane decrease systemic vascular resistance so that the major effect on blood pressure is a decrease in peripheral vascular resistance.²⁸

Anesthetic Dose Requirements of Neonates

Neonates and premature infants have lower anesthetic requirements than older infants and children.²⁹ The minimum alveolar concentration (MAC) of halothane for the premature infant is 0.6%; it is 0.89% for full-term neonates and 1.12% for 2- to 4-month-old infants.^{29,30} Isoflurane has the same differences in MAC requirement as does halothane. The easiest way to remember the MAC values is that the MAC value in the mature state (*i.e.*, late teenager or adult) is the same as for a full-term infant. By 6 months of age, the MAC value has increased by 50%. In the premature infant, the MAC value decreases by 20–30%. The reasons for the lower MAC requirements are thought to be an immature nervous system, progesterone from the mother, and elevated blood levels of endorphins, coupled with an immature blood–brain barrier. The neonate has an immature central nervous system with attenuated responses to nociceptive cutaneous stimuli. These responses rapidly mature in the first several months of an infant's life, along with an increase in the MAC. Progesterone has been shown to reduce the MAC of the pregnant mother. The newborn infant has elevated progesterone levels, similar to those of the mother. In a study in lambs, Gregory *et al*³¹ showed that the MAC increased progressively over the first 12 hours of life, with a concomitant decrease in progesterone levels. Elevated levels of b-endorphin and b-lipotropin have been demonstrated in infants in the first few days of postnatal life. The levels returned to mature concentrations by the time the infants were 24 days of age. Endorphins do not cross the blood–brain barrier in adults; however, it is thought that the neonate's blood–brain barrier is more permeable and that endorphins might well pass into the central nervous system, thus elevating the pain threshold and reducing the MAC requirement.

ANESTHETIC MANAGEMENT OF THE NEONATE

The anesthesiologist has a host of anesthetic techniques from which to choose and can tailor the anesthetic to the requirements of the surgery and the condition of the neonate. The neonate who is moribund or who has a severely compromised cardiovascular status needs resuscitation. If muscle relaxants are needed, pancuronium is the relaxant of choice. As the neonate's status improves, anesthetic drugs may be titrated in. The neonate with a questionable cardiovascular and volume status needs anesthetic drugs such as ketamine or an opioid. However, in neonates who have a stable cardiovascular state, the choice of drugs depends on the type of surgery and on whether the neonate will be extubated at the end of surgery.

The three major factors to consider in selecting an anesthetic technique are (1) whether it is anticipated that the neonate will be extubated at the end of surgery or shortly thereafter, (2) the need to control blood pressure, and (3) the need for postoperative pain relief. The drugs and techniques available to achieve these goals are many and include inhalational anesthetics, regional techniques, muscle relaxants, opioids, and ketamine. If extubation is anticipated at the end of surgery or shortly thereafter, the anesthetic must be tailored so that there are minimal residual effects from inhalational agents and muscle relaxants, thereby allowing the infant to be awake and in control of its airway reflexes, which promotes early extubation. The muscle relaxant of choice in this situation is atracurium because of its moderate duration of action (30–45 minutes), which is the same in the neonate as in the older child and adult. Vecuronium, by contrast, is metabolized by the liver and in the neonate is a long-acting muscle relaxant. The use of a regional anesthesia technique, such as a caudal technique, reduces the need for inhalational agents, opioids, and muscle relaxants. There are great advantages to using a combined general and regional technique when early extubation is anticipated. Yet, if the management plan is to leave the infant intubated and ventilated for a longer time, then the choice of anesthetic technique and muscle relaxant depends on other factors, such as the need to control blood pressure and the length of postoperative ventilation.

Nitrous oxide can be added provided oxygenation is closely monitored and expansion of any gas pocket in the body is considered. In the case of intestinal obstruction, the use of air along with appropriate concentrations of oxygen and a volatile drug is indicated. The normal full-term neonate has a systolic blood pressure between 60 and 70 mm Hg. For purposes of controlled hypotension, a blood pressure of 45–50 mm Hg is desired. The use of ketamine or opioids and a muscle relaxant can be advantageous when caring for the hemodynamically unstable infant. A study of the dose–response relationship of fentanyl in neonates undergoing surgery demonstrated that, in doses of 10–12.5 mg · kg⁻¹, fentanyl produced a stable hemodynamic state and reliable anesthesia as determined by the heart rate and blood pressure.²⁶ The doses were given in increments of 2.5 mg · kg⁻¹. In all infants in the study, heart rate and systolic blood pressure decreased with the administration of fentanyl. One of the concerns with the administration of opioids in neonates is the altered pharmacokinetics and pharmacodynamics.^{32,33} In one study, 25–50 mg · kg⁻¹ of fentanyl resulted in unpredictable respiratory effects and, in some neonates, postoperative respiratory depression. Four of 14 neonates studied, none of whom had any respiratory impairment secondary to surgery or disease, needed ventilatory support for 11–40 hours after operation. All infants had a rebound of fentanyl blood levels. There was a prolonged metabolism of the fentanyl, particularly in those with increased intra-abdominal pressure. This was thought to be due to a reduction in liver blood flow and hence metabolism of fentanyl—evidence of altered pharmacokinetics. In addition, it also appeared that newborns were more sensitive at the same plasma level to the respiratory depressant effects of fentanyl—evidence of altered pharmacodynamics.

Regional Anesthesia

There has been a tremendous increase in the use of regional anesthesia in children. In general, the regional techniques are combined with general anesthesia to permit early extubation and provide postoperative pain relief. Early extubation is possible because the use of regional anesthetic techniques eliminates the need for intraoperative narcotics in neonates, reduces or eliminates the need for muscle relaxants, and reduces the concentration of volatile agents needed for relaxation. Spinal anesthesia has been reported to be effective when used as the sole anesthetic technique in premature and high-risk infants, but this technique requires excellent cooperation between the anesthesiologist and an experienced surgeon. Even at a dose of $0.5 \text{ mg} \cdot \text{kg}^{-1}$, the effects of tetracaine last only approximately 90 minutes in the neonate. Total spinal anesthesia, produced either with a primary spinal technique or secondary to an attempted epidural puncture, presents as respiratory insufficiency rather than as hypotension because of the lack of sympathetic tone in infants.³⁴ The exact mechanism for the lack of cardiovascular change with spinal anesthesia in infants and young children is not clear. Initially it was thought that there was a relative lack of development of the sympathetic nervous system. A more recent study, however, suggests that the sympatholysis that results from high thoracic spinal anesthesia and is expected to cause a decrease in heart rate and blood pressure is offset by a decrease in parasympathetic activity resulting in the withdrawal of cardiac vagal activity. The overall effect is no change in heart rate and blood pressure.³⁵ The first indication of trouble is a falling oxygen saturation rather than a falling blood pressure. Sedation can be added to regional anesthesia but may cause problems of apnea in ex-premature infants.

The techniques of caudal, spinal, brachial plexus, and other blocks should be considered in all neonates. Caudal epidural block is frequently used for abdominal and thoracic surgery in neonates. There are several different techniques described for performing a caudal. We prefer the 22-gauge short-bevel needle; the caudal space is identified both by the loss of resistance and the ease of administering the anesthetic. Once the sacrococcygeal membrane is penetrated and there is a loss of resistance, gentle aspiration is applied to the needle to determine if there is blood or cerebrospinal fluid (CSF). Injection of the anesthetic is then attempted. If there is difficulty in injecting the solution, the tip of the needle is not in the caudal space and it needs to be repositioned. If the anesthetic can be injected easily, this confirms placement in the epidural space. The needle is not advanced up the caudal canal after proper placement in the caudal epidural space has been accomplished. In one study that uses Longwell catheters for the caudal epidural, the catheter is advanced up the caudal canal.³⁶ They report an iv injection incidence of approximately 6% with this technique. Evidence of an intravascular injection includes (1) peaked T-waves (which may be of relatively short duration, e.g., 30 seconds), and (2) an increase in heart rate. Epinephrine is added to local anesthetic solutions for the purposes of determining if there is an intravascular injection of the anesthetic. The other technique to minimize the potential difficulties of an intravascular injection is to fractionate the dose by dividing the dose into three aliquots and waiting approximately 20–30 seconds between each aliquot before continuing the injection. A recent survey details the epidemiology and morbidity of regional anesthesia in children.³⁷

Caudal anesthesia is particularly effective at reducing the concentrations of volatile anesthetics needed as well as relaxants and opioids. In addition, a single-injection caudal anesthetic can provide analgesia for 6–8 hours. The two local anesthetics currently in use are 0.25% bupivacaine or 0.2% ropivacaine. Epinephrine is added to local anesthetics to assist in determining if there has been an iv injection. The amount of epinephrine added should result in a 1:200,000 dilution of epinephrine ($5 \mu\text{g} \cdot \text{ml}^{-1}$). Although ropivacaine has not been approved for use in infants, it does have several theoretical advantages. Because it is used in a concentration of 0.2%, compared with 0.25% for bupivacaine, there is less drug being administered per milliliter of injectate. In addition, ropivacaine has been reported to be less cardiodepressant than equipotent doses of bupivacaine. If a caudal catheter is placed, an infusion of bupivacaine can be administered and provide analgesia for several days. Close attention must be paid to the dosing of bupivacaine for postoperative infusions. Several studies have reported cardiovascular and central nervous system toxicity. Current recommendations for infusions in neonates and young infants are for an initial loading dose of $0.2\text{--}0.25 \text{ mg} \cdot \text{kg}^{-1}$; after 1–2 hours, an infusion can be begun in a dose of $0.2 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$. For older infants, toddlers, and children, the dosage range is $0.4\text{--}0.5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$.

Another block that has become popular is a simple ring block of the penis for circumcision. Bupivacaine 0.25% is injected subcutaneously in a ring about the base of the penis. This way, there is no danger of causing a hematoma, which occasionally occurs with a penile block.

Postoperative Ventilation

The choice of an anesthetic drug should also be determined by the need for postoperative management of ventilation and by the drug's effects on the circulation. If the surgical procedure or the neonate's condition is such that postoperative ventilation is likely, the prolonged respiratory effects of opioids or any other drug are of little concern. However, if the surgical procedure is relatively short and by itself does not require postoperative ventilation, the clinician should carefully select drugs and doses of anesthetic drugs and relaxants that will not necessitate prolonged postoperative ventilation or intubation. Postoperative ventilation places the neonate at added risk because of the problems associated with mechanical ventilation, the trauma to the subglottic area, and the potential development of postoperative subglottic stenosis or edema. However, if there is any question about the neonate's ability to maintain protective airway reflexes or normal ventilation after anesthesia, the neonate should be returned to the recovery room or newborn intensive care unit with the trachea intubated, and either ventilated or treated with a small amount of PEEP (2–4 cm H_2O).

Postoperative Pain Management

The concepts of postoperative pain management are well known to most anesthesiologists. The use of intraoperative epidural anesthesia followed by postoperative epidural local anesthetics or opioids has been popular in older children and adults, and these techniques are being applied to neonates. In addition, most neonatologists are experienced with the iv administration of opioids for patient comfort. Each technique has its own risks and benefits.

Uptake and Distribution of Anesthetics in Neonates

Rapid induction of anesthesia with volatile drugs can cause a greater degree of hypotension in young infants than in older infants and children.³⁸ However, no adverse effects from this fall in blood pressure were reported in these studies. There are several possible reasons for this observation. Young infants achieve a higher end-tidal halothane or isoflurane concentration more rapidly than older children and adults because the uptake of anesthetic drugs is more rapid in infants than in adults. Brandom *et al*³⁹ reported a study of both computer-simulated and measured halothane concentrations in infants (see Fig. 43-10). Whereas in the adult it takes 15–20 minutes to arrive at approximately a 50–60% equilibration of the end-tidal to the inspired halothane concentration, the infant is 70–80% equilibrated in the same period. The computer simulation similarly showed a higher concentration of halothane in the hearts of infants (Fig. 43-12). The same anesthetic concentration would also be present in the brain.

Figure 43-12. Predicted concentration of halothane in the heart. The values were derived from a computerized model of anesthetic uptake and distribution. The model infant weighed 4 kg; the model adult weighed 70 kg. In both cases, normal ventilation and a constant inspired fraction of 0.5% halothane were used. Tissue levels are given in milligrams per 100 ml of tissue. (Reprinted with permission from Brandom BW, Brandom RB, Cook DR: Uptake of halothane in infants. *Anesth Analg* 62:404, 1983.)

Various reasons for the faster uptake of anesthetics in infants have been proposed: (1) the ratio of alveolar ventilation to FRC is 5:1 in the infant and 1.5:1 in the adult; (2) in the neonate, more of the cardiac output goes to the vessel-rich group of organs, which includes the heart and brain; (3) the neonate has a greater cardiac output per kilogram of body mass; and (4) the infant has a lower blood gas partition coefficient for volatile anesthetics. An appreciation of the lower MAC in neonates, along with recognition of the more rapid uptake, suggests that care must be taken not to "overpressure" the concentration of the volatile drugs to as great a degree or for as long before intubation as would be done with an older infant or adult. The use of end-tidal gas measurements to determine both inspired and end-tidal anesthetic concentrations of the various volatile drugs can be helpful. Another not well-recognized factor that may result in higher concentrations of volatile anesthetics being administered to infants has to do with the use of nonrebreathing systems such as the Bain or a Mapleson "D" circuit. When an adult circle system is used with infant tubes and bag, the clinician experienced with this equipment is used to reading the inspired and end-tidal as well as the dialed concentration. In the circle system, the inspired concentration is a result of the combination of the end-tidal concentration that is rebreathed through the soda lime absorber and the dialed concentration. The

inspired concentration is always lower than the dialed concentration, unless the flow rates are so high that a nonbreathing system has been created. In the nonbreathing system, the dialed concentration is the inspired concentration. Clinicians who use one system or the other are accustomed to these subtle differences. However, if the clinician switches back and forth between the circle system and a nonbreathing circuit, but does so infrequently, there is a danger of not recognizing the possibility of excessive overpressure of volatile anesthetics with the nonbreathing systems.

SURGICAL PROCEDURES IN NEONATES

For the purposes of discussion, surgical procedures in neonates are arbitrarily divided into two periods: those performed in the first week and those performed in the first month. Except for gastroschisis, which should be attended to within 12–24 hours, there are really no acute emergency operations in the neonate. This means that a period of 2–3 days can be allowed for stabilization or transport to an appropriate pediatric center for treatment. There is more to neonatal emergency surgery than just the immediate anesthetic and surgical procedure. Many of these infants require the support services of specialized nursing units, pediatric radiologists, pediatric intensive care physicians, and so forth. Managed care considerations should never take precedence over the appropriate care of infants and children.

Surgical Procedures in the First Week of Life

The five most frequent major surgical procedures performed in the first week of life are for congenital diaphragmatic hernia (CDH), omphalocele and gastroschisis, tracheoesophageal fistula (TEF), intestinal obstruction, and meningomyelocele. Some of these conditions, such as CDH, omphalocele and gastroschisis, and meningomyelocele, are obvious at birth. It may take hours or days for a TEF or intestinal obstruction to become manifest.

Two confounding factors in neonatal surgery are prematurity and associated congenital anomalies. The presence of one congenital anomaly increases the likelihood of another congenital anomaly. In conditions such as TEF, the mortality rate from the associated congenital heart defect is far higher than that from the surgical correction of the TEF. Prematurity, particularly when associated with the respiratory distress syndrome, may adversely affect surgical outcome. The use of surfactant in the treatment of the respiratory distress syndrome has greatly increased the number of survivors and has decreased the complexity of the issues of the infant with a combination of TEF and the respiratory distress syndrome. A neonatologist should be consulted in the case of any neonate with a congenital defect who is considered for surgery. The most serious associated congenital lesion is that of the cardiovascular system. Approximately 25–30% of infants with CDH have a cardiac anomaly.⁴⁰ Approximately 15–25% of infants with TEF have an associated congenital cardiac anomaly.⁴¹

Maternal Cocaine Use During Pregnancy

Maternal cocaine use during pregnancy leads to a host of problems for the fetus and neonate. Cocaine results in a reduced catecholamine reuptake, which may result in the accumulation of catecholamines. This has circulatory effects on the uterus, the umbilical blood vessels, and the fetal cardiovascular system. The three major problems affecting the infant are premature birth, intrauterine growth retardation, and cardiovascular abnormalities.⁴² One report documented a low cardiac output in infants of mothers who abused cocaine.⁴³ The cardiac output and stroke volume were reduced on the first day of life but had returned to normal by the second day. The clinical implication of this finding is that in infants of mothers who have abused cocaine, it may be advantageous to postpone any surgery until the second or third day of life. Cardiovascular abnormalities also were found in these infants. There was an increase in structural cardiovascular malformations and electrocardiographic abnormalities. The most frequent lesions were peripheral pulmonic stenosis, right ventricular conduction delay, right ventricular hypertrophy, and ST segment and T-wave changes.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia occurs with an incidence of approximately 1 in 4000 live births. Despite intensive, often heroic postoperative measures, the mortality rate from CDH remains in the range of 40–50% because of severe underdevelopment of the lung. A brief discussion of the embryologic characteristics of CDH will help the clinician understand the potentially enormous postoperative problems that may be encountered. It will become evident that the defect is more than a hernia of the diaphragm.

Early in fetal development, the pleuroperitoneal cavity is a single compartment. The gut is herniated or extruded to the extraembryonic coelom during the 5th to 10th weeks of fetal life (Fig. 43-13). During this period, the diaphragm develops to separate the thoracic and abdominal cavities (Fig. 43-14). The development of the diaphragm is usually completed by the seventh fetal week. In the 9th to 10th weeks, the developing gut returns to the peritoneal cavity. If there is delay or incomplete closure of the diaphragm, or if the gut returns early and prevents normal closure of the diaphragm, a diaphragmatic hernia will develop, producing varying degrees of herniation of the intestinal contents into the chest. The left side of the diaphragm closes later than the right side, which results in the higher incidence of left-sided diaphragmatic hernias (foramen of Bochdalek). Approximately 90% of hernias detected in the first week of life are on the left side.

Figure 43-13. Umbilical herniation of the intestinal loops in an embryo of approximately 8 weeks' gestation (crown-rump length, 35 mm). Coiling of the small intestinal loops and formation of the cecum occur during the herniation. (Reprinted with permission from Body cavities and serous membranes. In Sadler TW: Langman's Medical Embryology, 5th ed., p 150. Baltimore, Williams & Wilkins, 1985.)

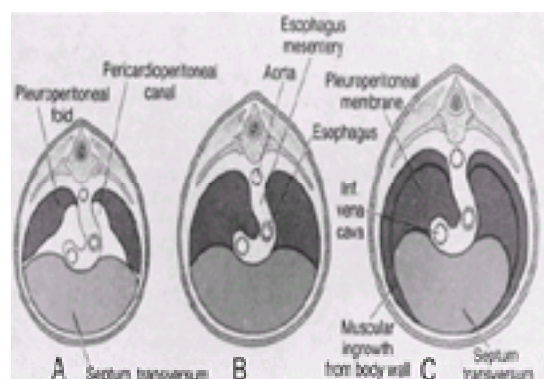

Figure 43-14. Schematic drawings illustrating the development of the diaphragm. (A) The pleuroperitoneal folds appear at the beginning of the sixth week. (B) The pleuroperitoneal folds have fused with the septum transversum and the mesentery of the esophagus in the seventh week, thus separating the thoracic cavity from the abdominal cavity. (C) In a transverse section at the fourth month of development, an additional rim derived from the body wall forms the most peripheral part of the diaphragm. (Reprinted with permission from Body cavities and serous membranes. In Sadler TW: Langman's Medical Embryology, 5th ed., p 147. Baltimore, Williams & Wilkins, 1985.)

The clinical presentation and the outcome from a diaphragmatic hernia are varied. At one end of the spectrum, the diaphragmatic hernia may develop early in fetal life so that the abdominal contents compress the developing lung bud, resulting in an extremely small, hypoplastic lung. Bilateral hypoplastic lungs may be found, with no chance for survival. At the other end of the spectrum, a moderately small diaphragmatic hernia may develop later in fetal life, so that the lung is normal but compressed

by the abdominal viscera. In between is a large range of possibilities. At the mild end of the scale the infant might have a relatively normal pulmonary vascular bed with varying degrees of PPH that may revert to normal. At the more serious end of the spectrum are severe pulmonary hypoplasia and abnormal pulmonary vasculature with a very low chance for survival. There is an irreducible mortality rate with CDH.

After closure of the pleuroperitoneal membrane, muscular development of the diaphragm occurs. Incomplete muscularization of the diaphragm results in the development of a hernia sac because of intra-abdominal pressure. The condition is known as eventration of the diaphragm, and the diaphragm may extend well up into the thoracic cavity. The other possibility is that the innervation of the diaphragm is incomplete and the muscle atonic. Eventration of the diaphragm usually is not symptomatic in the first week of life.

Clinical Presentation

Because the infant's status immediately at birth is determined primarily by the oxygenation of the placenta, the 1-minute Apgar score may well be normal. The occurrence of symptoms depends on the degree of herniation and interference with pulmonary function. At times, the degree of interference is so great that the neonate's clinical condition begins to deteriorate immediately, whereas in other situations it may be several hours before the infant's condition is fully appreciated. In the severely involved newborn, the initial clinical findings are usually classic and readily discerned. The infant has a scaphoid abdomen secondary to the absence of intra-abdominal contents, which have herniated into the chest (Fig. 43-15). Breath sounds on the affected side are reduced or absent. The diagnosis can be confirmed with an immediate radiograph. Immediate supportive care entails tracheal intubation and control of the airway, along with decompression of the stomach. Excessive airway pressure carries a high risk for pneumothorax and worsening of a bad situation.

Figure 43-15. Infant with congenital diaphragmatic hernia. Note scaphoid abdomen.

Antenatal Diagnosis

The diagnosis of CDH can be made prenatally by fetal ultrasonography or ultrafast fetal magnetic resonance imaging. Antenatal diagnosis has led to the identification of a “hidden mortality” in CDH, fetuses who did not survive gestation and neonates who died before diagnosis. One of the hopes of prenatal diagnosis is to identify predictors of poor postnatal outcome. Various factors have been proposed, including early gestation diagnosis, severe mediastinal shift, polyhydramnios, a small lung-to-thorax transverse area ratio, and the herniation of liver or stomach. The single most predictive factor is the right lung area-to-head circumference ratio, defined as the lung area measured at the level of the four-chamber view divided by the head circumference to account for fetal size. New techniques in fetal surgery, such as temporary fetal tracheal occlusion, may prove beneficial to fetuses with CDH who are identified to be at risk for not surviving to term.^{44,45} The other obvious advantage of prenatal diagnosis is that plans can be made for maternal or neonatal transport to a center with advanced neonatal critical care.

Preoperative Care

Congenital diaphragmatic hernia was traditionally treated as a surgical emergency. The infants were taken immediately to surgery for decompression and repair. The thought was that removing the abdominal viscera from the thorax would allow for re-expansion of the lung and improved oxygenation. However, as the pathophysiology of CDH was more clearly defined—irreversible pulmonary hypoplasia associated with a hyper-reactive pulmonary vasculature—a strategy of preoperative stabilization with delayed surgical repair was adopted. Frenckner *et al*⁴⁶ have used this strategy of prolonged preoperative stabilization since 1990 and report survival rates of 90%, significantly better than the frequently quoted rates of 40–60%.

The stabilization of an infant with CDH may require multiple treatment modalities. The use of aggressive ventilation strategies to induce hyperventilation alkalosis has been abandoned secondary to the high incidence of iatrogenic lung injury. Conventional ventilation with permissive hypercapnia is now favored. The goal is to maintain preductal arterial saturation above 90% using peak inspiratory pressures below 35 cm H₂O and allowing the PCO₂ to rise to 60–65 mm Hg. High-frequency oscillatory ventilation has been used in place of conventional ventilation in an attempt to reduce barotrauma, but has not been shown to improve survival.⁴⁷ The Neonatal Inhaled Nitric Oxide Study Group (NINOS) was unable to demonstrate a beneficial effect for inhaled nitric oxide in infants with CDH and hypoxic respiratory failure unresponsive to aggressive conventional therapy, although it may have some benefit post-ECMO.⁴⁸ Neonates born with CDH may also have a component of surfactant deficiency, and studies have shown improvement in oxygenation in those infants given surfactant prophylactically.⁴⁷ Partial liquid ventilation with oxygenated perfluorocarbon is also being studied in infants with CDH.⁴⁷

The use of ECMO in infants with CDH was initiated in the mid-1980s. Since then, over 2000 infants with CDH have been placed on ECMO. Despite extensive literature on the subject, there remains an ongoing debate as to whether ECMO improves survival in neonates with CDH. It is difficult to compare studies between institutions because of the different selection criteria used to initiate ECMO therapy. Some institutions use an oxygenation index (OI = [MAP × FIO₂ × 100]/PaO₂) of >40, whereas others use pH, preductal or postductal PaO₂, alveolar–arterial gradients, or ventilatory index (mean airway pressure × respiratory rate). The Congenital Diaphragmatic Hernia Study Group analyzed data from the multicenter CDH Registry and determined that ECMO improves the survival rate in CDH neonates with a predicted high risk of mortality (380%) based on birth weight and 5-minute Apgar score.⁴⁹

Perioperative Care

Because delayed surgical repair of CDH is now the norm, neonates with CDH frequently present to the operating room already intubated and on some form of ventilatory support. Despite a period of preoperative stabilization, some infants still have a component of reactive pulmonary hypertension. The goals of ventilatory management are to ensure adequate oxygenation and avoid barotrauma. Any sudden deterioration in oxygen saturation with or without associated hypotension should raise suspicion of pneumothorax. It is important to avoid hypothermia because this increases the oxygen requirement and could precipitate pulmonary hypertension. Blood loss and fluid shifts are usually not a problem, although maintenance of intravascular volume is essential to avoid acidosis, which could also precipitate pulmonary hypertension.

The anesthetic technique chosen depends on the size of the defect and the anticipated postoperative respiratory status. In those infants who will remain intubated after surgery, inhalational agents and narcotics may be used as tolerated. In those infants with a small defect who present to the operating room with little or no respiratory distress, it may be beneficial to avoid intraoperative narcotics and provide regional analgesia in anticipation of extubation. The use of nitrous oxide should be avoided, particularly in those situations in which abdominal closure could be difficult. Muscle relaxation is often needed to facilitate abdominal closure.

Some centers are performing repairs of CDH while the neonate is on ECMO. This may be performed in the operating room or in the neonatal intensive care unit (NICU). The anesthetic technique usually consists of narcotics with muscle relaxation. Surgical repair while on ECMO can be associated with significant bleeding, making fluid management more challenging and increasing the mortality rate. The use of antifibrinolytic therapy has been associated with decreased hemorrhage and improved outcome.⁴⁶

Postoperative Care

Most infants with CDH require intensive postoperative care. Recovery depends on the degree of pulmonary hypertension and pulmonary hypoplasia. It was previously believed that pulmonary hypoplasia was responsible for most deaths; however, it is now thought that potentially reversible pulmonary hypertension may be responsible

for as much as 25% of reported deaths.⁵⁰

Most infants require some form of ventilatory support in the postoperative period. Occasionally infants who were stabilized on conventional ventilation in the preoperative period require ECMO or inhaled nitrous oxide in the postoperative period. Some infants have long-term persistence of pulmonary hypertension. A study by Iacono *et al*⁵⁰ identified two parameters that were predictive of identifying patients with postnatal PPH at discharge with 100% sensitivity: an echocardiographic examination at 2 months of age demonstrating pulmonary hypertension; or requirement for respiratory support, either mechanical ventilation or supplemental oxygen, at 3 months of age.

There is evidence to suggest that cardiac development is impaired in infants with CDH. Relative left ventricular hypoplasia with an attenuated muscle mass and cavity size have been described. Many studies have confirmed that a calculated left ventricular mass less than $2 \text{ g} \cdot \text{kg}^{-1}$ on pre-ECMO echocardiography was predictive of subsequent death.⁵¹

Omphalocele and Gastroschisis

Although omphalocele and gastroschisis sometimes appear similar and may be confused, they have entirely different origins and associated congenital anomalies.⁵² During the 5th to 10th weeks of fetal life, the abdominal contents are extruded into the extraembryonic coelom, and the gut returns to the abdominal cavity at approximately the 10th week (see Fig. 43-13). Failure of part or all of the intestinal contents to return to the abdominal cavity results in an omphalocele that is covered with a membrane called the amnion. The amnion protects the abdominal contents from infection and the loss of extracellular fluid. The umbilical cord is found at approximately the apex of the sac (Fig. 43-16). Gastroschisis, by contrast, develops later in fetal life, after the intestinal contents have returned to the abdominal cavity. It results from interruption of the omphalomesenteric artery, which results in ischemia and atrophy of the various layers of the abdominal wall at the base of the umbilical cord. The gut then herniates through this tissue defect (Fig. 43-17). The degree of herniation may be slight, or major amounts of the abdominal viscera may be found outside the peritoneal cavity. The umbilical cord is found to one side of the intestinal contents. The intestines and viscera are not covered by any membrane and therefore are highly susceptible to infection and loss of extracellular fluid. There is a high incidence of associated congenital anomalies with omphalocele, but not with gastroschisis. The Beckwith-Wiedemann syndrome consists of mental retardation, hypoglycemia, congenital heart disease, a large tongue, and an omphalocele. Congenital heart lesions are found in approximately 20% of infants with omphalocele. Other associated congenital defects are found with gastroschisis and omphalocele; most involve the gastrointestinal tract and consist primarily of intestinal atresia or stenosis and malrotation.

Figure 43-17. Gastroschisis

Antenatal Diagnosis

α -Fetoprotein (AFP) is a normal closure protein present in fetal tissues during fetal development. Closure of the abdominal wall and the neural tube (see [Meningomyelocele](#)) prevents release of large quantities of this protein into the amniotic fluid. High levels of AFP in the amniotic fluid can cross the placenta and be detected in maternal blood. Thus, abnormal levels of AFP in the mother raise concerns over the possibility of either an abdominal wall defect or a neural tube defect in the fetus, as do high levels of AFP in fluid obtained during amniocentesis. Ultrasonography is reliable in helping to diagnose either condition.

Preoperative Care

There is controversy over the appropriate mode of delivery, vaginal or cesarean section, in parturients in whom the antenatal diagnosis has been made. Advocates of operative delivery maintain that it is necessary to prevent trauma to the exposed bowel and that it allows better coordination of the various medical specialties needed for immediate surgical management of the defect. Advocates of vaginal delivery point out that most infants with abdominal wall defects are born without injury to the bowel. The aspect of delivery room care unique to an infant with gastroschisis is the need to protect the exposed bowel and minimize fluid and temperature loss. This is best achieved by “bagging” the neonate, that is, placing its lower body in a sterile, clear plastic bag. The bag is then filled with warm saline and a drawstring is used to tighten the bag against the infant’s body. This fluid must be maintained at body temperature to prevent hypothermia. Use of a fluid-filled bag helps protect against infection and the massive fluid loss that can occur with exposed bowel. This procedure is not necessary with omphalocele because the bowel is still enclosed by amnion.

Preoperative stabilization of the neonate with an abdominal wall defect includes management of respiratory insufficiency, establishment of adequate iv access, and an assessment for associated congenital anomalies. Respiratory failure at birth in infants with omphalocele is a significant predictor of mortality.⁵³ Lung hypoplasia and abnormal thoracic development may be significant in infants with large omphaloceles. Fluid losses can be excessive, particularly in neonates with gastroschisis. Central venous access may be necessary to provide adequate fluid resuscitation. Serum electrolytes and glucose should be obtained before going to the operating room. In addition, the infant with an omphalocele should be assessed for any associated congenital anomalies prior to going to the operating room. Congenital heart disease is found in approximately 20% of patients. A difficult airway can be anticipated in the patient with Beckwith-Wiedemann syndrome. Infants with gastroschisis are at high risk for infection because of exposed bowel; therefore, the initial stabilization includes antibiotic therapy.

Traditionally, neonates with gastroschisis have been taken to the operating room urgently, within the first 12–24 hours, for reduction of closure. A recent British study describes a technique of “minimal intervention management” for gastroschisis. After a short period of stabilization in the NICU, midgut reduction was performed in the conscious neonate without anesthesia. The reduction was performed through the umbilical cord while monitoring respiratory status and lower extremity circulation. The reported advantages of such a technique include the avoidance of ventilation, a shorter time until full enteral feedings are established, and a scarless abdomen with an aesthetically normal umbilicus.⁵⁴

Surgery is not urgent in the neonate with an omphalocele, and can be delayed for several days until the infant is assessed and stabilized. In those infants with severe

respiratory distress or congenital heart disease who are too unstable for surgery, nonsurgical treatment with topical antiseptics and delayed closure is an option.

Perioperative Care

The two major perioperative concerns are fluid loss and ventilation. The fluid volume management of the infant often entails administration of large amounts of full-strength balanced salt solution. The adequacy of the peripheral circulation and urine output is an indicator of the adequacy of the volume resuscitation. Both conditions may present an intraoperative challenge to the anesthesiologist because with an omphalocele, after the amniotic membrane is removed, large volumes of fluid may transudate or exudate from the exposed abdominal viscera. The fluid that is lost is extracellular fluid, which should be replaced with full-strength balanced salt solution. An arterial line is often used for blood pressure monitoring and frequent blood gas monitoring to assess acid–base status.

If the defect in the abdominal wall is small, a primary repair of the deficit can be accomplished. However, with a large defect, it may be difficult to return the abdominal viscera to the peritoneal cavity because the muscle and peritoneum are underdeveloped. Because of concern for the increase in the volume of gas in the intestine, nitrous oxide should not be used. Excellent skeletal muscle relaxation is necessary to allow closure of the abdomen. With moderate-sized abdominal wall defects, it may not be possible to close the peritoneum, but there may be sufficient skin to close the defect. With large defects, the peritoneal cavity may be too small to contain the viscera, and attempted closure can impair circulation to the bowel, kidneys, and lower extremities as well as compromise respiration. A pulse oximeter probe on the foot can be helpful in monitoring circulation to the lower extremities during abdominal wall closure.

Attempts have been made to find objective criteria by which to determine whether the infant will tolerate primary closure of the defect and to avoid or minimize the circulatory and ventilatory problems. One study that measured intragastric pressure in infants who underwent primary closure found that if the intragastric pressure was 20 mm Hg or more, the infant needed reoperation and placement of a Dacron silo (Fig. 43-18) within 24 hours of the primary closure.⁵⁵ If the intragastric pressure was less than 20 mm Hg, the defect was successfully closed primarily. Intragastric pressure is measured by placing a nasogastric tube in the stomach and using a column of saline to measure the pressure. A value of 20 mm Hg is approximately 27 cm H₂O. Studies in dogs revealed a close correlation between bladder pressure and intra-abdominal pressure; thus, bladder pressure can be used as an alternative measurement of intra-abdominal pressure.⁵⁶

Figure 43-18. Dacron silo for extruded viscera. (Reprinted with permission from Physiology and surgery of the infant. In Berry FA [ed]: Anesthetic Management of Difficult and Routine Pediatric Patients, p 154. New York, Churchill Livingstone, 1990)

If primary closure is impossible, a silo is incorporated into the abdominal wall to contain and cover the abdominal viscera. The repair is then staged from this point onward. Every 2 or 3 days, the size of the silo is reduced, in much the same fashion that a tube of toothpaste is squeezed. The infant may feel some degree of discomfort as the peritoneum and skin are stretched. Small doses of ketamine, 0.5–1.0 mg · kg⁻¹, are titrated as the silo is reduced. The infant is allowed to breathe spontaneously and without intubation. Oxygen saturation should be monitored with a pulse oximeter, and the infant's pulse and blood pressure are also monitored. These measurements help the surgeon and anesthesiologist determine the appropriate silo reduction that allows adequate ventilation and circulation. This is a situation that requires clinical judgment. After several stages of silo reduction, the final operation is complete closure of the abdominal wall defect under full anesthesia with complete muscle relaxation.

Postoperative Care

The postoperative care of infants with omphalocele or gastroschisis is critical. Some need tracheal intubation and assisted ventilation of the lungs for as long as 3–7 days. Additional complications include postoperative hypertension and edema of the extremities. The increased abdominal pressure can reduce the circulation to the kidneys, which results in a release of renin. Renin activates the renin–angiotensin–aldosterone system, which is thought to cause the hypertension. Obstruction of the venous circulation of the lower body may cause a large amount of edema of the legs. These infants need large amounts of extracellular fluid resuscitation.

Tracheoesophageal Fistula

The treatment of esophageal atresia and TEF can be both challenging and satisfying for the anesthesiologist. Death in the perioperative period typically results from prematurity or from an associated congenital heart defect. TEF occurs in approximately 1 in 3000 live births. Approximately 85% consist of a fistula from the distal trachea to the esophagus and a blind proximal esophageal pouch. In 10% of cases, there is a blind proximal esophageal pouch with no TEF (Fig. 43-19). The embryologic defect results from imperfect division of the foregut into the anteriorly positioned larynx and trachea and the posteriorly positioned esophagus; the division should occur between the fourth and fifth weeks of intrauterine life. Fifty percent of affected infants have associated congenital anomalies, of which approximately 15–25% involve the cardiovascular system.

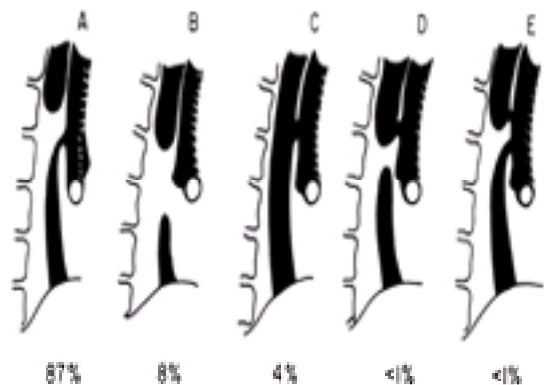

Figure 43-19. Diagrams of the five most commonly encountered forms of esophageal atresia and tracheoesophageal fistula, shown in order of frequency. (Reprinted with permission from Herbst JJ: Gastrointestinal tract. In Behrman RE, Kleigman RM, Nelson WE, Vaughan III WC [eds]: Nelson Textbook of Pediatrics, 14th ed, p 942. Philadelphia, WB Saunders, 1992.)

Clinical Presentation

Atresia of the esophagus leads to inability of the fetus to swallow amniotic fluid and the subsequent development of polyhydramnios. Ultrasound may well raise the possibility of a congenital anomaly. For that reason, if polyhydramnios is present, attempts should be made to pass a nasogastric tube shortly after delivery. Passing a nasogastric tube is not routine in the delivery room; therefore, the diagnosis may not become apparent until the infant is fed. Cyanosis and choking with oral feedings should raise suspicion.

There are two major complications of esophageal atresia with a distal tracheal fistula: aspiration pneumonia and dehydration. The presence of a distal TEF increases the likelihood of reflux of gastric juice up the esophagus and into the pulmonary system. Dehydration results from the fact that the proximal esophagus does not

communicate with the stomach. Therefore, preoperative preparation of these infants is aimed at evaluation and treatment of the pulmonary system and ensuring adequate hydration and electrolyte balance. At times, the degree of reflux and pneumonia is so great that a gastrostomy must be performed to protect the pulmonary system, and a period of several days is needed to improve the general condition of the infant. However, if the infant is in good condition, primary repair can be performed at 24–48 hours. This consists of ligation of the fistula and a primary repair with approximation of the two ends of the esophagus.

Anesthetic Considerations

The presence of a gastrostomy reduces the potential for reflux of gastric juice during the surgical procedure. If a gastrostomy is present, the gastrostomy tube should be open to air and left at the head of the table under the anesthesiologist's observation to avoid kinking and obstruction. Not all patients need a gastrostomy, however. There is some difference of opinion concerning the technique for intubation of the trachea. Some clinicians prefer an awake intubation, and others prefer intubation after induction of anesthesia. The important issue is to avoid excessive positive pressure ventilation, which distends the stomach, thereby increasing the risk for reflux and ventilatory compromise. If an awake tracheal intubation is done, it can be facilitated by the topical administration of lidocaine and with the use of $1 \text{ mg} \cdot \text{kg}^{-1}$ of lidocaine iv 1–2 minutes before laryngoscopic examination. Most clinicians prefer the technique described in the following paragraph.

There are two approaches to tracheal intubation after induction of anesthesia. One is to use an inhalation induction, followed by topical application of lidocaine and intubation while the infant is breathing spontaneously. The other technique is to use an iv or inhalation induction and intubate the trachea after muscle paralysis. This technique may lead to distention of the fistula and stomach with excessive positive-pressure ventilation. With either technique, topical anesthesia of the larynx may be achieved with $4\text{--}5 \text{ mg} \cdot \text{kg}^{-1}$ of 2% lidocaine sprayed on the larynx and vocal cords. Lidocaine 2% is preferred to higher concentrations in these small infants because it is easier to control the dose. When controlled ventilation of the lungs is used, attempts must be made to minimize the distention of the stomach and the potential for reflux. If a gastrostomy tube is in place, the point is moot. Alternatively, because the fistula is usually located just above the carina on the posterior wall of the membranous trachea, the endotracheal tube can be placed just distal to the TEF. To do this, the endotracheal tube is inserted until it enters one or the other mainstem bronchi. This is judged by unilateral expansion of the chest and unilateral breath sounds. The endotracheal tube is then slowly withdrawn until bilateral chest movement and breath sounds are confirmed.

The endotracheal tube might inadvertently enter the fistula either during the initial tracheal intubation of the infant, when the infant is turned, or during surgical manipulation. The clinical indications for this are increased difficulty in ventilation of the lungs and decreased oxygen saturation and end-tidal CO_2 . Because these findings may also be present when the lung is packed away to perform the surgery, and because there are other explanations for these findings, intubation of the fistula should always be included in the differential diagnosis. Any time ventilation is difficult and desaturation is occurring, the surgeon must stop the procedure and the lungs should be ventilated. The surgeon will be able to palpate the tip of the tube in the fistula if this is the problem.

The localization and isolation of H-type fistulas can be difficult. In this situation, bronchoscopy is performed by the surgeon, the fistula is identified, and a guide wire is fed through the fistula tract into the esophagus. The infant is then intubated, with care taken not to dislodge the guide wire. Once intubated esophagoscopy is performed, the guide wire is visualized and brought out through the mouth. In this way the surgeon can use fluoroscopy to determine the level of the fistula and decide whether a cervical or thoracic approach is necessary. During surgery, the anesthesiologist can apply traction to the wire loop to facilitate the localization of the fistula by the surgeon.⁵⁷

Other techniques for obliterating H-type fistulas, such as electrocauterization and neodymium–yttrium–aluminum–garnet laser, have been attempted with varying success.⁵⁸

Postoperative Care

Although there have been great advances in the treatment of TEF and esophageal atresia, postoperative care can be complicated by associated congenital heart disease, respiratory distress syndrome, and a need for continued postoperative ventilation. The compression of the lung for several hours, along with pre-existing aspiration pneumonia in some of these infants, suggests the need in the more difficult cases for a short period of postoperative ventilation or at least intubation with PEEP, as the most conservative technique for postoperative airway management. Some infants are in excellent condition at the time of surgery with no complicating factors, and therefore should be considered for extubation immediately at the end of surgery or shortly thereafter. If extubation of the trachea is planned for the end of surgery, the anesthetic technique must be tailored accordingly. Caudal anesthesia as part of the technique is useful in these situations, reducing the concentration of maintenance volatile anesthetics, the amount of muscle relaxants, and the need for intraoperative narcotics.

A high percentage of infants with esophageal atresia have residual difficulties of the tracheobronchial tree and esophagus for many years. These include tracheomalacia, gastroesophageal reflux, esophageal stricture, and recurrent fistulas.

Intestinal Obstruction

For purposes of discussion, obstruction of the gastrointestinal system can be arbitrarily divided into obstruction of the upper gastrointestinal tract (*i.e.*, duodenum) and obstruction of the lower gastrointestinal tract (*i.e.*, terminal ileum, colon, imperforate anus). Obstruction of the upper gastrointestinal tract usually is evident within the first 24 hours of life, when the institution of feedings leads to vomiting, whereas obstruction of the lower gastrointestinal tract becomes evident somewhere between 2 and 7 days of age, as the infant becomes progressively distended, little or no stool is passed, and there is vomiting.

Upper Gastrointestinal Tract Obstruction

If there has been persistent vomiting, this usually means that a deficit of fluids or electrolytes will develop in the infant. The stomach contains approximately $100\text{--}130 \text{ mEq} \cdot \text{l}^{-1}$ of sodium and $5\text{--}10 \text{ mEq} \cdot \text{l}^{-1}$ of potassium. The greatest deficit is for sodium. Another major concern in the infant with upper gastrointestinal tract obstruction is aspiration of gastric contents. Therefore, awake tracheal intubation may be indicated. Techniques for this are discussed in an earlier section.

The anesthetic management of these patients is directed toward ensuring adequate relaxation for abdominal exploration, repair of the congenital defect, and closure of the abdomen. Nitrous oxide can be used in high intestinal obstruction because there is essentially no gas in the gastrointestinal tract. The next concern is whether the infant's trachea should be extubated at the end of surgery. If the infant is robust, extubation of the trachea at the end of surgery can be anticipated. The preferred technique is for general anesthesia combined with caudal epidural anesthesia. This allows very light levels of volatile agent and minimal muscle relaxant use, resulting in an early extubation. Opioids are not administered until the postoperative period. However, if the infant is moderately debilitated or if the surgical incision is extensive, a period of postoperative intubation with PEEP may well be indicated, particularly if moderate doses of opioids have been used. These infants are also candidates for regional techniques.

Lower Gastrointestinal Tract Obstruction

The problems associated with lower gastrointestinal tract obstruction usually develop within 2–7 days after birth. It may take this long for the lesion to become evident because it is low in the gastrointestinal tract. An imperforate anus should be recognizable shortly after birth. Some of these infants may have vomiting secondary to the obstruction, which poses a problem for fluid and electrolyte management. An enormous amount of fluid can be sequestered within the intestinal tract. This fluid is essentially extracellular fluid and has a high sodium content. Therefore, these infants should be prepared carefully for surgery and have a serum sodium level of at least $130 \text{ mEq} \cdot \text{l}^{-1}$ and a urine volume of $1\text{--}2 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$.

If the infant has had minimal or no vomiting, rapid-sequence induction of anesthesia and tracheal intubation can be done. Rapid-sequence induction in an infant is the same as in an adult, with iv barbiturate or propofol, muscle relaxant, cricoid pressure, and oxygenation. If the infant is experiencing vomiting in the immediate preoperative period, the most conservative approach is an awake tracheal intubation after gastric decompression. Although a nasogastric tube may be in place, there is no guarantee that the stomach is empty. Nitrous oxide should not be used in any infant who has gaseous distention of the intestine, which is easily determined from the preoperative radiograph. Providing adequate muscle relaxation for surgery can be accomplished with various anesthetic techniques such as volatile anesthesia, muscle relaxants, and caudal epidural block.

The criteria for tracheal extubation at the end of surgery are the same as those described for upper gastrointestinal tract obstruction. When in doubt, leave the tracheal tube in place with PEEP. This is not to suggest that prolonged tracheal intubation is benign; it is not. There is a small but significant risk for the development of subglottic stenosis, but this is a situation in which the risk of subglottic stenosis and other airway trauma must be weighed against the risk of too early tracheal extubation with vomiting, aspiration, and airway obstruction.

Meningomyelocele

Clinical Presentation

Myelomeningocele is the most common congenital primary neural tube defect, occurring in approximately 1 of every 1000 live births. It results from failure of neural tube closure during the fourth week of gestation. Neural tube defects can be identified on prenatal ultrasound. Elevated maternal serum AFP detects 50–90% of open neural tube defects but has a false-positive rate of 5%. Amniotic fluid AFP is more reliable. Evidence also supports a relation between folic acid deficiency and the development of neural tube defects.

By definition, the lesion involves both the meninges and neural components, as compared with a meningocele, which does not contain neural elements. The infant is born with a cystic mass on the back comprising a neural placode, arachnoid, dura, nerve tissue and roots, and CSF. The lesion most commonly occurs in the lumbosacral or sacral region. The bony canal is also malformed, leading to multiple orthopedic problems as the child matures. Urologic complications correlate with the level of the spinal lesion.

Most infants born with myelomeningocele have an associated anomaly of the brain stem known as the Arnold-Chiari II (Chiari II) malformation. The Chiari II malformation is characterized by caudal displacement of the cerebellar vermis through the foramen magnum, caudal displacement of the medulla oblongata and the cervical spine, kinking of the medulla, and obliteration of the cisterna magna. Hydrocephalus requiring shunting develops in approximately 90% of infants with myelomeningocele. On the other hand, only 20% of patients have symptoms of brain stem dysfunction as a result of the Chiari II malformation, but the mortality rate among those symptomatic patients is high. Symptoms of brain stem dysfunction include stridor, apnea and bradycardia, aspiration pneumonia, sleep-disordered breathing patterns, vocal cord paralysis, incoordination, and spasticity. If the symptoms are not improved by shunting, posterior fossa decompression is necessary.^{59,60} and ⁶¹

The infant with a myelomeningocele is usually operated on within the first 72 hours of life. This reduces the risk for development of ventriculitis or progressive neurologic deficits. Most centers close the defect and place a shunt at the same time. However, some centers may delay placement of a shunt until the infant shows symptoms of hydrocephalus. There is some evidence that intrauterine repair of myelomeningocele may decrease the morbidity associated with the Chiari II malformation and brain stem dysfunction.⁶²

Preoperative Care

The safest route of delivery of an infant with a myelomeningocele remains controversial. Some question whether labor and vaginal delivery can adversely affect neurologic outcome. However, there are studies suggesting no difference in neurologic deficits between infants delivered vaginally or by cesarean section.

The preoperative stabilization period focuses on the prevention of infection, maintenance of extracellular fluid volume, and assessment for other congenital anomalies. The exposed neural placode is susceptible to trauma, leakage, and infection. The infant is usually placed in the prone position and the placode is covered with saline-soaked gauze to prevent desiccation. Because of the high risk of infection, antibiotic therapy is initiated in the preoperative period. Rupture of the cyst on the back can lead to ongoing CSF leakage. This fluid is replaced with full-strength balanced salt solution. The infant is also assessed for any potentially life-threatening congenital anomalies.

Perioperative Care

The high prevalence of clinical latex allergy and latex sensitization in children with myelomeningocele has drawn much attention. Studies show that the prevalence increases with increasing age. It is believed that an early, intense exposure to the allergen, as occurs with frequent surgery and bladder catheterization, contributes to this high prevalence. As a result, these infants are now labeled as latex sensitive and cared for in a latex-free environment.⁶³

Positioning is critical in the infant with myelomeningocele. For induction of anesthesia, the infant may be placed supine with the defect resting in a “donut” to minimize trauma. Alternatively, the induction can be performed with the infant in the lateral position, although this makes intubation more challenging. The infant is turned prone for surgery. Rolls are positioned to ensure that the abdomen and chest are free, avoiding pressure on the epidural venous plexus to minimize bleeding and allowing for adequate ventilation.

In most instances, the infant has an iv line placed before surgery and an iv induction is performed. Succinylcholine may be used to facilitate intubation without risking hyperkalemia.⁶⁴ Because increased intracranial pressure is rarely present before closure of the defect, inhalational induction is an alternative in the infant with difficult iv access. Identification of neural tissue may require nerve stimulation, and therefore muscle relaxants are avoided. Narcotics are used with caution in these infants because of the abnormal response to hypoxia and hypercarbia, predisposing to apnea and bradycardia. Careful monitoring of temperature is necessary because prolonged exposure during repair can lead to hypothermia. These infants must remain intubated until they are fully awake. The effects of general anesthesia in association with the abnormalities of respiratory control may warrant a prolonged period of respiratory support in some infants with myelomeningocele.

Regional anesthesia has been reported as a safe alternative to general anesthesia in the neonate with myelomeningocele. Viscomi *et al*⁶⁵ successfully administered tetracaine spinals to 14 infants undergoing repair of myelomeningocele. In this small series, there was no evidence of anesthetic-induced neurologic damage. Two of the 14 infants had a postoperative respiratory event (1 transient apnea/bradycardia and 1 brief desaturation with bradycardia). Both of these infants had received intraoperative midazolam for sedation.

Postoperative Care

These infants must be monitored closely in the postoperative period. Respiratory complications, including stridor, apnea and bradycardia, cyanosis, and respiratory arrest may develop after surgery in these infants with known brain stem abnormalities and potential disorders of central respiratory control. In addition, those infants who were not shunted during repair may show signs of hydrocephalus, including lethargy, vomiting, seizures, apnea and bradycardia, or cardiovascular instability. These infants need to return to the operating room for insertion of a shunt.

Hydrocephalus

Hydrocephalus may occur after closure of a meningomyelocele because of the Arnold-Chiari malformation. The cranial sutures in the neonate are open, so that intracranial pressure increases are blunted or minimized. However, infants with hydrocephalus eventually have an increase in head size and sometimes in intracranial pressure, resulting in lethargy, vomiting, and cardiorespiratory problems. The anesthetic approach and the technique for tracheal intubation depend on the infant's condition. The major concern is protection of the airway and control of intracranial pressure. Awake tracheal intubation, crying, struggling, and straining can increase intracranial pressure. A rapid-sequence induction of anesthesia to control the airway and intracranial pressure is preferred. Pretreatment before a rapid-sequence induction consists of the administration of iv curare or atracurium in a dose of 0.05 mg · kg⁻¹. A rapid-sequence induction with 3–4 mg · kg⁻¹ of thiopental or 2–3 mg · kg⁻¹ of propofol, 2 mg · kg⁻¹ of succinylcholine, and cricoid pressure can lead to rapid control of the airway. Hyperventilation, along with the administration of barbiturate, rapidly controls intracranial pressure. Volatile drugs, nitrous oxide, and opioids are all reasonable choices for maintenance of anesthesia. Noninvasive intracranial pressure measurements in neurologically normal preterm neonates have shown a decrease in intracranial pressure with all drugs, including ketamine, fentanyl, isoflurane, and halothane. The failure of volatile anesthetics and ketamine to increase intracranial pressure as in adults is attributed to the compliance of the neonate's open-sutured cranium. After surgery, the trachea of these infants should remain intubated and they should receive PEEP if they were experiencing periods of apnea or bradycardia before surgery because of the intracranial abnormalities. If not, the trachea can be extubated as soon as the protective reflexes have recovered.

Surgical Procedures in the First Month of Life

Surgical procedures in the first month also are considered emergent, or at least urgent, surgery. The six most frequent surgical procedures in the first month are exploratory laparotomy for necrotizing enterocolitis (NEC), inguinal hernia repair, correction of pyloric stenosis, PDA ligation, a shunt procedure for hydrocephalus, and placement of a central venous catheter.

Necrotizing Enterocolitis

Necrotizing enterocolitis is a disease that primarily affects premature infants who have survived the first days of life. One of the theories about NEC is that earlier, more rapid feeding places infants at greater risk for development of NEC. A study by Kliegman *et al*⁶⁶ supports this theory. They found that delayed feeding was related to a delayed onset of NEC. Another factor in the feeding issue is that the larger the feeding, the higher the incidence of NEC. It primarily affects the very-low-birth-weight infant, but it may also affect the larger premature and occasionally full-term neonates. The incidence of NEC among very-low-birth-weight infants varies between 5 and

15%.⁶⁷ It has been postulated that because the use of surfactant increases the survival of very small premature infants with respiratory distress syndrome, it may also increase the incidence of NEC.⁶⁷

The exact pathophysiology of NEC has yet to be determined. Kosloske proposed the hypothesis that NEC occurs by the coincidence of two of three pathologic events: intestinal ischemia, colonization by pathogenic bacteria, and excess protein substrate in the intestinal lumen.⁶⁸ NEC is more likely to appear after quantitative extremes (*i.e.*, severe ischemia, highly pathogenic flora, or significant excess of substrate). NEC develops only if a threshold of injury sufficient to initiate intestinal necrosis is exceeded. The condition is characterized by a cascade of pathologic events, beginning with an immature intestine that has a decreased ability to absorb substrate, leading to stasis. Stasis encourages bacterial proliferation, which leads to local infection. The picture is complicated by further pooling of fluid. The ischemia and infection may lead to necrosis of the intestinal mucosa, followed by perforation. The perforation leads to gangrene, fluid loss, peritonitis, septicemia, and disseminated intravascular coagulation. The first signs that NEC may be developing are abdominal distention, irritability, and the development of metabolic acidosis. NEC is primarily a medical disease and is treated by cessation of oral intake and administration of antibiotics and supportive care, particularly fluid and electrolyte therapy. In nonresponsive cases, the infant becomes more septic with severe peritonitis, and the only solution is to perform an exploratory laparotomy to remove the gangrenous bowel and create an ileostomy.

The preoperative problems are an acute abdomen with severe peritonitis, necrosis and gangrene of the intestine, septicemia, metabolic acidosis, and hypovolemia. These neonates may also have a coagulopathy. Preparation of the patient is directed toward these problems. Often the septicemia, coupled with the distended abdomen and the overall clinical deterioration of the infant, also necessitates the use of intubation and ventilation in the NICU. The anesthetic requirements are continuation of resuscitation, provision of abdominal relaxation for the surgery, and careful titration of anesthetic drugs. These infants are often so critically ill that they tolerate minimal anesthesia. One choice is to start with small doses of ketamine, 0.5–1 mg · kg⁻¹. This can be administered every 20–30 minutes. If the condition improves, fentanyl, 2–3 mg · kg⁻¹, can be administered, up to a total dose of 10–12 mg · kg⁻¹. If the infant's condition improves dramatically, small doses of volatile drug can be added as well. The use of nitrous oxide should be avoided because of the gas pockets in the abdomen.

These infants are among the most challenging cases in all of pediatric anesthesia. Monitoring of intra-arterial pressure and arterial blood gases has usually been started in the NICU. The fluid loss can be enormous. They need full-strength balanced salt solution for maintenance of blood pressure and urine output. If the hematocrit is below 30–35%, blood should be administered. These infants are returned to the NICU and their postoperative care coordinated carefully with the surgeon, neonatologist, or pediatrician.

Inguinal Hernia Repair in the Neonate

The development of a hernia in the premature infant or neonate is a different clinical problem from the development of a hernia in an infant older than 1 year of age.^{69,70} In one study of 100 infants younger than 2 months of age who needed inguinal hernia repair, 30% were premature, 42% had a history of respiratory distress syndrome, 16% had been ventilated, and 19% had congenital heart disease.⁶⁹ Furthermore, 31% of the infants had incarcerated hernias, 9% had an intestinal obstruction, and 2% had gonadal infarction. These data preclude waiting until a premature infant or neonate is 6 months or 1 year of age before performing “elective” surgery. The potential for emergent or urgent intervention is so great that surgical repair should be accomplished within a reasonable amount of time after an inguinal hernia is discovered. The “reasonable” time depends on the infant's condition. If the infant is normal and has no other life-threatening medical problems, repair can be done within several days or weeks. If the infant has another problem, the waiting period should be sufficient to stabilize the infant's condition.

Perioperative complications are frequent in these infants. In the 100 patients reported by Rescorla and Grosfeld,⁶⁹ 2 had apnea and bradycardia, 4 needed postoperative ventilatory support, 1 had a cardiac arrest resulting from digoxin toxicity, and 1 acquired *Klebsiella* sepsis. It has long been recognized that premature infants undergoing elective surgery have a higher rate of complications than full-term infants undergoing the same type of surgery.

Postoperative Apnea

A major concern with surgery in neonates is the development of apnea in the postoperative period. The infants at highest risk are those born prematurely, those with multiple congenital anomalies, those with a history of apnea and bradycardia, and those with chronic lung disease. The etiology of this apnea is multifactorial. Decreased ventilatory control and hyporesponsiveness to hypoxia and hypercarbia may be potentiated by anesthetic agents. Respiratory muscle fatigue may also play a role because neonates have a smaller percentage of Type I fibers in their diaphragm and intercostal muscles. Hypothermia and anemia may also contribute to the development of postoperative apnea.^{71,72,73} and ⁷⁴ The treatment of postoperative apnea may be as simple as tactile stimulation with “blow by” oxygen. However, some infants require prolonged intubation in ventilatory support. Infants with life-threatening apnea and bradycardia before surgery may be on central nervous system stimulants. Caffeine or theophylline both act by increasing central respiratory drive and lowering the threshold of response to hypercarbia as well as stimulating contractility in the diaphragm. Administering supplemental intraoperative doses to those infants to ensure adequate serum levels of drugs may prevent the need for prolonged periods of postoperative ventilatory support.^{75,76}

Those infants at high risk for development of postoperative apnea may benefit from the use of a regional anesthetic as opposed to general anesthesia. Multiple studies have shown that spinal anesthesia without supplemental sedation decreases the incidence of postoperative apnea and bradycardia in high-risk infants. Once supplemental sedation is used, inhalation or ketamine, this advantage is lost.^{77,78} The question remains as to which infant should be monitored after surgery, and for how long. The most conservative approach is to monitor all infants younger than 60 weeks postconceptual age for 24 hours after surgery.⁷¹ Many reports show that the incidence of significant apnea and bradycardia is highest in the first 4–6 hours after surgery, but they have been reported up to 12 hours after surgery. In addition, the incidence of apnea directly correlates to postconceptual age. Therefore, the most widely accepted guideline is to monitor all infants younger than 50 weeks postconceptual age for at least 12 hours after surgery, even infants who have had a spinal as their sole anesthetic.^{72,73}

Anesthetic Techniques for Hernia Repair

Surgical procedures below the umbilicus can be performed with either general or regional anesthesia. There is no consensus about which is preferred. The choice of whether to do general or regional depends on the preference of the surgeon or the anesthesiologist. Regional anesthesia can be used entirely for the surgery or as an adjunct to reduce general anesthetic requirements and produce postoperative analgesia. There has been some concern that general anesthesia is associated with a slightly higher incidence of postoperative apnea, although there have been no bad outcomes reported from the apnea. These episodes have not been increased when pure regional anesthesia is used, but if sedatives are added to regional anesthesia, then the same incidence of postoperative apnea occurs as with general anesthesia. Other methods of providing intraoperative anesthesia and postoperative analgesia include the ilioinguinal–iliohypogastric nerve block or local infiltration. Ilioinguinal–iliohypogastric nerve block with 0.25% bupivacaine or 0.2% ropivacaine, with epinephrine, can be administered shortly after the induction of general anesthesia; it affords excellent postoperative analgesia without the need for opioids.

Pyloric Stenosis

Pyloric stenosis is a relatively frequent surgical disease of the neonate and infant. It can appear as early as the second week of life. The pathologic characteristics include hypertrophy of the pyloric smooth muscle with edema of the pyloric mucosa and submucosa. This process, which develops over a period of days to weeks, leads to progressive obstruction of the pyloric valve, causing persistent vomiting. The vomiting leads to varying losses of fluids and electrolytes. Pediatricians are now adept at the early diagnosis of pyloric stenosis with ultrasound, so it is rare to find an infant with severe fluid and electrolyte derangements. However, an infant is occasionally seen whose problem has developed slowly over a period of weeks, resulting in severe fluid and electrolyte derangements. The stomach contents contain sodium, potassium, chloride, hydrogen ions, and water. The classic electrolyte pattern in infants with severe vomiting is a hyponatremic, hypokalemic, hypochloremic metabolic alkalosis with a compensatory respiratory acidosis. The anesthesiologist, pediatrician, and surgeon are all responsible for preparing these infants for surgery. Pyloric stenosis is a medical emergency and should not be converted into an anesthetic nightmare by premature surgical repair before adequate fluid and electrolyte homeostasis has been achieved. The infant should have normal skin turgor, and the correction of the electrolyte imbalance should produce a sodium level that is greater than 130 mEq · l⁻¹, a potassium level that is at least 3 mEq · l⁻¹, a chloride level that is greater than 85 mEq · l⁻¹ and increasing, and a urine output of at least 1–2 ml · kg⁻¹ · h⁻¹. These patients need a resuscitation fluid of full-strength balanced salt solution, and, after the infant begins to urinate, the addition of potassium chloride.

Anesthetic Management

One of the concerns in the anesthetic management of patients with pyloric stenosis is the aspiration of gastric contents. Affected infants are usually older and stronger than those in whom an intestinal obstruction appears in the first day or so of life. For this reason, a slightly different approach is used. A large orogastric tube is passed and the stomach contents aspirated.⁷⁹ This procedure greatly reduces the quantity of gastric fluid. Intubation of the trachea can be done while the patient is awake or after induction of anesthesia, which is preferred by most clinicians. If an iv line is not in place and cannot be placed with reasonable ease, then after the stomach-emptying regimen is followed, an inhalation induction of anesthesia is done with nitrous oxide and sevoflurane or halothane. Sevoflurane has proved to be an excellent volatile agent for the induction of anesthesia and establishment of endotracheal intubation. There is very little irritation of the respiratory tract and it has a very

rapid onset. Use of nitrous oxide should be discontinued as soon as the infant loses the lid reflex. If a vein becomes evident, an iv line is placed and rapid intubation of the trachea accomplished with the use of succinylcholine or a nondepolarizing muscle relaxant and cricoid pressure. If an iv line still cannot be placed easily, two options exist: the anesthesiologist should either deepen inhalation anesthesia with halothane or sevoflurane, insert the laryngoscope, topically anesthetize the vocal cords with 4 mg · kg⁻¹ of lidocaine, and intubate the trachea; or administer 4 mg · kg⁻¹ of succinylcholine intramuscularly before intubation. If iv access has already been obtained, a rapid-sequence tracheal intubation technique is preferred. The infant is preoxygenated with high-flow oxygen; curare 0.05 mg · kg⁻¹ is given, followed by thiopental 3–4 mg · kg⁻¹ or 3 mg · kg⁻¹ propofol, and succinylcholine 2 mg · kg⁻¹. If a nondepolarizing muscle relaxant is chosen, the dose is cisatracurium 0.4–0.6 mg · kg⁻¹ or rocuronium 0.4 mg · kg⁻¹. Cricoid pressure is applied as soon as tolerated and the infant's trachea is intubated. Anesthesia can be maintained by almost any technique the clinician prefers. The point to remember is that surgeons need muscle relaxation twice: when they deliver the pylorus at the beginning of surgery and when they replace the pylorus into the abdomen at the end of surgery, shortly before closing the peritoneum. Administration of a caudal anesthetic (1.25 ml · kg⁻¹ of 0.25% bupivacaine with epinephrine) after the induction of general anesthesia with tracheal intubation is recommended. Caudal anesthesia provides intraoperative relaxation, reduces the anesthetic requirement, and provides postoperative analgesia. Controlled ventilation with sevoflurane reduces or eliminates the need for muscle relaxants for this surgery. The infant's trachea should remain intubated until he or she is awake with eyes opened and is reaching for the endotracheal tube, or is crying. There has been some concern about the risk of postoperative apnea in these infants. With the use of regional anesthesia and avoidance of narcotics, these infants do not appear to be at increased risk.⁸⁰

Ligation of a Patent Ductus Arteriosus

As the number of small premature infants who survive has increased, so also has the number of infants who have PDA with heart failure and respiratory failure. Prostaglandins relax the smooth muscle of the ductus so that it cannot constrict. Indomethacin, a prostaglandin synthetase inhibitor, is administered to encourage closure of the ductus. However, indomethacin is often unsuccessful in the small premature infant because of the lack of muscle within the ductus. Infants with a PDA and heart failure need maximal medical management with fluid restriction and diuretics. These infants are at special risk because of the reduced blood volume and precarious cardiopulmonary system. Fentanyl with pancuronium is a frequent choice for anesthesia. The clinician must be prepared to augment volume rapidly with 10–15 ml · kg⁻¹ of lactated Ringer's solution. If the lactated Ringer's solution accompanies the administration of 20–25 mg · kg⁻¹ of fentanyl and pancuronium, the pressure changes are minimal and the infant will be appropriately anesthetized. The tracheas of these infants usually remain intubated and the lungs ventilated in the postoperative period, so concern about the length of action of muscle relaxants and opioids is minimized.

A new technique for closing the PDA in low-birth-weight infants has been developed, called video-assisted ligation of the PDA.⁸¹ Under general anesthesia, four small thoracotomy incisions are made that allow the insertion of an endoscope and various other instruments to ligate the PDA. The operation is accomplished without either spreading the ribs or cutting muscles, thereby offering a minimally traumatic and safe technique for the surgery. This operation has been accomplished both in the operating room as well as in the NICU; where the surgery is performed is more of a "turf" issue than a technical one.

Placement of a Central Venous Catheter

The use of a central venous catheter for monitoring serum electrolytes for hyperalimentation and for administering medications is increasing. It can be placed either as part of the surgical procedure or at some other time as a separate procedure. The three major concerns in central venous catheter placement are airway management, pneumothorax, and bleeding. The airway should be secured by an endotracheal tube in small infants because of the difficulty in sharing the head, neck, and upper chest with the surgeon and as an adjunct for treating complications such as pneumothorax and bleeding. The anesthetic technique depends on the infant's condition. A pneumothorax may occur with attempts at subclavian vein puncture. The first indication of trouble may be a decreasing oxygen saturation, hypotension, or difficulty with ventilation of the lungs. Because a fluoroscope is often used for central venous catheter placement, it can be used rapidly to diagnose a pneumothorax. If not, the chest should be rapidly aspirated for both diagnostic and therapeutic reasons. Bleeding is an unusual but serious complication of central venous catheter placement. It usually becomes manifest in the perioperative period as a hemothorax or as hypovolemia with a decreasing hematocrit or blood pressure. The question of whether an infant needs an iv catheter placed before proceeding with a central line has never been answered. The reason for the central line is usually that the infant has no veins and the clinician is left with a tradeoff between prolonged attempts at starting an iv versus proceeding without an iv line to obtain central venous line placement. The subclavian approach has a higher incidence of problems than an external or internal jugular approach. An iv catheter should be started when possible if it can be done within a reasonable time (*i.e.*, 15–20 minutes). If not, then central catheter placement continues as described previously, without an iv catheter, after discussion and agreement with the surgeon.

Respiratory Distress Syndrome

Because of the enormous technical ability of the neonatologist and the resources of NICUs, many very small infants survive who need surgery. One of the frequent problems of these infants is the occurrence of the respiratory distress syndrome secondary to a deficiency of surfactant. Respiratory distress syndrome is not an all-or-none disease; there are varying degrees of the disease and various treatments for it. Exogenous surfactant has been widely used in premature infants of low birth weight either to prevent or to treat respiratory distress syndrome.⁸² As a result, fewer infants now die of this entity, and the incidence of bronchopulmonary dysplasia in survivors has fallen. However, the use of exogenous surfactant appears to have had little impact on other complications of prematurity such as PDA, NEC, or intraventricular hemorrhage.

Retinopathy of Prematurity

Advances in neonatal medicine have led to the survival of extremely premature infants (*i.e.*, infants weighing <1000 g and infants <28 weeks' gestation). These infants are at high risk for development of retinopathy of prematurity (ROP).⁸³ ROP is a common cause of blindness in these extremely premature infants. Although the exact etiology is unknown, variations in arterial oxygenation (hypoxia or hyperoxia) and prolonged exposure to bright light are believed to play a significant role. Hyperoxic vasoconstriction of retinal vessels, induction of vascular endothelial growth factor, and damage to spindle cells by oxygen free radicals are some of the currently supported hypotheses in the pathogenesis of ROP.⁸⁴

Advances in the treatment of ROP have followed the advances in neonatal care that led to the increased incidence of ROP. ROP is staged as follows:

Stage 1: Presence of a demarcation line between vascularized and avascularized retina

Stage 2: Presence of a demarcation line that has height, width, and volume (ridge)

Stage 3: Presence of a ridge with extraretinal fibrovascular proliferation

Stage 4: Partial retinal detachment

Stage 5: Total retinal detachment

The early stages are treated with cryotherapy or laser. These treatments may be performed with sedation in the NICU or under general anesthesia in the operating room. The later stages require retinal surgery (scleral buckle or vitrectomy) to be performed under general anesthesia.⁸⁵ In addition, the anesthesiologist may be called on to anesthetize an infant with ROP for an unrelated surgery, such as hernia repair or ventriculoperitoneal shunt or central line placement.

The question the anesthesiologist faces is what inspired oxygen concentration is safe under general anesthesia. There are no studies that document some threshold PaO₂ above which ROP develops. In addition, there are no studies that document the length of time that the PaO₂ has to remain above some threshold number. A study by Flynn *et al*.⁸⁶ suggested that the longer the time the premature infant had a documented TcO₂ (transcutaneous oxygen) above 80 mm Hg, the higher the incidence of ROP. The guidelines for the administration of oxygen in premature infants is a goal of 50–80 mm Hg.⁸⁷ An oxygen saturation of 90–95% represents a PaO₂ of somewhere between 60 and 80 mm Hg. Therefore, it seems reasonable to try to maintain an oxygen saturation of 95% with minimal inspired oxygen while these premature infants are under general anesthesia. If the infant is experiencing episodes of hypotension or problems with ventilation, then attempts to micromanage the oxygen saturation should be secondary to the management of the primary problems. However, if an infant is stable, it might be appropriate to dilute the inspired oxygen with room air, nitrogen, or nitrous oxide until the saturation is in the neighborhood of 95%.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant younger than 1 year of age that remains unexplained after complete autopsy, death scene investigation, and review of family history. SIDS is the most frequent cause of death in infants between the ages of 1 month and 1 year. Death from SIDS is relatively rare in the first month of life, with the peak occurring at the third to fourth months of life. Premature infants are known to be at increased risk to die of SIDS.

However, studies have failed to prove a relationship between apnea of prematurity and SIDS.⁸⁸ Epidemiologic studies suggest that the risk factors for SIDS include low birth weight, maternal smoking, maternal cocaine use, young maternal age, low socioeconomic status, and African-American race.⁸⁹ There is currently no evidence that general anesthesia triggers SIDS.⁹⁰

The relationship between infant sleep position and SIDS was evaluated in the early 1990s. It was noted that there was a 50% reduction of SIDS rates in those countries where there was a decline in prone positioning of infants. As a result, the American Academy of Pediatrics recommended that all well infants at term with no other problems be placed either on their side or back when sleeping.^{91,92}

Sudden infant death syndrome remains a mystery in many ways. Multiple theories have been proposed over the years, including the "infant apnea syndrome." The more current theories focus on abnormalities of cardiorespiratory control during sleep states. Recent evidence suggests an abnormality in the maturational process of brain stem nuclei, particularly the arcuate nucleus. As a result, it is believed that these infants lack the normal homeostatic mechanisms necessary to respond to exogenous stressors during sleep.⁹³ A separate theory focuses on abnormalities in autonomic control during obstructive sleep events in infants at risk.⁹⁴

The provision of safe anesthesia for the pediatric patient requires a clear understanding of the psychological, physiologic, and pharmacologic differences between a premature infant and an adolescent, as well as between a newborn and a toddler. A thorough understanding of these differences must be applied to each pediatric patient presenting for surgery. This chapter presents an overview of the important issues in pediatric anesthesia. There are many specialized pediatric anesthesia texts that expand on topics introduced here.^{1,2,3,4,5} and ⁶ In addition, neonatal anesthesia, pediatric pharmacology, equipment, and other general topics are covered elsewhere in this text.

During the first several months of life, an infant experiences rapid growth, organ maturation, and neurologic development. In the first 3 months of life, circulatory and ventilatory adaptation are completed and thermoregulation is altered to a more adult state. The sizes of body fluid compartments approach adult values. Skeletal muscle mass and hepatic enzyme systems are developing and renal function is maturing (Table 44-1). Over the next 18 months, the infant is physically transformed to a miniature adult. Psychological maturation (which continues through adolescence) is a much more gradual process⁷ (Table 44-2).

| Body Compartment | Percentage of Body Weight | |
|---------------------|---------------------------|-------|
| | Infant | Adult |
| Total body water | 73 | 60 |
| Extracellular fluid | 44 | 15-20 |
| Blood volume | 8-10 | 7 |
| Intracellular water | 33 | 40 |
| Muscle mass | 20 | 50 |
| Fat | 12 | 18 |

Table 44-1. BODY COMPOSITION DURING GROWTH

| | |
|-------------------|--|
| 0-6 mo: | Maximum stress for parents, minimum for child because he or she is not old enough to be frightened of strangers or to remember unpleasant events. |
| 6 mo-4 yr: | Fear of separation at maximum, able to remember but not to understand previous hospital experiences. Hospitalization is followed by the most severe emotional upset and behavioral regression. |
| 4-6 yr: | Almost able to understand explanations. Accepts separation more easily. Concerned about integrity of body and may have wild misconceptions of surgical mutilation. |
| 6 yr-adolescence: | Tolerates separation well. Better able to understand explanations. May communicate fear of waking during surgery or "not waking up." |
| Teenagers: | "Physiologic schizophrenia." Developing sexuality. Need for conformity. Need for dignity. Fear of losing control, narcissism. Need for information. |

Table 44-2. SPECIFIC ANXIETIES OF PEDIATRIC PATIENTS

PREANESTHETIC EVALUATION AND PREPARATION

The preoperative visit and preparation of the child for surgery is more important than the choice of premedication. During this brief period, the anesthesiologist evaluates the medical condition of the child, integrating this information with the planned surgical procedures. The history should begin with a review of the perinatal period and seek information regarding history of a recent or intercurrent upper respiratory infection.⁸ The pediatric anesthesiologist should be aware of the increasing prevalence of reactive airway disease in pediatric patients; routine or "as-needed" use of nebulized bronchodilators occurs in up to 10% of pediatric patients, especially during high-risk times of the year. The possibility of loose teeth should be evaluated in school-age children. The anesthesiologist should recall that congenital anomalies frequently present in combination rather than as single entities. Other medical problems should be assessed and pediatric caregivers consulted as appropriate to ascertain that the child is in the best possible physiologic state before surgery.^{9,10} and ¹¹

In addition, the anesthesiologist must assess the psychological makeup of the child and family. He or she should establish rapport with the child and reassure the parents. In addition, the anesthesiologist must realize that the entire family is undergoing the psychological stress of the child's surgery, in addition to the feelings of guilt, helplessness, and inconvenience that even outpatient surgery may cause. Parental anxieties concerning both the anesthesia and surgical procedure are transmitted to even very young children. Both realistic concerns and misconceptions ("How do they put the eye back in its socket after they fix the muscles?") can be addressed during the preoperative interview.

Anesthesia and surgery represent an enormous time of stress for the child. The reasons for the stress are many, but include primarily (1) separation from parents, (2) strange surroundings, (3) painful procedures, (4) frightening procedures, and (5) survival. Coping with this stress and pain requires honest and consistent communication between the child and his or her parents, all physicians involved in the anesthesia and surgery, and all other staff involved in the child's care. The more information the parents and child have, the more easily they will cope with the period leading up to surgery and hospitalization. Presurgical programs, including written literature, videotapes, or hospital tours, have been shown to decrease preoperative anxiety in both the patient and the family.¹² Unfortunately, the stress caused by mask induction of anesthesia and postoperative care is not necessarily ameliorated by these interventions.

Many institutions have adopted policies that allow parents to participate actively in the anesthetic induction.^{13,14} and ¹⁵ Very young children benefit most from parental reassurance and a hypnotic voice, whereas older children and adolescents benefit from choices and ability to maintain some control over their environment.¹⁶ Although

many parents prefer to be with their child during the stressful and somewhat frightening time of anesthesia induction, not all parents and not all children benefit from this opportunity. In fact, one prospective, randomized study found that only certain personality types of children and parents had improvement in anxiety levels at the time of induction when parents were allowed to be present.¹⁷ Parents can become quite emotional if their child continues to struggle even in their presence, and again when the child lies quietly, not moving, at the end of induction. Parents who have been questioned after such an experience express the need for a great deal of education about what to expect and how they can help their child. In addition, institutions that have such a program emphasize the need for an escort to provide support (and be certain that the parent leaves the operating room or induction room). A consistent policy for age and medical status of children who are eligible to have parental accompaniment is also important, as is the recognition that the final decision always rests in the hands of the anesthesiologist responsible for the safe care of that child during that anesthetic. Other children, even preschoolers, may benefit from the opportunity to exhibit independence and bravery.

Preoperative sedation has been studied carefully with respect to effect on stress and postoperative behaviors. The most complete and recent information suggests that adequate preoperative sedation (midazolam $0.5 \text{ mg} \cdot \text{kg}^{-1}$ orally) decreases anxiety for parents and children in the immediate presurgical time frame and at the time of mask induction. Preoperative sedation has been found to be superior to parental presence for decreasing anxiety during induction of anesthesia and increasing cooperation with inhalation induction.¹⁸ In addition, children who are sedated before coming to the operating room may have fewer stress-related behavioral changes in the immediate postoperative time compared with groups of patients who receive no sedation. Almost all of these behaviors extinguish by 2 weeks after the operation, however, and much of this work was performed on first-time surgical patients. Further studies are needed to clarify the role of sedation with respect to postoperative behavior changes.¹⁹

Minimal Laboratory Evaluation

As with adults, preoperative laboratory evaluation is guided by the medical history.²⁰ Most children require no laboratory evaluation, and can be spared the psychological and physical pain of venipuncture. Determination of electrolytes or other chemistries should be limited to those children who have a clinical history consistent with a significant probability of abnormalities. Many institutions still require preoperative hematocrits for infants younger than 2 months of age, largely because the frequency of postoperative apnea and bradycardia in newborns has been shown to increase with anemia. Outside of this subgroup, there is little evidence that testing for hematocrit levels is helpful in the management of routine pediatric outpatients.²¹

There is controversy as to what constitutes the minimal acceptable hemoglobin value for elective pediatric surgery. The arbitrary value of $10 \text{ g} \cdot \text{dL}^{-1}$ (the nadir of hemoglobin in a healthy term infant) has been cited for infants older than 3 months, with higher values for the younger infants, depending on gestational age and general health status. Children whose hemoglobin values are less than this arbitrary standard should have the cause of their anemia investigated and corrected. A decision to proceed with anesthesia and surgery should include an assessment of the surgical procedure and the possibility of blood loss. Elective major surgery in which blood loss is anticipated, but transfusion is not usually required, should be postponed until the anemia is corrected. A decision to proceed with major surgery in which blood transfusion is planned, as well as brief minor surgery with little anticipated blood loss, might be appropriate in a child with iron-deficiency anemia.

Transfusion to raise a hemoglobin value to an arbitrary number to perform elective surgery is rarely justified. Even in premature infants, where apnea is correlated with anemia, appropriate supervision in the postoperative period and perioperative caffeine to treat apnea is preferred over the risks of transfusion.

Patients with sickle cell anemia or other hemoglobinopathies require special preoperative preparation. Debate continues as to the exact need for preoperative transfusion to a target hemoglobin level, or to a given percentage of hemoglobin A.²² This is reviewed in the standard texts mentioned previously.^{1,2,3,4,5 and 6}

Preoperative Fasting Period

Evidence is accumulating that children allowed clear fluids until 2 hours before surgery have similar gastric contents as those fasted for more than 4 hours.^{23,24} In fact, Coté et al²⁵ have demonstrated that up to 76% of children have sufficient volume of acid gastric contents at time of induction to cause chemical pneumonitis regardless of their fasting status. In spite of this, the best estimates of aspiration in pediatric patients place the incidence at a relatively rare 1 in 5000–10,000.²⁶

The exact length of time that a child must not eat or drink various foods and liquids before surgery has not been completely settled. A survey of pediatric anesthesia fellowship programs found significant variation in recommendations for restriction of breast feeding, formula feeding, and solids.²⁷ Various experts recommend 2- or 4-hour restriction of breast feeding, 4- or 6-hour restriction of formula feeding, and 6-hour or “after midnight” restrictions on solids. In spite of the lack of complete agreement among pediatric anesthesiologists, an American Academy of Pediatrics/American Society of Anesthesiologists task force has set recommendations that advise restriction of clear fluids for 2 hours, breast milk for 4 hours, formula or light meals for 6 hours, and fatty solid meals for 8 hours.

When counseling parents, recommendations need to be unambiguous. Clear liquids should be specifically listed and the time that they should stop should be noted. Many pediatric institutions have chosen to make the absolutely nothing by mouth (NPO) time 4 hours before scheduled surgery, although it is recognized that 2 hours is sufficient for gastric emptying of clear fluids. The longer fasting times allow for flexibility in patient scheduling; should an earlier surgical case be canceled, the next child can be safely moved up. Of course, gastric emptying after trauma is delayed in children as well as adults, and even a prolonged fast may not result in significant gastric emptying.

If these details of feeding and fasting are not clearly defined with stated hours, infants and children are likely to go without fluids for protracted times.^{28,29} Because young children do not understand the need for fasting, they should still be scheduled early in the day, or at least at a specified time to minimize their discomfort and that of the parents, who must keep them away from the water fountain. Anesthesiologists should be alert to delays and make sure that the child's fluid restriction is modified if a long delay is anticipated.

Preanesthetic Medications

Preanesthetic sedation is usually used to decrease apprehensiveness and stress for pediatric surgical patients and their families. Preoperative anxiolytics may also greatly improve cooperation with mask induction of anesthesia. The large number of studies in this area have produced approximately the same results: all sedatives are effective in a large percentage of patients if administered in a timely fashion. Other preanesthetic medications may be administered to prevent vagal reflexes or dry oral secretions in a child with an anticipated difficult airway. In some cases, premedications can serve to reduce gastric volume and acidity in a child with increased risk of vomiting.

Because of children's exaggerated psychological response to needles, other routes of administration are almost always preferable. Some children simply refuse to cooperate at all with preanesthetic medication, and for them the only sure method of administration is intramuscular or intravenous. Although it is desirable to provide analgesia for the child who is to undergo anesthesia and surgery, the respiratory “cost” of this state may sometimes be excessive, particularly in patients who have predisposing factors that increase the respiratory effects of sedation. An example of such a patient would be an obese 3-year-old with sleep apnea coming for a tonsillectomy. In addition, although a heavily sedated and unresponsive child will have no memory of the surgery, he or she may also undergo prolonged emergence from anesthesia and experience postoperative respiratory depression, especially after short surgical procedures.

Oral

By far the most popular oral premedication at this time is midazolam, in a dose of $0.5\text{--}0.75 \text{ mg} \cdot \text{kg}^{-1}$. Midazolam is first and foremost an anxiolytic; the child's eyes are usually open and he is aware of the environment, but nothing seems to disturb him. The effects of this medication peak approximately 30 minutes after administration, and last approximately 30 minutes.^{30,31} An oral syrup preparation is now available in a concentration of $2 \text{ mg} \cdot \text{mL}^{-1}$ that is palatable to all but the most uncooperative of patients.

Serious side effects after oral midazolam are uncommon. However, loss of balance and head control occurs in as many as 20% of children receiving oral midazolam. Consequently, strict adult supervision is necessary in children who receive this drug. Dysphoria has also been noted—in these patients, the drug has the opposite effect to that desired. The crying and disorientation that ensue usually abate with the drug effect.

As mentioned in the Preoperative Preparation section of this chapter, midazolam has been shown in one study to be superior to parental presence in decreasing perioperative stress for patients and families. It has been shown to increase cooperation with induction of anesthesia and has also been suggested to decrease the incidence of adverse behavioral changes that may occur in the 2 weeks after a surgical intervention.¹⁸ Further studies are required to confirm these findings.

Oral ketamine has also been used as a sedation medication. One study evaluated doses of $5\text{--}6 \text{ mg} \cdot \text{kg}^{-1}$ for children 1–6 years of age.³² Maximal sedation occurred within 20 minutes. Nystagmus occurred in 60% of children, and increased oral secretions in 33%, but there were no emergence phenomena in any child at these doses. Nausea and vomiting rates were slightly increased in children who received oral ketamine. Discharge from the day surgery unit was slightly delayed compared

with children sedated with midazolam. Although effective, this drug is probably best reserved for patients who would benefit from the tachycardia and increased blood pressure that usually accompany its administration.

Oral transmucosal fentanyl represents the first commercial attempt to deliver medication to children by the transmucosal oral route.³³ It is available in 200-, 300-, and 400-mg strengths; onset is 10–20 minutes, with a duration of action of 30 minutes. The current dosage recommendation is 10–15 mg · kg⁻¹. Intense supervision is required to ensure the medication is absorbed by the transmucosal route and not chewed and swallowed. In addition, difficulties with perioperative emesis and arterial oxygen desaturation have been reported.³⁴ One advantage of oral transmucosal fentanyl is its postoperative analgesic properties. The dose indicated previously offers similar pain control as that provided by 2 mg · kg⁻¹ given iv. However, safe use of this medication does require more intensive nursing care than do the other oral sedatives commonly in use.

Nasal

Although this route of administration also bypasses the dreaded “shot,” any parent who has administered nose drops to a child recognizes that lack of cooperation may also defeat this mode of administration. Most clinicians have found this mode of drug administration no better than intramuscular injection, and consequently its use has never been widespread. Rapid absorption as well as avoidance of first-pass hepatic metabolism of medications are advantages of this route of administration. This route should be reserved for the rare patient who refuses oral medication and has a contraindication to intramuscular injection.

When required, midazolam (for intravenous use) can be administered undiluted (5 mg · ml⁻¹) by dropper or syringe to the nose in a dose of 0.2 mg · kg⁻¹. Clinical effects of midazolam are evident in 10 minutes, and these children are conscious but glassy-eyed, just as with oral administration.³⁵ Drawbacks of this form of administration are the intense stinging of nose drops on the nasal mucosa and the undisguised bitterness of the medication that reaches the oral cavity.

The use of sufentanil and other sedatives intranasally has largely been abandoned because of untoward side effects.

Rectal

Both methohexital and thiopental have been used in rectal formulations in a dose of 25 mg · kg⁻¹. Onset of sedation requires approximately 10 minutes. Respiratory depression and oxygen desaturation may occur because of variable absorption of the medication in the rectum. Care must be taken that the medication is not expelled immediately on placement. In spite of these drawbacks, there are a number of institutions that report a high success rate in infants and toddlers with this type of preoperative sedative.

Intramuscular

Parenteral administration of sedation may be the only alternative in a child who refuses to cooperate with other modalities. Injection should be accomplished with a very small gauge needle or a CO₂-powered needleless injection system. When done quickly, intramuscular injection can be less upsetting than the other modes of delivery mentioned previously.

Intramuscular midazolam in a dose of 0.3 mg · kg⁻¹ provides anxiolysis in 5–10 minutes and dissipates in 25–30 minutes.

Ketamine in an intramuscular dose of 3–4 mg · kg⁻¹ provides a quiet, breathing, yet minimally responsive patient in approximately 5 minutes. Analgesia for intravenous placement is more than adequate. Previous studies have shown that smaller doses of 2–3 mg · kg⁻¹ provide sedation without prolonging hospital stay even after brief procedures.³⁶

A combination of intramuscular morphine 0.05–0.1 mg · kg⁻¹, atropine 0.02 mg · kg⁻¹, and pentobarbital 4 mg · kg⁻¹ is still used in children presenting for repair of congenital heart disease in some institutions. Although mixtures such as this are effective in experienced hands, they also markedly increase the chance of medication errors and respiratory depression. The use of these combinations is no longer widespread.

ANESTHETIC AGENTS

The choices of anesthetic drugs for infants and children are not strikingly different from those for adults. There are few specific contraindications to any of the commonly used drugs on the basis of age alone. Selection of drugs and techniques should be based on the anesthesiologist's experiences, preferences, and skill. Nitrous oxide in combination with potent inhalation agents or intravenous drugs is frequently used to induce and maintain anesthesia in pediatric patients; muscle relaxants and local anesthetics are also common adjuncts to anesthesia.

Potent Inhalation Agents

Mask induction of general anesthesia is the most common induction technique in the United States. Although in general very safe, it can be complicated by breath-holding, laryngospasm, dysrhythmias, and distention of the stomach by anesthetic gases (both from crying and from difficulty in ventilation). Difficulty in maintaining a mask fit may also occur, particularly in a struggling infant.

Although very young infants may interpret the mask as a nipple and attempt to suck as they breathe, increasing the concentrations of anesthetic agents, toddlers and preschool children usually fight the claustrophobic feeling of a tight mask fit. Older children may be persuaded to assist in holding the mask if they have chosen this induction over a “shot.” Halothane and sevoflurane are the only agents available for reliable and safe inhaled induction of anesthesia. The incidence of bradycardia, hypotension, and cardiac arrest during inhalation induction of anesthesia is higher in infants younger than 1 year of age than in older children and adults.³⁷ This greater propensity for untoward events from potent inhalational agents may be attributed to age-related differences in uptake, anesthetic requirements, and sensitivity of the cardiovascular system.³⁸ Uptake of inhalational anesthetics is faster in infants and small children than in adults because of the much greater ratio of alveolar ventilation to functional residual capacity and the altered distribution of cardiac output. The high inspired concentrations (overpressure) used early in induction can lead to very high tissue concentrations of anesthetic early in induction and result in severe cardiac depression.³⁹ The incidence of severe myocardial depression is similar with equipotent concentrations of both halothane and sevoflurane.^{40,41} Mask anesthesia induction in this age group must be accompanied by vigilant monitoring of blood pressure and pulse. Early administration of muscle relaxants to facilitate intubation in young infants may be more prudent than attempting endotracheal intubation under deep volatile anesthesia alone.

Although intracardiac shunts can, in theory, alter the uptake of anesthetic agents and affect the speed of induction, this is rarely clinically evident. A right-to-left shunt slows the induction of anesthesia because anesthetic concentration in the arterial blood increases more slowly. A left-to-right shunt should have the opposite effect; volatile agent induction is speeded up because the rate of anesthetic transfer from the lungs to the arterial blood is increased. In practice, decreased delivery of anesthetic to the target tissues largely negates the increased uptake.

The minimum alveolar concentration (MAC) of anesthetic required in pediatric patients differs with age, usually in an inverse relationship (Fig. 44-1). Two- to 3-month-old infants actually have the highest anesthetic requirements.

Figure 44-1. The minimum alveolar concentration (MAC) of isoflurane and postconceptual age. (Data from Le Dez KM, Lerman J: The minimum alveolar concentration

[MAC] of isoflurane in preterm neonates. *Anesthesiology* 67:301, 1987.)

Halothane has a long history of efficacy as an inhaled agent for pediatric anesthesia. It has the least noxious smell of the older agents and is very well accepted by most patients. In terms of emergence characteristics (in spite of a higher blood–gas partition coefficient), studies of time to awakening have shown little clinical difference between halothane and isoflurane.⁴² Although there has been some concern regarding sensitization of the myocardium to catecholamines, there is little problem in the absence of hypercarbia or light anesthesia.⁴³ Up to 10 mg · kg⁻¹ of epinephrine may be used with minimal risk of cardiac dysrhythmia in normocarbic pediatric patients.

Halothane can cause myocardial depression. This effect is exaggerated in young children, and in those who are relatively hypovolemic. Addition of muscle relaxants to a lighter halothane anesthetic (in conjunction with regional anesthetic techniques or opioids) can ameliorate this effect.

Isoflurane has a long track record as a safe and efficacious agent for maintenance of anesthesia in infants and children. Like halothane, it decreases blood pressure in pediatric patients. Although the myocardial depression in children may be less than that caused by halothane in equipotent doses, isoflurane reduces peripheral vascular resistance, whereas halothane does not. (In neonates, equal myocardial depression has been demonstrated with both drugs.⁴⁴) The major disadvantage of isoflurane is its pungent odor and high incidence of laryngospasm when this agent is used for inhaled induction of anesthesia. It should not be used for inhaled induction of anesthesia.

Desflurane has also been used as a maintenance anesthetic in pediatric patients of all ages. Unfortunately, an unacceptable incidence of coughing, increased secretions, and laryngospasm preclude its use as a mask induction agent.⁴⁵ Although desflurane appears to be associated with faster initial awakening when used as a maintenance anesthetic agent in pediatric patients, studies have shown no difference between halothane and desflurane in time to discharge after ambulatory surgery.⁴⁶

Sevoflurane is now well established as an excellent choice for inhaled induction of anesthesia in pediatric patients. Its low blood-gas solubility allows rapid induction and emergence from anesthesia. There appears to be a relatively low level of myocardial depression even when given at maximum vaporizer output for induction of anesthesia. Numerous studies have documented a decreased incidence of dysrhythmias compared with halothane. However, some confusion is apparent in studies citing sevoflurane's superiority over other potent inhalational agents; in many studies, higher MACs of halothane are compared with lower MACs of sevoflurane.^{40,41}

The nonpungent smell of sevoflurane allows smooth mask induction.^{47,48} Its safety and efficacy have been well established in hundreds of studies from around the world. In spite of its excellent clinical track record, concerns about the possible accumulation of toxic metabolites in a rebreathing circuit at low fresh gas flows remain to be worked out; at this time, flows of 2 l · min⁻¹ or greater are recommended. Sevoflurane is also relatively expensive compared with the other inhalation agents. In addition, the one advantage of any agent with low solubility (*i.e.*, rapid awakening) is accompanied by a high rate of postoperative excitement.^{49,50} Close attention to postoperative analgesia is imperative when either desflurane or sevoflurane is used.

Intravenous Agents Sedative–Hypnotics

Sedative–hypnotic medications are often used after intravenous placement in pediatric patients (after mask induction) to facilitate deepening of anesthesia. Older children frequently undergo intravenous induction rather than mask inhalational anesthesia induction. Application of EMLA (eutectic mixture of local anesthetics) cream or iontophoresis of lidocaine can increase cooperation and patient comfort during venous cannulation, particularly in children who must undergo frequent needle procedures.^{51,52} Propofol, thiopental, methohexital, and ketamine have been used extensively for anesthetic induction in pediatric patients; there is much less experience with etomidate. Children usually require larger doses of these drugs (on a per kilogram basis) to achieve obtundation than adults. Pediatric patients receiving antiseizure medications require even larger doses than their nonmedicated counterparts to achieve the same effect.

Propofol's chemistry and pharmacokinetics are reviewed elsewhere in this text. Induction doses of 2.5–3 mg · kg⁻¹ are required in children younger than 2 years of age, whereas older children need doses of 2.0–2.5 mg · kg⁻¹.⁵³ The major drawback with use of this drug (aside from the requirement for intravenous access) is pain on administration. This pain is enhanced if the drug is injected into a small vein. The injection of intravenous lidocaine 0.2–1 mg · kg⁻¹ immediately before propofol injection can reduce this pain, as can administration through a small-gauge (22–27) catheter in a large antecubital vein. As in adults, a modest reduction in systolic blood pressure usually accompanies bolus administration. Propofol may be used for induction or maintenance of anesthesia. When used for maintenance of anesthesia (150–200 mg · kg⁻¹ · min⁻¹), propofol is associated with decreased postoperative vomiting.⁵³ In addition, propofol infusions can be very useful for sedation during magnetic resonance imaging as well as other minimally invasive procedures where patient cooperation is essential.⁵⁴

Opioids

Fentanyl 1 mg · kg⁻¹ or morphine 0.05–0.1 mg · kg⁻¹ are often used as adjuncts to nitrous oxide–volatile agent anesthetics. Sufentanil 1–2 mg · kg⁻¹ or alfentanil 50–100 mg · kg⁻¹ have also been successfully used in pediatric patients. In addition to blunting hemodynamic responses to intubation and decreasing required MAC for inhaled agents, these doses of fentanyl and morphine also provide postoperative analgesia. The ultra–short-acting opioid remifentanil has been successfully used in children for both general anesthesia and sedation.⁵⁵ No postoperative analgesia is provided, and further experience is required to prove its cost effectiveness and safety.

The issue of sensitivity to the respiratory depressant effects of opioids and at what age it decreases has yet to be resolved. It is apparent that altered pharmacokinetics and immaturity of the blood–brain barrier may alter disposition of these drugs in very young children. Morphine is the least lipophilic of the opioid class; a greater proportion of any blood concentration may be able to cross the immature blood–brain barrier of the neonate or young infant compared with adults. Therefore, this medication should be administered with caution in infants younger than 6 months of age.

Bradycardia and chest wall rigidity are two other potential difficulties associated with opioid anesthesia. Early administration of a vagolytic agent or muscle relaxant should be considered in all infants when using these medications.

Muscle Relaxants

Succinylcholine has a long history of use in children. Since 1990, the drug has received much attention because of the severity of its possible complications.⁵⁶ Reports of rhabdomyolysis, hyperkalemia, masseter spasm, and malignant hyperthermia have caused the U.S. Food and Drug Administration to label this drug relatively contraindicated in pediatric patients.

The hydrophilic nature of succinylcholine and its rapid redistribution into the extracellular fluid volume mandate higher doses in infants (2 mg · kg⁻¹) than in older patients. Optimal intubating conditions are achieved within 1 minute when administered iv. Reliable muscle relaxation is also achieved within 1–2 minutes after intramuscular administration of 4–5 mg · kg⁻¹; this route may be life saving if laryngospasm occurs before establishment of intravenous access.

Atropine is frequently administered before or with succinylcholine to prevent potential associated dysrhythmias such as marked bradycardia or sinus arrest, especially with repeat dosing. Although both of these cardiac dysrhythmias may occur at any age, they are more frequent in young pediatric patients.

Succinylcholine administration has also been associated with spasm of the masseter muscles. There is an association of masseter spasm with malignant hyperthermia, and some debate remains as to the appropriate action when masseter spasm occurs.⁵⁷ At the very least, extreme vigilance for signs of malignant hyperthermia is warranted whenever masseter spasm occurs. Malignant hyperthermia is evidenced by high end-tidal carbon dioxide along with tachycardia and hypertension. Treatment with cooling measures and dantrolene must be initiated immediately to avoid serious morbidity and mortality.

Although malignant hyperthermia remains the most dreaded consequence of succinylcholine administration, another life-threatening complication has been reported.⁵⁸ Succinylcholine-induced hyperkalemic cardiac arrest has been reported in children with previously undiagnosed myopathies. Hyperkalemic cardiac arrest is heralded by tall, peaked T waves on the electrocardiogram, proceeding swiftly to bizarre, wide-complex tachydysrhythmias, ventricular tachycardia, and possible ventricular fibrillation. In addition to immediate cardiopulmonary resuscitation efforts, calcium and bicarbonate administration can be life saving in this situation.

In spite of the aforementioned catastrophes, airway-related complications are a far more frequent cause of serious morbidity in pediatric patients undergoing

anesthesia. Although use of succinylcholine should probably be limited to patients with a full stomach or laryngospasm, it remains the drug of choice when rapid onset of muscle relaxation is essential.

All of the nondepolarizing muscle relaxants used in adults are effective for pediatric patients as well. Neonates have a significantly larger volume of distribution for these drugs than older children and adults.⁵⁹ In addition, infants appear relatively sensitive to nondepolarizing muscle relaxants. The recommended effective doses for nondepolarizing muscle relaxants (reviewed elsewhere in this text) are similar in children and adults, but the duration of action tends to be slightly longer in pediatric patients. Selection of muscle relaxant should be done with an understanding of side effects and desired duration of effect. Rocuronium has the fastest onset of action in this class (60–90 seconds for a $1 \text{ mg} \cdot \text{kg}^{-1}$ dose); however, the variability of onset time in pediatric patients has left its use as a reliable rapid-sequence drug uncertain. Although intramuscular administration of rocuronium provides rapid onset of muscle relaxation, intubating conditions are inadequate.⁶⁰ Thus, succinylcholine remains the only reliable intramuscular muscle relaxant.

The new, rapid-onset agent rapacuronium is being evaluated in children. Early reports indicate that the same profiles of hemodynamic stability and rapid onset noted in adults are evident in pediatric patients. Higher doses administered intramuscularly provided optimum intubating conditions much less rapidly than succinylcholine, although faster than rocuronium.⁶¹

Antagonism of neuromuscular blockade should be carefully considered in all neonates and small infants, even if they have recovered clinically. Any increase in the work of breathing may cause fatigue and respiratory failure, particularly if concomitant opioid administration occurs. In general, if an infant or child can vigorously flex at the hips, adequate muscle strength is present for spontaneous respiration.

Antinausea Medications

Nausea and vomiting are among the most frequent causes for unanticipated hospital admission in pediatric ambulatory surgery patients. This is a particular problem in children undergoing tonsillectomy, strabismus surgery, or orchiopexy.

The same medications have been shown to be effective in children as in adults. Droperidol in doses of $20\text{--}70 \text{ mg} \cdot \text{kg}^{-1}$ has been successfully used; however, some studies report a delay in discharge at higher doses.⁶² Metoclopramide has also been used in doses of $0.15 \text{ mg} \cdot \text{kg}^{-1}$, whereas ondansetron at doses of $0.05\text{--}0.15 \text{ mg} \cdot \text{kg}^{-1}$ has also proven useful.⁶³ Use of propofol as a *primary* anesthetic decreases nausea and vomiting after surgeries associated with a high rate of nausea; use of propofol solely as an induction agent does not decrease nausea and vomiting.⁶⁴ Many studies have demonstrated that the use of high doses of dexamethasone decreases nausea and vomiting after tonsillectomy and other procedures.^{65,66}

What is lacking in pediatric, as in adult patients, is a clear cost–benefit analysis showing a hierarchy of use of these various medications as either prophylactic or rescue medications.⁶⁷ It is clear, however, that in addition to pharmacologic intervention, the simple policy of not requiring children to drink fluids before discharge itself decreases vomiting.⁶⁸ It is also clear that administration of even a single dose of opioid increases nausea and vomiting. Optimal use of nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and regional analgesia techniques can help avoid this annoying complication.⁶⁹

AIRWAY MANAGEMENT

Attention to appropriate management of the airway in pediatric patients remains the single most important aspect of pediatric anesthesia. Many pediatric anesthetics in older infants and children are conducted by face mask or (more often) laryngeal mask airway (LMA). Most pediatric anesthesiologists still believe that endotracheal intubation is particularly valuable in young infants and neonates. Mask ventilation is technically more difficult in young infants, and sizing/securing an LMA can be uncertain. In addition, these infants are more sensitive to the myocardial depressant effects of volatile anesthetics and often benefit from the use of muscle relaxants as part of the anesthetic technique.

Laryngeal mask airways are available in sizes for all patients, including newborns.⁷⁰ Their use has become ubiquitous in outpatient pediatric anesthesia. The LMA is now a standard airway for lower extremity and genito-urinary surgery. More recently, it has been incorporated into tonsillectomy and adenoidectomy procedures as well as eye muscle surgery.^{71,72} In addition, the LMA has proven useful in assisting airway management in infants and children with difficult airways, particularly those for whom conventional mask ventilation may be difficult.⁷³ As in older patients, the use of LMAs is not without problems; oxygen desaturation and difficulty in placement as well as aspiration around the device can occur.

Tracheal intubation in infants and children is not more difficult than in the adult, but the anesthesiologist must be familiar with the anatomic differences of the pediatric airway as well as the specialized equipment required. Trauma can be minimized by gentle airway manipulation at a sufficiently deep plane of anesthesia or after adequate muscle relaxation. The most common morbidity associated with endotracheal intubation (postextubation croup) has been associated with tight endotracheal tube fit. An air leak at $20\text{--}25 \text{ cm H}_2\text{O}$ pressure or lower has been shown to decrease the risk of postextubation croup; use of a cuffed endotracheal tube usually requires a half-size decrease in tube diameter to provide the same leak as an uncuffed tube, but its use is by no means contraindicated.

Several formulas have been used for endotracheal tube selection; for children older than 1 year of age, $(\text{age}/4) + 4.5$, or French size $+ 18/4$ are two of the more popular formulas. Appropriate size has also been correlated with the tip of the child's fifth finger. It is important to have endotracheal tube sizes above and below the estimated size, and to begin with the smaller tube if an estimated size falls between available tubes. If an air leak is present at too low a pressure, replacement of a smaller tube with one a half-size larger causes less trauma than the reverse.

PEDIATRIC BREATHING CIRCUITS

Much has been written about the advantages and disadvantages of various anesthesia circuits for use in pediatric patients (see [Chapter 22](#)). Pediatric circuit design has been directed to the physiology of the neonate and ways of reducing the work of breathing while preventing rebreathing. Nonrebreathing circuits minimize the work of breathing because they have no valves to be opened by the patient's respiratory effort. In addition, because the total volume of the circuit is less, the partial pressure of inhaled agent increases faster. Compression and compliance volumes are also decreased compared with a standard breathing circuit.

A number of combinations of the simple T-piece tubing, reservoir bag, and sites of fresh gas entry and overflow are possible. Mapleson classified the various combinations into five types ([Fig. 44-2](#)). The Jackson Rees modification is functionally identical to the Mapleson D, as are coaxial systems. Carbon dioxide is removed most effectively in the D configuration when controlled ventilation is used, whereas spontaneous ventilation is most effective in the A system.

Figure 44-2. Mapleson classification (A–E) of some rebreathing systems. V_{FG} is the fresh gas flow. (From Mushin WW, Jones PL: *Physics for the Anaesthetist*, 4th ed, p 375. Boston, Blackwell Scientific, 1987.)

Circle breathing systems can also be used very effectively in infants and children. Newer anesthesia machines use valves with much less resistance than older models. In addition, most neonates and small infants (for whom resistance would be the biggest problem) are ventilated mechanically during surgery, making work of breathing a nonissue. Dead space in these systems is no more than that of the Mapleson circuits.^{74,75}

MONITORING

Monitoring decisions for pediatric patients are similar to those in adults. The pediatric patient should be monitored continuously with precordial or esophageal stethoscope. This simple device allows the anesthesiologist to detect changes in the rate, quality, and intensity of the heart sounds, which is helpful in evaluating the depth of anesthesia when potent inhalational agents are used. Pulse oximetry, capnometry, blood pressure (measured noninvasively with appropriately sized cuffs), temperature, and electrocardiogram should also be monitored routinely in children as in adults. More invasive or sophisticated monitoring should be used in appropriate circumstances.

INTRAVENOUS FLUID THERAPY

Fluid therapy is divided into three portions: deficit, maintenance, and third-space/blood replacement. Fortunately, modern fasting guidelines have greatly reduced the fluid deficit that pediatric surgical patients must replace. It is, however, important to elicit when the child last took fluid, and an estimate of how much the child drank.

An understanding of intravenous fluid management in the pediatric patient must consider the high metabolic demands and the high ratio of body surface area to weight that children have.⁷⁶ The basis for calculating maintenance fluid need derives from the fact that daily fluid requirements depend directly on metabolic demand; 100 ml of water is required for each 100 calories of expended energy. Relating this to weight produces the hourly fluid requirements, as seen in [Table 44-3](#).

| Weight (kg) | Hourly Fluid (ml) | 24-hr Fluid (ml) |
|-------------|---|---|
| <10 | 4 ml · kg ⁻¹ | 100 ml · kg ⁻¹ |
| 11-20 | 40 ml + 2 ml · kg ⁻¹ > 10 kg | 1000 ml + 50 ml · kg ⁻¹ > 10 |
| >20 | 60 ml + 1 ml · kg ⁻¹ > 20 kg | 1500 ml + 20 ml · kg ⁻¹ > 20 |

Table 44-3. MAINTENANCE FLUID REQUIREMENTS FOR PEDIATRIC PATIENTS (LEAN BODY MASS)

There is a trend to provide maintenance fluids, as well as deficit fluids with a balanced salt solution, with or without glucose. The optimum fluid to avoid hypoglycemia and hyperglycemia is dextrose 2.5% in lactated Ringer's solution; however, this fluid is not commercially available.²⁸ Even though symptomatic hypoglycemia is very rare in children beyond the infant age, it is important to monitor blood glucose if it is not included in the intravenous therapy for infants. Another approach might be to provide 5% dextrose in 0.45% normal saline (D₅ 0.45 NS) for maintenance, piggybacked into a balanced salt solution for the deficit and third-space fluid. This double-iv fluid system may be quite costly because it does require a second intravenous administration setup.

The fluid deficit incurred during fasting should be replaced during anesthesia. Vasodilation from anesthetic agents may cause hypotension, even in patients who are not significantly hypovolemic. Aggressive intravenous hydration improves patient well-being. As mentioned earlier, aggressive hydration in the perioperative period combined with no requirement for oral intake before discharge decreases both postoperative nausea and vomiting and time to discharge home in pediatric outpatients.⁷⁷

Assuming a healthy infant is in water and electrolyte balance at the time oral feeding stopped, the fluid deficit at the start of anesthesia can be calculated by multiplying the infant's hourly maintenance fluid requirement by the number of hours since the last oral intake. This deficit may be replaced by giving half of the calculated volume during the first hour of anesthesia, and the other half over the next 2 hours in addition to intraoperative maintenance fluids. An alternative formula for short surgical cases is to administer 20 mg · kg⁻¹ of deficit fluid, plus 5 mg · kg⁻¹ of maintenance fluid in the first hour, followed by maintenance fluid for the rest of the brief procedure. It is important not to give large amounts of hypotonic solutions or dextrose in water (D₅W) because these hypotonic solutions can result in hyponatremia.⁷⁸

Replacement of third-space intraoperative losses and blood is administered in a fashion similar to that in adult patients. The magnitude of third-space loss varies with the surgical procedure, and is highest in infants undergoing intestinal surgery. Evaporative losses are also highest in these procedures. Estimated third-space loss during intra-abdominal surgery varies from 6 to 15 ml · kg⁻¹ · h⁻¹, whereas in intrathoracic surgery it is less (4–7 ml · kg⁻¹ · h⁻¹). Lactated Ringer's solution is frequently used to replace these third-space losses. In cases of massive volume replacement, some advocate the use of 5% albumin. The end point of fluid therapy is sustained adequate blood pressure, tissue perfusion, and urine volume (0.5–1 ml · kg⁻¹ · h⁻¹). Because baroreceptor reflexes are blunted by volatile anesthetic agents, pulse rate often is not an accurate reflection of decreased intravascular volume.

All blood loss should be replaced in some way. Accurate measurement and calculation of acceptable blood loss in the infant are vital to any replacement plan. The concept of the maximum allowable blood loss (MABL) takes into account the effects of patient age, weight, and starting hematocrit on blood volume. In general, blood volume is approximately 100–120 ml · kg⁻¹ for the preterm infant, 90 ml · kg⁻¹ for the term infant, 80 ml · kg⁻¹ for the child 3–12 months of age, and 70 ml · kg⁻¹ for the patient older than 1 year. These estimates of blood volume can be used in calculating the individual patient's blood volume by multiplying the child's weight by the estimated blood volume (EBV) per kilogram:

$$\text{MABL} = \frac{\text{EBV} \times (\text{starting hematocrit} - \text{target hematocrit})}{\text{Starting hematocrit}}$$

Therefore, if an infant weighs 6 kg and has a starting hematocrit of 32%, and if clinical judgment estimates the desired postoperative hematocrit to be 25%, the calculation would be:

$$\text{MABL} = \frac{(6 \times 90) \times (32 - 25)}{32} = \frac{540 \times 7}{32} = 118 \text{ ml}$$

This MABL would be replaced with 3 ml of lactated Ringer's per milliliter of blood loss (118 ÷ 3 = 354 ml). If blood loss remains less than MABL, no further blood loss is anticipated in the perioperative period, and hemodynamics remain stable, there is no need for blood transfusion. If significant perioperative blood loss occurs or is anticipated, discussion of potential transfusion needs with the surgeon is important.

As mentioned earlier, the incidence of apnea is higher in neonates and premature infants with hematocrits below 30%. A discussion with the surgeon and neonatologist may be helpful regarding transfusion management for surgical procedures for which significant perioperative blood loss is anticipated in these tiny patients.

Packed red blood cells have a hematocrit between 55 and 65%. On the average, 1 ml · kg⁻¹ of packed red blood cells increases the hematocrit by 1.5%. Units of blood can be subdivided into pediatric packs of 50–100 ml; thus, the remainder of a single unit is not wasted.

Rapid administration of citrated blood products can result in hypocalcemia as well as hypothermia. Fresh frozen plasma contains the greatest amount of citrate per unit volume of any blood product; rapid administration of fresh frozen plasma causes the greatest decrease in ionized calcium. Although under most circumstances, mobilization of calcium and hepatic metabolism of citrate are sufficiently rapid to prevent precipitous decreases in ionized calcium, infants have smaller stores of calcium. Infusion of fresh frozen plasma at a rate of 1–2.5 ml · kg⁻¹ · min⁻¹ may be associated with transient decreases in ionized calcium and decreased arterial blood pressure.

POSTANESTHETIC CARE

Monitoring

Continued monitoring of vital signs is important in infants and children, just as in adults. Pulse oximetry, pulse rate, and noninvasive blood pressure measurement should continue in the postanesthesia care unit, just as in older patients. Administration of supplemental oxygen may be guided by pulse oximetry.

Analgesia

It is the responsibility of the adult to provide analgesia, not the responsibility of the child to request pain relief. Pain assessment in pediatric patients is complicated by children's changing but relatively limited cognitive ability to understand measurement instructions or to articulate descriptions of their pain.⁷⁹ Children's responses are also affected by their developing behavioral repertoire and their constantly changing psychology.

Children older than 4–6 years of age can self-report pain. Younger children are usually assessed using a behavioral or physiologic–behavioral scale. Pain in children is much more difficult to assess than in adults because discrimination between pain and distress may be very challenging, particularly in the younger pediatric patient. Selecting a consistent means of pain assessment, performing that assessment at regular intervals, intervening, and reassessing are probably more important than which tool is selected. The prevailing philosophy among pediatric anesthesiologists is as follows: if I were having the procedure/surgery that this child is undergoing, would I require pain medication? If the answer is yes, the child is assessed, pain medication is administered, and a reassessment is made. If the reassessment shows a decrease of pain behaviors, pain management is considered successful, and continued evaluations are planned. If pain behaviors persist, the child receives additional pain treatment.

In addition, it is recognized that the emotional component of pain is very strong in children. Nonpharmacologic methods of pain management are also important. Although the most important of these is minimal separation from parents, other methods such as reassurance, cuddling, stroking, and distraction should also be used.

Nonopioid analgesics, usually acetaminophen or an NSAID, act at peripheral sites of injury by inhibiting prostaglandin synthesis and decreasing activation of primary afferent nerve injuries. These analgesics are useful for the treatment of mild to moderate discomfort (such as in many ambulatory procedures). When given in appropriate doses, all of these medications reduce the need for opioids in more severe pain conditions by approximately 30%.

The most common oral analgesic used in pediatric patients continues to be acetaminophen. This medication has been shown to be safe and efficacious in neonates as well as older children, with similar pharmacodynamics and pharmacokinetics in all but the youngest age groups.⁸⁰ Doses of 15 mg · kg⁻¹ orally every 4 hours or 30–40 mg · kg⁻¹ rectally as a loading dose followed by 15–20 mg · kg⁻¹ every 6 hours, with a maximum dose of 90 mg · 24 h⁻¹, produce therapeutic plasma levels with good analgesia.⁸¹ Acetaminophen should be administered only for a few consecutive days to reduce the risk of hepatic toxicity. Although rectal administration is less convenient and absorption more erratic than oral doses, acetaminophen suppositories can be inserted after induction of anesthesia to achieve effective blood levels in approximately 90 minutes.

Ketorolac has been shown to be an effective and safe analgesic for pediatric patients.⁸² Because a child often denies pain rather than submit to an intramuscular injection, intravenous administration of ketorolac has become very popular—in spite of the fact that it is an off-label use of the drug. Intramuscular doses of 0.75 mg · kg⁻¹ provide highly effective postoperative analgesia, as does an intravenous dose of 1 mg · kg⁻¹ as a loading dose, with 0.5 mg · kg⁻¹ administered every 6 hours thereafter.

As with other NSAIDs, ketorolac should be avoided in patients with pre-existing nephropathy or bleeding diathesis. Attention to fluid balance is also important; acute renal failure can occur with the use of NSAIDs in dehydrated patients after even one dose. Gastritis does not appear to be a problem. Although the bleeding time is not increased after administration of this drug, there is an increasing tendency to avoid its administration in surgical procedures that place a large stress on platelet and clotting mechanisms, such as tonsillectomy and adenoidectomy.

Ibuprofen is the most popular NSAID given orally to children. It comes in several palatable preparations. When given in the recommended oral dose of 10 mg · kg⁻¹ it has similar analgesic effects as acetaminophen or ketorolac. Gastrointestinal side effects are uncommon.

Codeine can be administered orally or parenterally, and provides effective control of mild to moderate postoperative pain. The bioavailability of codeine after oral administration is approximately 60%. Orally administered codeine (0.5–1 mg · kg⁻¹) is often combined with acetaminophen (10 mg · kg⁻¹). This combination reduces the overall codeine requirement, thus limiting dose-dependent side effects. Although available, this medication is rarely used in its intravenous form because it has no advantage over morphine, and may be associated with a higher incidence of nausea and vomiting. Oxycodone (0.2 mg · kg⁻¹) is available only as a tablet, and is also often combined with acetaminophen or an NSAID. This agent appears to cause less nausea than codeine at equipotent doses.

As mentioned in the Opioids section of this chapter, all of the intravenous opioids used in adult patients can be successfully used in the pain management of children. Doses need to be reduced for neonates and infants younger than 4–6 months of age. Patient-controlled analgesia with opioids is used very effectively in children. The developmental level of the child must be considered, but most 5-year-olds and almost all 6-year-olds can be taught to use patient-controlled analgesia for postoperative pain control.

Regional anesthetic techniques have been shown to be particularly useful in pediatric ambulatory surgery procedures. They are most often used as adjuncts to general anesthesia, decreasing volatile agent requirement and providing postoperative analgesia. Simple techniques such as ilioinguinal–iliohypogastric nerve block, ring block of the penis, or caudal block can be very useful for common pediatric surgical procedures.^{82,83,84} and ⁸⁵ Direct local infiltration of surgical wounds can also be very helpful. Strict attention must be paid to the dose of local anesthetic, the dose of epinephrine (if used), and the technique of administration. More sophisticated techniques such as continuous caudal or epidural analgesia using combinations of opioids and local anesthetics are useful for inpatients after thoracic, abdominal, or lower extremity procedures. These regional techniques usually are used in combination with general anesthesia (catheters are placed after the child is induced) and the regional block is maintained for postoperative pain control.⁸⁶ Meticulous attention to technique and close monitoring of the child must take place when these continuous infusions are used.

Subglottic Edema (Postextubation Croup)

Subglottic edema after extubation usually manifests itself by arrival in the postanesthesia care unit, and if not, within 2 to 4 hours. In most cases, a “barky” cough and stertorous respirations are observed. With severe croup, there may be suprasternal retractions, tachypnea, labored respirations, and arterial oxygen desaturation.⁸⁷

Mild cases require little therapy other than high concentrations of humidified oxygen. Racemic epinephrine (0.5 ml of a 2% solution diluted to a volume of 2–4 ml) administered by nebulizer is the next step. If this treatment is used, the child should be observed for 4 hours before discharge so that an evaluation of respiratory status postepinephrine effect can be made. If a second treatment is required, the child should be admitted for overnight observation and treatment.

Even if racemic epinephrine is not used, if there is any doubt as to the child's fitness for discharge, admission is the prudent course. Although their efficacy is unproven, systemic steroids are often administered in severe cases of postextubation croup.

CONCLUSION

“Children are not just little adults.” However, most principles of adult anesthesia are also applicable in pediatric patients. A thorough understanding of the differences is crucial to the skilled administration of anesthesia to this challenging group of patients. The smaller the child, the less margin of reserve is present. The smile on the face of a child who is comfortable in her mother's arms in the postanesthesia care unit is one of the greatest rewards any practitioner can receive.

Advances in nutrition, public health, education, and social services have produced major changes in human longevity in industrialized societies. Life expectancy for adult males has increased by more than 30 years since the introduction of the term “geriatrics” at the beginning of the twentieth century.¹ Elderly patients account for 48% of all hospital care days in the United States. Currently, at least one of every four surgical patients is 65 years of age or older, and an even larger fraction is anticipated in the next two decades. Therefore, unless intentionally limited to pediatrics or obstetric patients, every anesthesiologist in contemporary practice must acquire expertise in geriatric medicine. The sections that follow define the current concepts of aging that are relevant to anesthetic practice. They discuss the distinction between aging and age-related disease and present strategies useful for perioperative assessment of the elderly patient, and they summarize practical aspects of anesthetic management and anticipating perioperative outcome in geriatric surgical patients.

CONCEPTS OF AGING AND GERIATRICS

Extreme variability of signs, symptoms, and physical presentation among older patients has long been recognized as an important characteristic of geriatric medicine. As they age, adults exhibit an increasingly varied array of physical responses to concurrent disease states which, in turn, reflect life-long exposure to environmental and socioeconomic conditions and to the accumulated stigmata of prior traumatic injuries and medical therapies. Prolonged longevity also enables complete expression of intrinsic genetic qualities in all their subtle physiologic manifestations. Discrete “biologic markers of aging” such as visual acuity or the racemization of structural amino acids in connective tissue have been of some value for highly specialized nonclinical applications such as the evaluation of “anti-aging” therapies administered to laboratory animals. Currently, however, there is no consensus as to when the “geriatric” era begins in human subjects or whether any single physiologic marker can identify a physiologically “elderly” patient. Therefore, establishing a rigid and finite chronological definition of the term “geriatric” has little medical value other than for administrative, actuarial, or epidemiologic applications. For clarity and consistency, however, the terms “elderly” and “geriatric” will be used synonymously within this chapter to describe human subjects who, by arbitrary convention, are about 65 years of age or older. Because clinical experience and large-scale outcome studies suggest that there may be some predictive value in subdividing elderly patients into chronological subgroups, the term “aged” will be used to describe individuals older than 80 years.

“Life-span” is an idealized, species-specific, relatively fixed biologic parameter that quantitates maximum attainable individual age under optimal conditions. Historical anecdote and contemporary demographic data suggest that human life span has, indeed, remained constant at about 110–115 years for the past 20 centuries.² In contrast, “life-expectancy” describes typical longevity under prevailing conditions in society. This has changed dramatically during different periods in history. Recently, advances in medical science and health care have improved life expectancy and have increased the relative “agedness” of voting populations in democratic societies to the point that the economics and politics of healthcare for the elderly have, for the first time, assumed roles of major importance.

Most studies of human aging are cross-sectional studies that measure physiologic parameters simultaneously in young and elderly subjects. Although straightforward in design and in execution, even a comprehensive cross-sectional approach may not identify patients with subtle preclinical manifestations of disease. In addition, cross-sectional experimental design cannot be controlled for cohort-specific factors such as nutritional and environmental history, for genetic background, or for prior exposure to infectious agents. Therefore, many changes now known to be due to age-related disease have been attributed erroneously to aging. The “young” and “old” patient groups being compared in cross-sectional studies often differ not only in age but also in terms of their overall physiologic, anatomic, and biochemical characteristics. Therefore, data from cross-sectional studies rarely permit unambiguous conclusions regarding the effect of age itself on a measured parameter.

Longitudinal studies of aging, in contrast, require that the investigator obtain repeated measurements in each individual subject over several decades. Each subject therefore generates his own “young adult” control value for comparison with subsequent measurements. If any of the subjects in a longitudinal study eventually manifest signs of age-related disease, their data points can be excluded from the study, thereby leaving behind a smaller but more homogeneous group of healthy elderly subjects. Although difficult and expensive to organize and maintain, long-term longitudinal studies have produced substantial amounts of extremely valuable data related to human aging.

Despite considerable efforts by many scientists, however, the mechanisms that control the aging process remain unknown. The impressive consistency of observed life span may not, as was once believed, necessarily imply a genetically or centrally coordinated, hypothalamic “biological clock” for each species. Instead, age-related decline in organ and tissue function may simply be the inevitable accumulation of nonspecific, degenerative phenomena such as ionizing radiation.³ Currently, there is also great interest in the role of declining mitochondrial bioenergetics as the underlying mechanism for deterioration of organ function. Throughout adulthood, increasing levels of oxygen-derived free radicals within the mitochondria appear to disrupt the structural and enzymatic machinery of oxidative phosphorylation.⁴ As the ability to scavenge these byproducts of aerobic metabolism declines, it creates a “vicious cycle of aging” within the mitochondria (Fig. 45-1). Viewed from this perspective, the unique life span demonstrated by each species could be explained as a stochastic interaction between genetically determined biochemical and physiologic attributes for each species and the destructive environmental factors that disorder biologic systems.

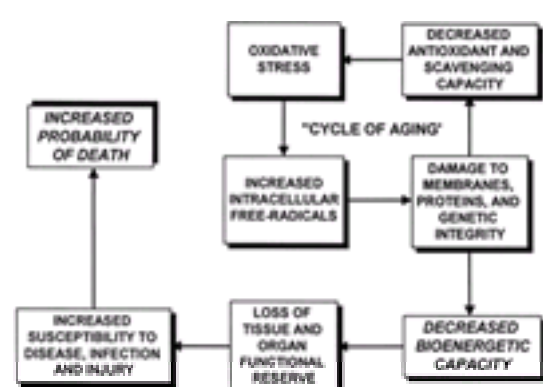

Figure 45-1. At a cellular level, there may be a self-sustaining “cycle of aging” within mitochondria in which oxidative stress damages the metabolic machinery needed to provide adequate bioenergetic capacity for full organ system functional reserve.

AGING AND ORGAN FUNCTION

For these reasons, contemporary definitions of aging are conceptual rather than quantitative. Aging is a universal and progressive physiologic phenomenon characterized by degenerative changes in both the structure and the function of organs and tissues. At one time, global age-related physiologic degeneration was depicted as linear decline of maximal function beginning in young adulthood and continuing inexorably downward thereafter. However, a more contemporary analysis describes nonlinear change in maximal organ function that first becomes apparent following the years that represent the peak of somatic maturation, in the fourth decade of human life (Fig. 45-2). Additional decrements of function during the middle adult years appear to be relatively subtle but subsequently become progressively more dramatic during the traditional years of geriatric senescence, the seventh decade of life and beyond. Elderly patients who maintain greater than average

functional capacities are considered “physiologically young.” When organ function declines at an earlier age than usual, or at a more rapid rate, elderly patients appear to be “physiologically old.”

Figure 45-2. Differences in the rate at which maximal organ system functions decline with increasing age, and, to a lesser extent, differences in initial functional levels explain the inevitable variability seen in geriatric patients commonly described as physiologically “younger” or “older” than average.

Nevertheless, the competence of integrated organ system function varies greatly from one elderly patient to the next, even in the absence of disease, and is significantly altered by activity level, social habits, diet, and genetic background. In healthy geriatric patients, however, maximum organ system function at all ages is greater than basal demand. The difference between maximal organ system capacity and basal function represents organ system functional reserve (Fig. 45-3). Organ system functional reserve is the “safety margin” of organ capacity available to meet, for example, the additional demands for cardiac output, carbon dioxide excretion, or protein synthesis imposed upon the patient by trauma or disease, or by surgery and convalescence. Cardiopulmonary functional reserve can be assessed clinically and quantified using various exercise or aerobic stress tests. It is generally assumed that the functional reserve of all organ systems is progressively and significantly reduced in elderly patients, although there are at present no techniques for assessment of hepatic, immune, or nervous system functional reserve. In fact, many gerontologists consider the increased susceptibility of elderly patients to stress- and disease-induced organ system decompensation to be a defining characteristic of physiologic aging. Consequently, preoperative testing in the elderly patient is most effective when it provides the anesthesiologist with a quantifiable assessment of organ system reserve and it is clinically directed according to symptoms and complaints referable to age-related disease and the erosion of physiologic homeostasis.

Figure 45-3. For any organ system “functional reserve” represents the difference between basal (minimal) and maximal organ system function. The age-related decline in functional reserve may not be clinically apparent until demands made upon the organ system are increased by stress, disease, polypharmacy, or surgical intervention.

CARDIOPULMONARY FUNCTION

Classic studies suggested that aging inevitably produces a progressive depression of cardiac output. This conclusion, however, is contradicted by more recent studies of fit and active elderly subjects in whom demand for cardiopulmonary function is maintained through daily exercise or even enhanced by aerobic training.⁵ In young and elderly adults alike, resting cardiac output appears to be determined largely by the metabolic demands of lean tissue mass, and maximal cardiac output responds to vigorous physical activity. Consequently, the modest decrease in resting cardiac index observed in most healthy elderly subjects is not evidence of degenerative cardiovascular change. Rather, it represents an appropriate integrated response to the reduced requirements for perfusion and metabolism that occur with age-related atrophy of skeletal muscle and the loss of tissue mass in major organs with high intrinsic metabolic rates.⁶ From the perspective of integrated cardiovascular function, exercise, and aerobic capacity, aging simply produces a progressively smaller “machine.”

Under conditions of submaximal demand, myocardial contractility as assessed by rates of myocardial shortening and ventricular pressure generation or ejection fraction appears to remain uncompromised by increasing age, at least until the eighth decade.⁷ Similarly, there is little evidence of significant change at a cellular level in the contractile proteins or in the enzymatic substrate required for energy production within the myocardial sarcomeres. Short-term increases in cardiac output are accomplished in the elderly patient at first by modest increases in heart rate, and then by increased left ventricular end-diastolic volumes and pressures that produce progressively larger stroke volumes (Fig. 45-4). However, because aging reduces both the inotropic and chronotropic responses to adrenergic stimulation and to β -agonists, maximal heart rate is age-limited, and unlike young adults, older adults exhibit little enhancement of ejection fraction under these conditions.

Figure 45-4. In healthy elderly subjects (*broken lines*), demand for increased cardiac output is met by significant increases in stroke volume (SV) and left ventricular end-diastolic volume (LVEDV) that compensate for reduced maximal heart rate. In contrast, high levels of cardiac output are achieved in younger subjects (*solid lines*) through large increases in heart rate and only modest enhancement of SV, the latter achieved through β -adrenoceptor-mediated inotropy that increases ejection fraction but actually reduces LVEDV.

The heart, unlike other major organs, does not atrophy significantly with age. Both heart size and myocardial tissue mass are increased in older adults. However, the aging left ventricle is thicker and less elastic than its younger counterpart, exhibiting symmetric hypertrophy and an increase in collagen cross linking in the myocardial cytoskeleton to which the myocytes are attached.⁸ The stiffer, less compliant ventricular and atrial myocardium of the aging heart therefore undergoes complete myocardial relaxation relatively late in diastole, and the contribution of passive ventricular filling, which occurs during the early phase of diastole, is significantly reduced (Fig. 45-5). The hemodynamic importance of diastolic dysfunction has been recognized only recently, but it is now clear that age-related diastolic dysfunction makes the elderly subject significantly more dependent upon the synchronous atrial contraction of sinus rhythm for complete ventricular filling at end-diastole.⁹ Therefore,

relatively small decreases in venous return such as those produced by positive-pressure ventilation, surgical hemorrhage, or venodilator drugs may significantly compromise stroke volume, especially when cardiac dysrhythmias are present.

Figure 45-5. Left ventricular (LV) cardiac pressure–volume loops for fit young (*solid line*) and elderly (*broken line*) subjects. Older subjects have a slightly higher end-diastolic ventricular volume (EDV) and larger stroke volume (SV) as well as slightly elevated intracavitary pressures throughout the cardiac cycle because of increased myocardial stiffness and delayed active relaxation during diastole.

Virtually all longitudinal studies of aging confirm the universal nature of progressive systolic arterial hypertension, a phenomenon due to fibrotic replacement of elastic tissues within the cardiovascular system. Age reduces the ability of the aorta and large arteries to store hydraulic energy, increasing vascular impedance to cardiac ejection and raising ventricular wall tensions and cardiac workload. These forces appear to explain the development of symmetric ventricular hypertrophy described above. Because vascular impedance is a frequency-dependent form of hydraulic resistance, increases in impedance to ejection of stroke volume can occur even when systemic vascular resistance (SVR) is unchanged.¹⁰ Increased vascular stiffness and loss of arterial cross-sectional area increase the reflection of arterial pressure waves within the arterial tree, producing the familiar “overshoot” characteristics of radial artery waveform tracings in geriatric patients as well as generating large discrepancies between blood pressure values obtained by invasive techniques and those measured by more traditional occlusive cuff techniques. In the absence of disease, however, neither intrinsic myocardial contractility nor integrated cardiovascular function actually limits cardiac output at rest or during moderate exercise. The heart increases its output to meet imposed metabolic demands as needed within the limits of its maximal capacity. Even sedentary geriatric subjects benefit dramatically from programmed increases in aerobic activity, and many aged individuals participate in strenuous athletic events such as marathon running events.

Age-related loss of tissue elasticity is ubiquitous. It occurs in the lung as well as in the cardiovascular system. In fact, loss of lung elastic recoil is a primary anatomic mechanism by which aging exerts deleterious effects on pulmonary gas exchange.¹¹ With increasing age, there is an increase in fibrous connective tissue within the lung parenchyma and progressive degeneration and cross-linking of lung elastin fibers. It remains unclear whether there is an actual decline in lung elastin content, however. Whatever the mechanism, elderly individuals experience virtually inevitable emphysema-like increases in lung compliance because lung elastic recoil declines. The patency of small airways, normally maintained by elastic recoil, may be compromised, moving closing capacity (CC) above functional residual capacity (FRC), the volume of the lung at rest.¹² However, calcification and stiffening of the costochondral joints of the thorax actually reduce chest wall compliance, so net pulmonary compliance is almost unchanged.¹³

Although aging produces only a minor progressive increase in FRC, vital capacity (VC) is significantly and progressively compromised¹⁴ as residual volume increases at the expense of inspiratory and expiratory reserve volumes (Fig. 45-6). The costochondral calcification that makes the thorax more rigid and decreases the compliance of the chest wall also increases the work of breathing in elderly subjects. Increased airway resistance associated with partial obstruction of small airways also produces a modest increase in the total work of breathing of elderly subjects. Although the strength and endurance of muscles of ventilation remain adequate for moderate demands,¹⁵ compromised ability to meet heavy ventilatory workloads predisposes the elderly patient to acute postoperative ventilatory failure.¹⁶

Figure 45-6. Total lung capacity, the sum of vital capacity (VC) and residual volume (RV), is reduced only modestly in older adults of either gender. VC, however, is markedly compromised by age-related increases in thoracic rigidity and loss of ventilatory muscle power. RV increases because intrinsic lung elastic recoil is progressively reduced.

These changes in the physical composition of the lung parenchyma also reduce the efficiency of gas exchange within the aging lung. Although, as in every organ system, variability is great, age-related decline in perioperative arterial oxygenation is significant and progressive. Breakdown of alveolar septae reduces total alveolar surface area, increasing both anatomic and alveolar dead space. Because these changes in the physical properties of the lungs are nonuniform, they severely disrupt the normal matching of ventilation and perfusion, increasing both physiologic shunting and dead space.¹⁷ Therefore, pulmonary dysfunction in older adults during general anesthesia is best described as diffuse ventilation–perfusion mismatch (Fig. 44-7) due to deterioration of alveolar architecture and anesthetic induced depression of active hypoxic pulmonary vasoconstriction. Consequently, virtually all surgical patients 70 years of age or older should receive supplemental oxygen perioperatively because they are at increased risk of hypoxemia following sedation, diagnostic procedures, or surgical intervention.

Figure 45-7. During general anesthesia, the efficiency of oxygenation decreases with age. Venous admixture, expressed as the percentage of cardiac output, rises significantly as both intrapulmonary shunting and relative ventilation/perfusion (\dot{V}/\dot{Q}) mismatch become more prevalent. (Data courtesy of Dr. G. Hedenstierna.)

In contrast, the moment-to-moment control of ventilation by neural structures and the ventilatory responses to changes in pH and respiratory gases appear to be essentially unchanged in healthy elderly subjects. However, the cardiovascular and the ventilatory stimulation normally mediated by homeostatic reflex mechanisms in

response to imposed hypoxia or hypercarbia are delayed in onset, and of considerably smaller magnitude, in geriatric patients.¹⁸ For reasons not completely understood, elderly subjects also experience a higher incidence of transient apnea and episodic respiration when given narcotics, and may be more sensitive to the respiratory depression produced by non-narcotic central nervous system depressant drugs such as the benzodiazepines.

Opioid-induced rigidity of the chest wall also occurs more frequently in older than in younger adults, although this may be a manifestation of opiate-induced nervous system toxicity. Like virtually all forms of sensory input in elderly subjects, the threshold stimulus magnitude needed for vocal cord closure is markedly elevated,¹⁹ increasing the risk of pulmonary injury due to aspiration of gastric contents in older patients, especially if level of consciousness is depressed. Consequently, geriatric surgical patients are clearly at greater risk of unrecognized respiratory failure in the typical postoperative setting of residual anesthetic depression and the use of opioids for pain management.

HEPATORENAL AND IMMUNE FUNCTION

In general, age is associated with loss of hepatic tissue mass and splanchnic blood flow and not a qualitative impairment of hepatocellular function. Hepatic enzyme activities are similar to those of young adults,²⁰ and “normal” values for plasma concentrations of transaminases and other hepatocyte-derived enzymes are unchanged in the elderly adults,²¹ although the bromsulphthalein (BSP) retention approaches the upper limit of the “normal” range by the seventh decade of life even in individuals who demonstrate no other evidence of hepatic dysfunction. Nevertheless, the overall functional capacity of the liver is largely determined by its size and blood flow, and age-related changes in hepatic and splanchnic anatomy are dramatic. Age-related loss of hepatic tissue mass is generally thought to be the primary explanation for the delayed biotransformation and prolonged clinical effects of narcotics and many other xenobiotics in geriatric subjects.²² Liver tissue mass declines about 40% by the age of 80 years, and hepatic blood flow is reduced proportionally.²³

Some clinical studies suggest that this organ system may undergo subtle physiologic changes that are both age- and gender-specific. For example, elderly women metabolize benzodiazepines at rates close to that of their younger counterparts, yet elderly men do not. Elderly men, but not women, frequently have significant reductions in the activity of the hepatically synthesized enzyme plasma cholinesterase.²⁴ Hepatic metabolism and drug biotransformation may also be unpredictably altered in this patient subpopulation because they are also likely to have sustained exposure to the polypharmacy of age-related chronic disease. For example, cimetidine, widely used in geriatric patients to relieve gastritis that occurs because of age-impaired secretion of protective gastric mucus, significantly depresses the hepatic biotransformation of benzodiazepines. Although liver blood flow remains relatively constant as a percentage of cardiac output and therefore provides adequate function to meet basal metabolic needs, the hepatic synthetic reserve needed for wound healing or response to sepsis may be inadequate, especially if associated with arterial hypotension, low cardiac output, hypothermia, or any form of direct hepatic injury.

Age-related tissue atrophy is also evident in anatomic and postmortem observations of the kidneys,²⁵ with 30% of renal tissue mass lost by the eighth decade. Total renal blood flow decreases almost 50%, a decline of about 10% per decade beginning in early adulthood (Fig. 45-8). Cellular attrition is especially marked in the renal cortex, although the extent of parenchymal loss is grossly masked by a reciprocal increase in renal fat and by a diffuse and generalized process of interstitial fibrosis. The effects of aging on the renal microarchitecture is dramatic. More than one-third of the glomeruli and their associated nephron tubular structures disappear in the elderly.²⁶ In 10–20% of those glomeruli that remain, sclerosis impairs effective filtration by producing tubular diverticuli and dysfunctional continuity between afferent and efferent glomerular arterioles.²⁷

Figure 45-8. Renal blood flow (solid line) declines more rapidly than does renal tissue mass (broken line) with increasing age. Glomerular filtration rate (not shown) falls somewhat more slowly than plasma flow because filtration fraction actually increases in some elderly individuals.

The renal cortex appears to be particularly sensitive to progressive reduction of tissue vascularity, with relative sparing of the renal medulla. Shifting of renal perfusion from cortex to medulla appears to produce a slight compensatory increase in filtration fraction in elderly subjects. Therefore, although both renal plasma flow and glomerular filtration rate (GFR) decline more rapidly than would be expected from the loss of renal tissue mass alone,²⁸ GFR decreases less rapidly than expected. Despite compromise of renal functional reserve, serum creatinine concentration usually remains within the normal range in elderly patients because their declining skeletal muscle mass generates a progressively smaller creatinine load. A lower level of basal renal function is therefore adequate to maintain metabolic equilibrium, and GFR is sufficient to avoid uremia and to maintain normal plasma osmolarity and electrolyte concentrations.²⁹

Elderly patients release large concentrations of antidiuretic hormone (ADH) in response to a hypertonic saline load, but water retention is still less efficient than that of young adults. The elderly also demonstrate a decreased maximal reabsorption rate for glucose as well as significant impairment of the response to aldosterone and the extent to which they conserve sodium. Excretion of a free water load is also markedly delayed. Diminished thirst, poor diet, and the use of diuretic agents to decrease age-related hypertension also predispose elderly surgical patients to intravascular and intracellular dehydration.³⁰ Geriatric surgical patients do not appear to require a unique fluid replacement protocol, but their renal functional reserve is usually inadequate to withstand gross disruptions of water and electrolyte balance. They may not respond promptly or appropriately to imposed contractions or expansions of intravascular volume, and they therefore require meticulous monitoring and management of fluid and electrolyte balance.

Even fit elderly subjects exhibit some general characteristics of decreased immune responsiveness. The quantitative age related change in thymic mass and progressive alteration of thymic cellular composition both play a central role in senescence of the immune system. Lymphocyte numbers remain within the range established as normal for young adults, yet older adults have decreased B- and T-cell lymphocyte activity and depressed serum titers of immunoglobulin E, depressed skin response to allergens, and compromise of delayed hypersensitivity.³¹ Aging appears to have little effect upon macrophage and other phagocytic activity, yet older adults are particularly predisposed to streptococcal pneumonia, meningitis, and septicemia.³² In fact, sepsis is second only to respiratory failure as a cause of morbidity and mortality in elderly trauma patients.³³

METABOLISM, BODY COMPOSITION, AND PHARMACOKINETICS

Aging, particularly in men, produces a progressive and generalized loss of skeletal muscle mass as well as atrophy of metabolically active areas in brain, liver, and kidney.³⁴ Reciprocal increases in the lipid fraction of total body mass are typical during the middle adult years but are extremely variable in magnitude. In general, changes in body composition reduce the basal metabolic requirements of aging patients by 10–15% compared with their young adult counterparts.³⁵ Reduction in body heat production and impairment of autonomically mediated thermoregulatory vasoconstriction³⁶ put the elderly surgical patient at increased risk for inadvertent intraoperative hypothermia. Intraoperative core temperature decreases at a rate twice as great as that observed in young adults under comparable conditions.³⁷ The time needed for spontaneous rewarming postoperatively also appears to increase in direct proportion to the patient's age.³⁸ Because skeletal muscle and liver normally provide storage for carbohydrates, aging is also associated with progressive impairment of the ability to handle a glucose challenge. However, because both the timing and the magnitude of insulin release itself appear to remain normal, age-related glucose intolerance may also reflect, at least in part, a progressive impairment of insulin function³⁹ or subtle antagonism of its effect on these target tissues.⁴⁰ In any case, iv fluid replacement using glucose-containing solutions should be limited to environments that permit frequent measurement of blood sugar levels in elderly patients.

From young adulthood on, most men initially gain about 12 kg of adipose tissue and lose about 8 kg of skeletal muscle mass, changes that may eventually result in the loss of 10–15% of their total body water (Fig. 45-9). The change in total body weight seen during and following the young adult years is biphasic, characterized by the middle-adult-year increases in adipose fraction and total body weight commonly described as “middle-aged spread.” However, in aged men, continuing loss of muscle and central organ atrophy eventually produce a significant decline in total body weight, often to levels less than those of young adulthood.⁴¹ In women, however, dehydration and bone loss due to osteoporosis are largely offset by increasing body fat, and total body weight usually returns to, but rarely below, young adult body

weight. Virtually all of the age-related changes in body water remain limited to intracellular compartments, with decrease in circulating blood volume usually restricted to the deconditioned elderly subject or to those with essential hypertension.⁴² Plasma volume, red cell mass, and extracellular fluid volumes are normally well maintained in nonhypertensive elderly individuals who maintain their habits of daily physical activity.

Figure 45-9. Age-related changes in body composition are gender specific. In women, total body mass remains constant because increases in body fat (*upper shaded segment*) offset bone loss (*middle segment*) and intracellular dehydration (*lower shaded segment*). In men, body mass declines despite maintenance of body lipid and skeletal tissue elements because accelerating loss of skeletal muscle and other components of lean tissue mass produces marked contraction of intracellular water (*lower shaded segment*).

These age-related changes in body composition are universal, progressive, and relatively irreversible, although the rate at which skeletal muscle mass is lost may be minimized by vigorous exercise, and the progressive increase in adipose tempered by changes in diet or by maintenance of high caloric expenditure. Nevertheless, many of these physiologic and anatomic changes reflect the unavoidable consequences of genetic predisposition and reduced testosterone, thyroid hormone, or other endogenous modulators of tissue metabolism at least as much as they reflect individual lifestyle and the social environment. Therefore, as aging increases the lipid fraction of body mass relative to the proportion of aqueous, well-perfused body tissues, it also enlarges the distribution volumes available to function as reservoirs for inhalational anesthetics, benzodiazepines, barbiturates, and other drug molecules that are preferentially soluble in lipid.⁴³ If iv drugs are administered in dosage determined by total body weight, the increased lipid fraction of total body weight seen in elderly subjects may delay elimination to a degree greater than would be expected solely from reduced rates of hepatic and renal drug clearance. Consequently, age-related changes in body composition have a significant impact on the elimination or beta-phase pharmacokinetic processes that occur after anesthesia,⁴⁴ although immediate recovery from anesthetic effects is predominantly determined by redistribution or alpha-phase parameters.

CENTRAL NERVOUS SYSTEM

Many age-related changes within the human brain and spinal cord are well described, yet their functional significance remains unclear. As in other organ systems, it is often difficult to distinguish between aging and age-related disease. Many aspects of “senile” neurologic dysfunction, in particular those with a neurohumoral basis, may eventually be recategorized as age-related diseases and no longer seen simply as the inevitable deterioration of an aging nervous system. Nevertheless, there are some unequivocal hallmarks of aging within this organ system. Aging reduces brain size. Average adult brain mass is about 20% less by the age of 80 years than respective values measured postmortem in young adults.⁴⁵ The fraction of intracranial volume occupied by brain tissue falls from 92% to 82% over the same time period, with the most rapid reduction in gray matter tissue mass and the greatest rate of compensatory increase in cerebrospinal fluid occurring after the sixth decade. Aging, in effect, produces a form of low-pressure hydrocephalus.⁴⁶ Most of this loss of nervous system tissue reflects attrition of neurons, particularly in the gray matter because there appears to be little atrophy of the supportive, non-neuronal glial cells that normally constitute almost half of total brain mass. Estimates of the average rate of neuronal cell death, 50,000 per day from an initial pool of about 10 billion, are a misleading generalization because neuronal loss is highly selective according to type and region, and the rate of neuronal loss also varies greatly at different ages and under different circumstances.⁴⁷

In general, the most metabolically active, highly specialized neuronal subpopulations, particularly those that synthesize neurotransmitters, appear to suffer the most severe degree of loss. Fully 30–50% of the neuronal population of the cerebral and cerebellar cortices, thalamus, locus ceruleus, and basal ganglia disappear in the aged subject. The residual neuropil also demonstrates a markedly simplified pattern of synaptic interconnection.⁴⁸ There are reduced intraneuronal stores of dopamine, noradrenaline, tyrosine, and serotonin, and a simultaneous increase in the activity of enzymes essential to the destruction of the neurotransmitters such as monoamine oxidase and catechol-*O*-methyltransferase.⁴⁹ The up-regulation or increase in number of neurotransmitter receptor sites that appear in young neural tissues in response to a reduction of neurotransmitter activity appears to be slow and incomplete in the aging brain.⁵⁰

In the healthy elderly individual, decreased cerebral blood flow (CBF) is a consequence, not a cause, of brain tissue atrophy. Total CBF falls in proportion to reduced brain tissue mass. Specific CBF in the gray matter, expressed per 100 g of brain tissue, declines 20–30% from the maximal values seen in the young adult, a rate that parallels the age-related decline in the neuronal density of cortical tissues. Nevertheless, the intrinsic mechanisms that couple regional cortical and subcortical perfusion to local variation of metabolic demands is maintained in older adults,⁵¹ and the blood–brain barrier is functionally intact. Age does not impair autoregulation of cerebrovascular resistance (CVR) in response to changes in arterial blood pressure, and the cerebral vasoconstrictor response to hyperventilation remains intact in the healthy geriatric patient.⁵² Therefore, the use of controlled hyperventilation to produce deliberate cerebral vasoconstriction should be appropriate for use in elderly neurosurgical patients, at least in those individuals without extensive cerebrovascular disease.

Despite the long-established bias that aging inevitably produces deterioration of mental function, most recent studies suggest that the most complex aspects of “crystallized intelligence” such as language skills, esthetics, and personality do not decline with increasing age. Even in aged individuals, general knowledge base, comprehension, and long-term memory are well maintained in active and fit older adults,⁵³ although there may be some unavoidable decline in short-term memory, visual and auditory reaction time, and other aspects of “fluid intelligence.”⁵⁴ It remains unclear whether those intellectual functions that require immediate processing or rapid retrieval of information suffer intrinsic deterioration or whether they are incidentally compromised by an age-related limitation of attention span. In general, however, across the entire range of adult life span, complex nervous system functions persist at levels sufficiently close to those seen in young adults that they are more dependent upon individual capabilities than upon age itself. Anatomic and functional redundancy within the central nervous system appear to compensate adequately for the attrition of cellular elements, reduction of neurotransmitter concentrations, and the simplification of neuronal interconnections within the neuropil that occur in the aging brain.

Some elderly patients with impaired cognition of uncertain etiology may have hypothalamic–pituitary–adrenal (HPA) dysregulation and elevated cortisol levels. Aging within the central nervous system leads to selective hippocampal cell loss. Neuronal attrition in the hippocampus produces symptoms of impaired cognition as well as activation of the HPA axis due to removal of chronic hippocampal suppression of HPA activity. The resulting long-term increase in plasma cortisol further accelerates hippocampal cell loss and perpetuates the stress/injury cycle (Fig. 45-10). In fact, increases in serum cortisol levels over time may predict the development of cognitive deficits in an otherwise healthy elderly individual.⁵⁵ Acute stress-related glucocorticoid responses to tissue injury, pain, or the psychosocial consequences of disability are also now thought to produce or accelerate cognitive decline in aged adults in whom nervous system tissue and neurotransmitter reserve is most severely reduced.⁵⁶

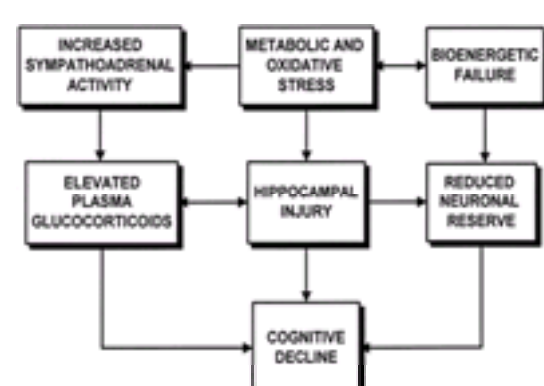

Figure 45-10. Perioperative cognitive decline in elderly adults may reflect the complex interaction of neuroendocrine stress, decreased neuronal reserve due to neuron

and transmitter loss, and bioenergetic decline from mitochondrial injury.

PERIPHERAL NERVOUS SYSTEM

Within the geriatric era, the threshold intensities of stimuli needed to initiate all forms of perception, including vision, hearing, touch, joint position sense, smell, peripheral pain, and temperature are all markedly elevated (Fig. 45-11). This process of progressive age-related deafferentation is due, at least in part, to degenerative changes within specialized sense organs such as the pain-generating Meissner's corpuscles in skin. However, there are also age-related changes at central sites of pain processing such as the thalamus and throughout peripheral pathways for conduction of pain impulses. In addition, attrition of the individual nerve fibers within afferent conduction pathways in both the peripheral nervous system and spinal cord reduce the velocity and amplitude of both evoked sensory potentials.

Figure 45-11. Age-related processes of deafferentation produce logarithmic increases in the thresholds for the various sensory modalities and increase the risk of hypoxia by raising the threshold for activation of protective laryngeal reflexes.

Similarly, peripheral motor nerve conduction velocity decreases by about $0.15 \text{ m} \cdot \text{sec}^{-1} \cdot \text{yr}^{-1}$,⁵⁷ and impairment of efferent corticospinal transmission increases the time needed between intention and onset of voluntary motor activity. Isometric muscle strength appears to be well maintained, but failing proximodistal protoplasmic transport in aging motor neurons reduces the myotrophic support normally provided to skeletal muscle. Although mitochondrial volume within skeletal muscle cells is reduced, there appear to be no significant changes in skeletal muscle metabolism or intrinsic contractile function.⁵⁸ Nevertheless, this process of neurogenic skeletal muscle atrophy⁵⁹ causes the dynamic strength, control, and ability to maintain steadiness of the skeletal muscles in the extremities to decline 20–50% by the age of 80 years and produces disseminated neurogenic atrophy at the neuromuscular junction.⁶⁰ The postjunctional muscle membrane thickens and spreads and new, atypical “extrajunctional” cholinergic receptors appear on the skeletal muscle surface.⁶¹ The increase in the total number of cholinergic receptors at each endplate and in the surrounding areas of the muscle cell surface appears to mask the age-related decline in the number and the density of motor neuron/endplate units.

AUTONOMIC NERVOUS SYSTEM

As in all of the peripheral nervous system, neurons in sympathoadrenal pathways are subject to significant cellular attrition. Adrenal tissue mass atrophies and cortisol secretion declines at least 15% by the age of 80. Nevertheless, plasma concentrations of norepinephrine are 2- to 4-fold higher in elderly subjects than in younger adults during sleep, at rest, and even in response to exercise-induced physical stress.⁶² Plasma epinephrine levels are far less predictable. High plasma levels of catecholamines are rarely apparent clinically in elderly patients, however, because aging markedly and progressively depresses autonomic end organ responsiveness.⁶³ There is a significant impairment of the ability of β agonists such as isoproterenol to enhance the velocity and force of cardiac contraction and a general decline in maximal chronotropic response.⁶⁴ In effect, aging produces “endogenous β blockade.” There appears to be little change in adrenoceptor or muscarinic cholinergic activity in older adults and no intrinsic changes in the basic contractile properties of peripheral vascular smooth muscle.⁶⁵

The complex integrated autonomic reflex responses that maintain cardiovascular and metabolic homeostasis precisely in young adults are nevertheless progressively impaired in elderly individuals.⁶⁶ This may explain the increased incidence and severity of arterial hypotension seen in older patients following anesthetic induction.⁶⁷ Baroreflex responsiveness, the vasoconstrictor response to cold stress, and beat-to-beat heart rate responses following postural change in elderly subjects become progressively less rapid in onset, smaller in magnitude, and less effective in stabilizing blood pressure under a variety of circumstances.⁶⁸ The autonomic nervous system in the elderly patient is “underdamped,” permitting wider variation from homeostatic set points and delayed restabilization during hemodynamic stress.⁶⁹ Therefore, anesthetic agents that disrupt end-organ function or reduce plasma catecholamines, or techniques associated with a pharmacologic sympathectomy such as spinal or epidural anesthesia produce arterial hypotension that is more severe in elderly than in young patients.⁷⁰

ANALGESIC AND ANESTHETIC REQUIREMENTS

The age-related structural and functional changes within the nervous system described above are measurable and consistent, but their net effect on pain-related neurologic function remains controversial. The study of amplification, modulation, and selectivity of afferent input within the spinal cord, thalamus, and other locations within the aging nervous system does not yet permit broad generalizations regarding aging and perception of pain.⁷¹ Some clinical evidence suggests that elderly patients have slightly elevated thresholds for discrete and superficial discomfort.⁷² However, severe visceral or postoperative pain is a diffuse, emotionally enhanced phenomenon. Therefore, perceived intensity of pain perioperatively is extremely unpredictable⁷³ and appears to be far more dependent upon anxiety, personality, and the prospect of long-term debility than upon age itself.⁷⁴

Nevertheless, systemic morphine requirements have also long been known to be inversely related to patient age and essentially independent of body weight.⁷⁵ When a fixed drug dose and volume of local anesthetics protocol is used, slightly higher levels of sensory blockade occur in elderly patients undergoing spinal anesthesia.⁷⁶ Segmental dose requirements for epidural analgesia are also reduced,⁷⁷ suggesting a modest reduction in afferent peripheral pain traffic or increased susceptibility to neural blockade. Some recent data⁷⁸ suggest that these clinical observations may be due largely to pharmacokinetic, not pharmacodynamic, phenomena, and in any case the age-dependent aspects of major conduction anesthesia become clinically insignificant after middle age.⁷⁹

The effect of nervous system aging on requirements for general anesthesia is less controversial. Between young adulthood and the geriatric era, relative minimum alveolar concentration (MAC) values for the newer inhalational agents decline progressively by as much as 30%,^{80,81} the same decrement seen with older anesthetics (Fig. 45-12). The mechanisms producing age-related increases in sensitivity to anesthetic agents remain unknown, but the consistency of this phenomenon for anesthetic agents with markedly different chemical characteristics⁸² suggests that it is the result of a fundamental neurophysiologic process such as loss of neuronal mass or cerebral blood flow. The decline in anesthetic requirements also parallels the reduction in brain neurotransmitter activity that occurs with increasing age, however, and a direct relationship between brain catecholamine levels and MAC is well established for patients treated with drugs that deplete or to enhance these neurotransmitters.⁸³ Whatever the mechanism of age-related increase in anesthetic potency, changes in anesthetic requirement may be a clinically relevant indicator of nervous system functional reserve.

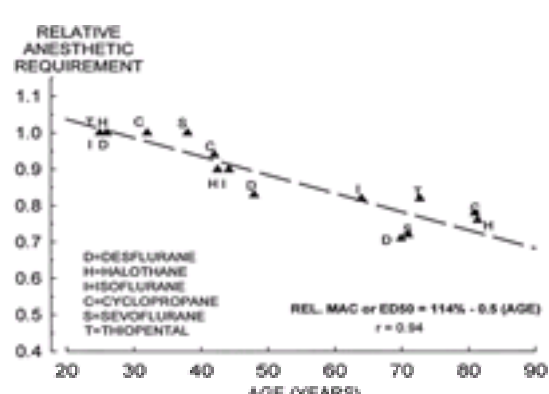

Figure 45-12. The age-related decline in relative anesthetic requirement (MAC or ED₅₀) in unsedated human subjects is a consistent characteristic reported for a wide variety of inhaled and injected anesthetic agents.

The data for the effect of aging on the pharmacodynamics, or dose requirements, for opioids, barbiturates, and benzodiazepines are less consistent than those for inhalational anesthetics. There is considerable controversy as to whether the clinically apparent age-related increase in the potency of these drugs is truly a pharmacodynamic phenomenon or whether it simply reflects age-related changes in “alpha” or early-phase redistribution pharmacokinetics because plasma drug concentrations immediately after intravenous injection are often higher in elderly subjects than in young adults.⁸⁴ This may reflect delayed intercompartmental transfer of drug rather than a decreased initial volume of distribution.⁸⁵ In any case, the concentrations of short-acting iv agents in plasma change so rapidly, and in such a complex manner, that the traditional two-compartment pharmacokinetic model may be of little value for studying the early- or alpha-phase behavior of these drugs and their subsequent redistribution in elderly subjects.⁸⁶

Interpretation of data from clinical studies of iv agents is further complicated by difficulty in defining the anesthetic endpoint in a process, that, in contrast to the conditions under which MAC is determined, does not represent pharmacokinetic equilibrium. Therefore, both onset and duration of clinical effects can be influenced by pharmacodynamic (drug sensitivity) or by pharmacokinetic (molecular drug disposition) processes. Clinical experience suggests that there are significant age-related reductions in the dose requirements for thiopental⁸⁷ as well as virtually all other agents that depress consciousness. Most studies also suggest that aging increases brain sensitivity to narcotics,^{88,89} but there are only insignificant pharmacodynamic changes for barbiturates or etomidate.⁹⁰ Overall, it appears that there is a complex interaction in older patients between subtle changes in pharmacodynamics and altered alpha-phase redistribution pharmacokinetics due to age-related hemodynamic factors⁹¹ that must be characterized for each drug in order to predict the implications of aging for clinical drug action and drug dosage.⁹²

Despite the inevitable loss of skeletal muscle mass in elderly subjects, the median effective doses (ED₅₀) and steady-state plasma concentrations required for half-maximal neuromuscular blocking effect (EC₅₀) remain virtually unchanged or may actually increase slightly in the elderly patient.⁹³ However, maximal relaxant effect may be delayed in onset relative to that produced in young adults.^{94,95} Duration of neuromuscular blockade is markedly prolonged (Fig. 45-13) for those relaxants requiring hepatic or renal elimination because plasma clearance declines dramatically with increasing age.^{96,97} However, as in younger adults, the intensity of neuromuscular blockade at time of antagonism or “reversal” by neostigmine or edrophonium and the choice and dosage of reversal agent, not patient age itself, determine the speed and the completeness of recovery of neuromuscular transmission.

Figure 45-13. The time needed for clinical recovery from neuromuscular blockade (RI = recovery index—the time required for spontaneous recovery from 25% to 75% of the control evoked neuromuscular response) is significantly increased in older adults (shaded bars) for nondepolarizing relaxants that requires organ-based clearance from plasma but is little different for atracurium, cisatracurium, or mivacurium because they are hydrolyzed in plasma.

PERIOPERATIVE MANAGEMENT AND OUTCOME

Overall, perioperative mortality and major morbidity increase with advancing age after young adulthood. However, age-related disease, not aging itself, largely determines the morbidity and mortality that characterizes an elderly surgical population,^{98,99,100} and ¹⁰¹ although advanced age itself may have additional negative prognostic significance if associated with severe multiple organ system dysfunction. Morbidity and mortality rates, therefore, are higher in elderly surgical patients largely because this surgical patient subpopulation has a greater incidence and severity of concurrent disease, and greater exposure to invasive medical interventions, than do younger adults (Fig. 45-14). The high prevalence of polypharmacy associated with chronic disease and its treatment also produces an age-related increase in adverse drug reactions that complicate perioperative management. Therefore, there are probably no healthy patients “too old” for anesthesia, even for ambulatory surgical procedures.¹⁰²

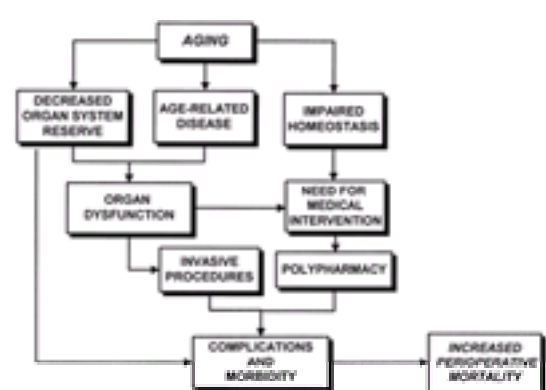

Figure 45-14. Increased rates of perioperative morbidity and mortality in elderly surgical patients can be attributed primarily to interactions between age-related decreases in organ system reserve, a high prevalence of disease in the elderly, and the inherent risk associated with therapy and surgical intervention.

The probability of a serious pulmonary or hemodynamic complication after surgery is determined both by the site of operation and by the patient's physical status. When they occur in geriatric surgical patients, adverse outcomes show a relative predominance of disorders of cardiac rate or rhythm, myocardial ischemia, or general hemodynamic instability. Pulmonary complications, infections and sepsis, and renal failure also contribute significantly to their morbidity. Many members of the geriatric surgical population summarily “cleared” for major surgery by medical consultants on empirical clinical grounds may nevertheless have mild to severe cardiopulmonary functional deficits. Consequently, adequate time for diagnosis, treatment, and preparation of the anesthetic plan is essential if the rate and severity of complications are to be reduced.¹⁰³

Although many clinical studies have shown that some perioperative complications are associated more frequently with one form of anesthesia than another,^{104,105,106,107} and ¹⁰⁸ it may not be possible to determine whether there is a single “best” anesthetic for elderly patients.¹⁰⁹ All anesthetic techniques are appropriate and in widespread use for geriatric patients in general, and none appears to have universal advantage for the elderly surgical patient with regard to survival. From the perspective of major adverse surgical outcome and eventual mortality, a brief intraoperative period of exposure to anesthesia is often only an insignificant component of a prolonged, difficult, and complex hospital course. In effect, neither regional anesthesia nor general anesthesia has clearly demonstrable superiority of outcome in elderly patients, although one or the other may be preferred for use in specific procedures or certain patients for other medical reasons.¹¹⁰ The use of newer intravenous agents such as remifentanyl^{111,112} and cisatracurium¹¹³ minimizes dependence upon organ system functional reserve for drug elimination. New inhalation agents such as desflurane and sevoflurane provide rapid recovery of consciousness even in the aged adult. Therefore, well-conducted general anesthesia is a safe and appropriate anesthetic plan for

older adults, even for those having same-day surgery in which rapid recovery and prompt ambulation are essential.¹¹⁴

Figure 45-15. The probability of adverse postoperative outcome increases only gradually with age across middle adulthood. Analyzed prospectively from a large series of randomized patients,⁹⁹ pre-existing cardiovascular or pulmonary disease and physical status (*solid lines*) were found to be the primary determinants of perioperative morbidity, although the widening of the separation between physical status lines shown here suggests that age itself may further amplify the negative prognostic value of impaired physical status in surgical patients who are well into the geriatric era.

Prompt and complete postoperative recovery of mental function is particularly important in elderly patients if mentation is already compromised by age-related disease or drug therapy. Recent large-scale prospective studies of outpatients suggest that there is less nausea and vomiting in older adults¹¹⁵ after general anesthesia but a greater likelihood of prolonged postoperative confusion.¹¹⁶ The most common cause of failure to emerge promptly from anesthesia is simply the use of too much anesthesia or too many anesthetic agents.¹¹⁷ Local anesthesia or regional techniques, if they can be comfortably performed without heavy intravenous sedation, may significantly improve postoperative mental function immediately after surgery, although there is no evidence of any long-term benefits to this approach.^{118,119} In addition, nerve palsies, residual paresthesias, and other neuropraxias due to regional anesthesia may occur more often in older than in young adults.^{120,121 and 122}

Even when anesthetic management of the older patient is appropriate and surgical convalescence uncomplicated, full return of cognitive function to preoperative levels may require 5–10 days after a prolonged general anesthetic. Perioperative environmental factors such as chronic medication and drug interaction,¹²³ disorientation due to sensory deprivation, or the disruption of normal routine needed to maintain “implicit” memory¹²⁴ may also explain the high incidence of “delirium” in older surgical patients.¹²⁵ However, the neurophysiologic or pharmacologic explanation for prolonged disruption of nervous system function remains unknown. Psychometrically defined postoperative cognitive dysfunction can be demonstrated 3 months after otherwise uncomplicated surgery in 10–15% of patients 60 years of age or older who have had major procedures and a hospital stay of 4 or more days.¹²⁶ This suggests that, at least in older adults with reduced central nervous system functional reserve, either the process of general anesthesia itself or the drugs used to produce it may have effects upon the metabolic and neurotransmitter functions of neuronal tissue that can actually produce residual neurologic injury.

The physical management of elderly patients in the operating room and afterward also requires specific precautions. Aged skin and bones are fragile, joints are stiff, and their range of motion is limited, especially if compromised by age-related arthritic processes. The elderly surgical patient therefore requires gentle and expert routine care if traumatic injuries from improper positioning, bandaging, or enforced bed rest are to be avoided. Avoiding hypothermia is important, but active heating devices in contact with poorly perfused skin or connective tissue pressure points can quickly produce ischemic lesions requiring surgical treatment. In all elderly patients, postoperative bleeding diatheses or hypercoagulable states and bacterial infection are more frequent than in younger adults.¹²⁷ Because of diastolic dysfunction and increased ventricular stiffness, rates of iv fluid administration that would be modest for young adults may, in the geriatric patient, produce increases in atrial and pulmonary artery pressures large enough to disrupt the fragile balance of forces that control lung water, precipitating congestive heart failure and pulmonary edema.

Whatever anesthetic approach is selected, major surgery and the resultant tissue injury produce extensive neuroendocrine and sympathoadrenal stress. Suppression of excessive sympathetic activity appears to promote rewarming and healing, reduce cardiovascular and pulmonary demands, and eliminate the long periods of emotional stress due to the inadequate analgesia sometimes imposed upon geriatric patients owing to exaggerated fears of opioid side-effects. To some extent, “ageism” may influence caregivers to withhold diagnostic or therapeutic measures that would be offered routinely to a younger adult.¹²⁸ Untreated pain and related emotional stress itself may significantly impair immune responsiveness in older adults and increase the risk of perioperative infection.¹²⁹ Therefore, an anesthetic plan that includes postoperative epidural sympathectomy and analgesia¹³⁰ or a parenteral sympathetic modulator such as dexmedetomidine¹³¹ may be of special value in the elderly surgical patient. Overall, elderly and aged patients do not require a “special” kind of anesthetic. Rather, if complications are to be minimized, their perioperative care simply requires the highest standards of preparation and diagnosis and control of pre-existing disease, vigilance, and meticulous execution of all details of anesthetic and postoperative management.

The first ether anesthetic was given for ambulatory surgery. The patient, James M. Venable, had a small cystic tumor removed from the back of his neck by Dr. Crawford W. Long on the evening of March 30, 1842, after school was dismissed. The patient described the procedure in this way: "I commenced inhaling the ether before the operation was commenced and continued it until the operation was over. I did not feel the slightest pain from the operation and could not believe the tumor was removed until it was shown to me."¹ The modern concept of an independent surgical center for outpatients was popularized in the early 1970s by Wallace Reed. Since then, ambulatory surgery has been so well accepted that the majority of patients currently return home within 24 hours of an operative procedure. Because of this fact, anesthesiologists have had to refine the method of performing anesthesia so that the anesthetic is not responsible for hindering a patient from returning to normal activities.

Cost-savings partially prompted the original ambulatory centers. In the late 1960s, an uninsured barber's two children needed myringotomies, which in those days meant 2 days of hospitalization before the procedure. The surgeons, astounded by how many haircuts they would receive instead of payment, began the cost-reducing measure of ambulatory surgery. Patient selection today is based on the desire to reduce cost while at the same time maintaining quality of care, so that morbidity from the procedure or pre-existing disease is no greater than if the patient were hospitalized. The length and complexity of operations performed in an ambulatory setting have increased, especially with the arrival of many new procedures. In the past, only patients with physical status evaluated as American Society of Anesthesiologists (ASA) Class I or II were candidates for ambulatory surgery. Today, patients classified as ASA III or IV whose systemic disease is medically stable are considered for procedures as outpatients. Preoperative screening, preferably in a clinic or by telephone, is essential both for reduction of patient anxiety and to ensure that medical management is appropriate. Specific laboratory tests before these operations are discussed elsewhere (see [Chapter 18](#)). In this chapter, we review the patients and procedures suitable for ambulatory surgery and how to manage anesthesia for outpatients. An excellent review of the history of ambulatory surgery is provided by Vandam.²

PLACE, PROCEDURES, AND PATIENT SELECTION

Ambulatory surgery occurs in a variety of settings. Some centers are within a hospital or in a freestanding satellite facility that is either part or independent of a hospital. Physicians' offices may also serve for procedures. In fact, by 2005, 20% of all surgical procedures will be performed in doctors' offices.³ The independent facilities are often for-profit and not located in rural or inner city areas. Although freestanding, independent facilities continue to grow, some consumers prefer care in units affiliated with hospitals.

Procedures appropriate for ambulatory surgery are those associated with postoperative care that is easily managed at home, and with low rates of postoperative complications that require intensive physician or nursing management. The definition of a low rate of postoperative complication depends on the relative aggressiveness of the facility, surgeon, patient, and payer. For example, procedures such as cholecystectomy, vaginal hysterectomy, reduction mammoplasty, open arthroscopy with ligament repair, and thyroidectomy are performed in some ambulatory surgery centers, whereas in other settings, these procedures are limited to inpatients. Lists of ambulatory procedures quickly become outdated simply because they exclude certain procedures which in a short time may become routine in ambulatory settings. In 1986, a patient would have been hospitalized for cholecystectomy but not for cataract extraction. When laparoscopic cholecystectomy was first introduced, a much higher percentage of patients required open cholecystectomy afterward, hence inpatient admission. Now some ambulatory surgery centers perform cholecystectomy on selected outpatients (generally healthy ones who live nearby) when an uneventful operative procedure is anticipated. Patients undergoing breast surgery have, in the past, been hospitalized for 1–7 days afterward. Yet in one series of 118 patients undergoing various types of breast surgery, including modified radical mastectomies and axillary node dissection, only three patients required hospital admission for relatively minor complications.⁴ For modified radical mastectomy performed as ambulatory surgery, compared to the same surgery with a three-day hospital stay, hospital costs were reduced by 75%. Some have argued that ambulatory tonsillectomy is not advisable because of the risk of hemorrhage as much as 24 hours after the procedure. Tonsillectomies, however, are performed safely in outpatients unless they are suffering from allergic episodes during the pollen season; have bleeding abnormalities or sickle cell anemia; are within 5 weeks of an acute attack of tonsillitis; have heart disease, sleep apnea, or congenital malformations; or experience bleeding within 8 hours of the procedure.⁵ It is suggested also that tonsillectomies for outpatients be performed in the morning. In another series, preoperative apnea, age less than 12 months, and the presence of accompanying medical conditions were associated with a higher incidence of postoperative airway complications.⁶ The investigators recommended that tonsillectomy in patients younger than 36 months be planned as an inpatient procedure.

Length of surgery is not a criterion for ambulatory procedures because there is little relationship between length of anesthesia and recovery ([Fig. 46-1](#)).⁷ Patients undergoing longer procedures, though, should have their operations earlier in the day. In a study of unplanned admission of patients undergoing ambulatory ophthalmic surgery, the variable most highly correlated with admission was the completion of surgery later in the day.⁸ The need for transfusion also is not a contraindication for ambulatory procedures. Some patients undergoing liposuction as outpatients, for example, are given autologous blood. Some surgeons, however, are uneasy about performing transfusion-requiring operations in an ambulatory setting because blood loss is a factor in unexpected hospital admission after surgery.^{9,10}

Figure 46-1. Length of anesthesia has little correlation with recovery time. (Reprinted with permission from Meridy HW: Criteria for selection of ambulatory surgical patients and guidelines for anesthetic management: A retrospective study of 1553 cases. *Anesth Analg* 61:921, 1982.)

Preterm infants (gestation age 37 weeks) who are younger than 50 weeks postconceptual age should not be discharged from an ambulatory surgery center for at least 23 hours after a procedure because they are at risk of developing apnea even without a history of apnea. In one study using pneumography, 37% of infants as old as 55 postconceptual weeks had prolonged apnea up to 12 hours after operation.¹¹ This study prompted the suggestion that the upper age limit for infants admitted for overnight stays should be extended to 60 postconceptual weeks. Some of the infants in the study underwent typical outpatient procedures like herniorrhaphy; others underwent laparotomy. In a similar study of infants who underwent inguinal herniorrhaphy only, 64% with a conceptual age of less than 44 weeks had periodic breathing afterward, two as late as 5 hours postoperatively.¹² No infant who was 44 conceptual weeks or older had periodic breathing postoperatively (conceptual age = gestational age plus postnatal age). Anemia (hematocrit < 30%) is also associated with an increased incidence of apnea in preterm infants less than 60 postconceptual weeks old at the time of operation.¹³

Some techniques have been tried to eliminate postoperative apnea in infants to allow them to go home on the same day of a procedure. When caffeine 10 mg · kg⁻¹ was administered immediately after induction of anesthesia, no preterm infants \geq 44 conceptual weeks old developed postoperative apnea.¹⁴ Spinal anesthesia, without the use of other drugs intraoperatively or postoperatively, also was not associated with apnea (Fig. 46-2).¹⁵ Although preterm infants who have received caffeine or an unsupplemented spinal anesthetic may be discharged on the day of the procedure, they should probably be observed overnight in a hospital until more data confirm the safety of this practice.

Figure 46-2. Postoperative apnea in premature infants with and without a history of apnea is significantly less if only spinal anesthesia is used. (Reprinted with permission from Welborn LG, Rice LJ, Hannallah RS *et al*: Postoperative apnea in former preterm infants: Prospective comparison of spinal and general anesthesia. *Anesthesiology* 72:838, 1990.)

At the other extreme of life, advanced age alone is not a reason to disallow surgery in an ambulatory setting. Age, however, does affect the pharmacokinetics of drugs. Even short-acting drugs such as midazolam and propofol have decreased clearance in older individuals. In a study of outcome after 6000 procedures, some for patients older than 90 years, longer recovery time was not correlated with older age.¹⁶ Transurethral resection of the prostate is performed in the ambulatory setting. In two studies, increased age was correlated with unexpected hospital admissions.^{17,18} In a third study of more than 6,000 patients undergoing ambulatory surgery, age was not a predictor of return; however, patients <40 years who returned after ambulatory procedures were more likely to be treated in the emergency room, whereas patients >65 years were more likely to be hospitalized.¹⁹ Admission, by itself, is not necessarily bad if it results in a better quality of care or uncovers the need for more extensive surgery. With proper patient selection for ambulatory procedures, which are usually elective, the incidence of readmission should be very low. Most medical problems that older individuals may experience after ambulatory procedures are not caused by age, but by specific organ dysfunction. For that reason, all individuals, whether young or old, deserve a careful preoperative history and physical examination.

Whatever their age, ambulatory surgery is no longer restricted to patients of ASA physical status I or II. Patients of ASA physical status III or IV are appropriate candidates, providing their systemic diseases are medically stable. In one study of 6000 ambulatory surgery procedures in a public teaching hospital, perioperative complications related to surgery (1:105) were more frequent than those related to pre-existing medical problems (1:500).¹⁶ Nonetheless, pre-existing medical illness is a factor in both intraoperative difficulties and postoperative complications that require unexpected patient admission.

Patients who undergo ambulatory surgery should have someone to take them home and stay with them afterward to provide care. Before the procedure, the patient should receive information about the procedure itself, where it will be performed, laboratory studies that will be ordered, and dietary restrictions. The patient must understand that he or she will be going home on the day of surgery. The patient, or some responsible person, must be able to see that all instructions are carried out. Once at home, the patient must be able to tolerate the pain from the procedure, assuming adequate pain therapy is provided. The majority of patients are satisfied with early discharge, although a few prefer a longer stay in the hospital. Patients for certain procedures such as laparoscopic cholecystectomy or transurethral resection of the prostate should live close to the ambulatory facility because postoperative complications may require their prompt return. "Reasonable" distance and time for the patient to get care if problems arise are not easily defined. This issue must be addressed by each facility and by each patient and depends on the type of surgery to be performed. In one series, one-half of the deaths in patients within 30 days of ambulatory surgery were due to traffic accidents.²⁰

PREOPERATIVE EVALUATION AND REDUCTION OF PATIENT ANXIETY

Each outpatient facility should develop its own method of preoperative screening to be conducted before the day of surgery. The patient may visit the facility, or staff members may telephone to obtain necessary information about the patient, including a complete medical history of the patient and family, the medications the patient is taking, and the problems the patient or the patient's family may have had with previous anesthetics. In a study of the usefulness of a preoperative screening telephone call, patients were less likely to cancel surgery if they had been screened beforehand.²¹ Unscreened patients were more likely to be hospitalized after surgery. Overall, cancellation rates did not differ between patients evaluated within 24 hours of surgery or days or weeks before surgery. The screening may uncover the need for transportation to the facility or the need for child care. The process also provides the staff with an opportunity to remind patients of arrival time, suitable attire, and dietary restrictions (*e.g.*, nothing to eat or drink after midnight, no jewelry or makeup). Staff members can determine whether a responsible person is available to escort the patient to and from the facility and care for the patient at home after surgery. The screening is the ideal time for the anesthesiologist to talk with the patient, but if that is not possible, the anesthesiologist may review the screening record to determine whether additional evaluation by other consultants is necessary and if laboratory tests must be obtained.

Automated history-taking may also prove beneficial during the screening of a patient. Computerized questionnaires or checklists with plastic overlays automate the taking of patient histories, flag problem areas, and suggest laboratory tests to be ordered. Such devices can also be used in a surgeon's office, both to guide the surgeon in the selection of laboratory tests and to serve as a medical summary for the anesthesiologist. Such devices are particularly useful to control the cost of preoperative testing. They enable test ordering based on information obtained from a patient's responses to health questions, thus eliminating requests for tests that are not warranted by history or physical examination.

Another important reason for preoperative screening is to help alleviate a patient's anxiety. In a classic study, Egbert *et al*²² found that a preoperative visit by an anesthesiologist was more effective in decreasing anxiety than administration of a barbiturate. Other authors also have confirmed the value of a preoperative visit. Preoperative reassurance from nonanesthesia staff and the use of booklets also reduce preoperative anxiety. Patients given maximally informative booklets to prepare them for surgery have less anxiety than those given minimally informative booklets or only routine care.²³ However, use of such booklets is less effective than a preoperative visit by the anesthesiologist. Audiovisual instructions also reduce preoperative anxiety. Certain relaxation techniques for reducing anxiety are best taught before the surgery. In one study, for example, relaxation training was given to ambulatory patients scheduled for excision of a skin cancer without general anesthesia.²⁴ The relaxation response was elicited for 20 min · day⁻¹ until the day of surgery; the control group spent 20 min · day⁻¹ reading. Patients who were taught the relaxation response said their anxiety was highest before entering the study; control patients said their anxiety was greatest during surgery and when facing the results of biopsy. However, anxiety levels (as assessed by the State-Trait Anxiety Inventory) were the same immediately before and after surgery for both the control and study groups. In another study of outpatients, in which a tape-recorded procedure guided relaxation, the treatment significantly reduced preoperative anxiety, the time required for the induction of anesthesia, and the amount of anesthetic agent (isoflurane) needed to maintain anesthesia.²⁵ Patients receiving the relaxation treatment also had more favorable perceptions of their treatment than did a control group.

For children, information-modeling and coping-based programs have been shown to reduce anxiety and enhance coping, particularly during the preoperative period. Behavior during induction, in the PACU, or postoperatively does not seem to be affected by this effort. A child's anxiety seems to be maximally reduced if the effort to

reduce it is made before surgery.

Chronic Medications Before Ambulatory Surgery

As the severity of illness increases in patients who present for ambulatory surgery, the number of potent drugs that they may be taking to treat disease also increases. Drugs that may significantly affect anesthetic management may be proscribed before a procedure. What follows is a partial list of some long-term medications and how they interact with drugs commonly used for ambulatory anesthesia.

Antihypertensive Agents

Withdrawal of antihypertensive therapy can exacerbate intraoperative hypertension. Most antihypertensive agents affect storage, uptake, metabolism, or release of neurotransmitters and thus may interact with drugs used intraoperatively. In addition, they can produce adverse effects such as depression, nightmares, and drowsiness. Clonidine, an α_2 -adrenergic agonist that centrally inhibits release of catecholamines, has been used as a premedicant to control intraoperative hypertension. Calcium channel-blocking drugs inhibit the transmembrane flux of calcium ions into cardiac and vascular smooth muscle. The effects of inhalation agents with calcium channel-blocking drugs may be additive, causing a decrease in blood pressure and contractility. Calcium channel-blocking drugs may also protect against myocardial ischemia or dysfunction during anesthesia, reduce anesthetic requirement, and potentiate both depolarizing and nondepolarizing muscle relaxants. Withdrawal of β -adrenergic receptor blocking drugs, such as propranolol, is associated with an increase in sympathetic stimulation. Antihypertensive agents, except for diuretics, should be continued on the day of surgery.

Mood-Altering Drugs

Mood-altering drugs, such as fluoxetine (Prozac), the monoamine oxidase inhibitors, lithium, and tricyclic antidepressants, are among the most common chronic medications. Fluoxetine, a selective inhibitor of the neuronal uptake of 5-hydroxytryptamine (5-HT), is probably the most frequently prescribed antidepressant. No interactions have been described between anesthetics and fluoxetine or ondansetron, a 5-HT₃ antagonist. Fever may result when fluoxetine is combined with drugs with antidopaminergic properties that control nausea.

The tricyclic antidepressants inhibit, to a varying degree, the neuronal uptake of norepinephrine, 5-HT, and dopamine; and they act as antagonists at muscarinic, cholinergic, α_1 -adrenergic, and H₁ and H₂ receptors. These actions may produce dry mouth, tachycardia, delirium, and urinary retention. Because these drugs block the reuptake of norepinephrine, injections of epinephrine (with local anesthetics) or indirectly acting sympathomimetics, such as ephedrine, can result in severe hypertension. Cardiac dysrhythmias and sinus tachycardia are more prevalent when imipramine pretreatment is followed by halothane and pancuronium. Anesthetic requirement may be greater because of increased central levels of norepinephrine.

Lithium is used to treat manic depression and, in particular, the manic portion of this illness. It can replace sodium during an action potential, prolong neuromuscular blockade with either depolarizing or nondepolarizing muscle relaxants, and prolong the time for reversal by neostigmine. Because lithium blocks brainstem release of epinephrine or norepinephrine, anesthetic requirements may be decreased.

Monoamine oxidase (MAO) inhibitors block the enzyme MAO from breaking down catecholamines. They are used to treat depression when tricyclic or other antidepressants, or even electroconvulsive therapy, cannot be used. Their interactions with drugs and foods containing amines produce serious effects including severe hypertension, intracranial bleeding, and death. Five patients who had taken the MAO inhibitor dextromethorphan died after receiving meperidine for analgesia.²⁶ With phenelzine, pseudocholinesterase levels may be reduced, so that the action of succinylcholine could be prolonged. With reversible inhibitors of MAO-A alone, rather than the nonspecific blockers of both A and B enzyme activity, the potential for fatal reaction is probably reduced.

Aspirin

Many people in the United States take aspirin or other nonsteroidal anti-inflammatory agents. These drugs can alter platelet function within a few hours of ingestion and prolong bleeding times for at least 7 days. Studies of patients undergoing hip arthroplasty or coronary bypass surgery showed that blood loss was greater in patients who took aspirin or nonsteroidal anti-inflammatory drugs before surgery. If bleeding times are normal, though, blood loss may not be increased. Although no large study in patients undergoing ambulatory surgery has been performed to show that it makes any clinical difference if patients do or do not stop taking aspirin, there is no reason to discontinue aspirin when the risk of bleeding during surgery is small.

Upper Respiratory Tract Infection (URI)

A patient might be seen several days before surgery without any contraindication to the upcoming procedure. On the day of surgery, the patient may have a URI. Some retrospective studies have noted an increased incidence of laryngospasm or bronchospasm in such patients. Other studies have failed to show an effect of URI. In one study of patients who developed laryngospasm, they were more than twice as likely to have a URI compared to control patients.²⁷ Once the decision is made to perform surgery in spite of URI, there is no difference in incidence of laryngospasm if a laryngeal mask airway or endotracheal tube is used.²⁸ Generally, if a patient with a URI has a normal appetite, does not have a fever or an elevated respiratory rate, and does not appear toxic, it is probably safe to proceed with the planned procedure.

Restriction of Food and Liquids Before Ambulatory Surgery

To decrease the risk of aspiration of gastric contents, patients are routinely asked not to eat or drink anything (*non per os* [NPO], "nothing by mouth") for at least 6–8 hours before surgery. Gastric volumes are actually less when patients are allowed to drink some fluids before surgery. One study comparing patients given diazepam orally with 50 ml of water and a similar group given diazepam im found that gastric volume was smaller (median volume 1.5 vs. 20 ml) and pH was higher (median pH 2.4 vs. 1.8) for patients given diazepam and water.²⁹ When 100 ml of water was ingested 2 hours before surgery without a pill but in conjunction with an im premedicant (meperidine and promethazine), gastric volume and pH were not affected by ingestion of water.³⁰ In one study, patients either drank orange juice or coffee 2–3 hours before surgery or fasted overnight.³¹ The incidence of gastric volume exceeding 25 ml and of gastric pH < 2.5 did not differ between the groups.

Similar findings are reported in children. For example, when 3 ml · kg⁻¹ of apple juice was given 2.6 ± 0.4 hours preoperatively to healthy children 5–10 years of age, gastric volume was less and gastric pH was no different than if they had fasted.³² In addition, patients who drank fluids beforehand were less irritable, less thirsty, less hungry, and better able to tolerate the preoperative waiting period. Similar results were found in a study of children who were allowed to drink clear liquids *ad libitum* until 2 hours before surgery, with the last intake before surgery limited to 240 ml.³³ In a national survey of preoperative fasting practices conducted in 1992 and published in 1996, the majority of respondents abided by the traditional NPO policy (NPO after midnight); 24% allowed liquids up to 4 hr before surgery; 68% allowed liquids for children (Table 46-1).³⁴ One advantage of allowing coffee drinkers their morning coffee is that the incidence of headaches after surgery is reduced.³⁵

Table 46-1. CURRENT NPO GUIDELINES FOR CLEAR LIQUIDS FROM A NATIONAL SURVEY OF AMBULATORY SURGERY CENTERS AND UNIVERSITY ANESTHESIOLOGY PROGRAMS, CONDUCTED IN 1992

MANAGING THE ANESTHETIC: PREMEDICATION

The outpatient is not that different from the inpatient undergoing surgery. In both, premedication is useful to control anxiety, postoperative pain, nausea, and vomiting and to reduce the risk of aspiration during induction of anesthesia. Because the outpatient is going home on the day of surgery, the drugs given before anesthesia should not hinder recovery afterward. Most premedicants do not prolong recovery when given in appropriate doses for appropriate indications. For example, when patients who received $1 \mu\text{g} \cdot \text{kg}^{-1}$ fentanyl and $0.04 \text{ mg} \cdot \text{kg}^{-1}$ midazolam before induction were compared with patients who received no premedication, maintenance requirements (desflurane), airway irritability, and blood pressure increases during induction were reduced for the former and discharge times were unaffected.³⁶

Controlling Anxiety

Patients scheduled to undergo surgery tend to be anxious long before they come to the outpatient area. In one study, the level of anxiety was measured daily from 4 days before hospital admission to several days after surgery.³⁷ Anxiety was high before admission, between admission and surgery, and 2 days after surgery (Fig. 46-3). Some patients, however, are not anxious. A study to examine the efficacy of drugs for relief of anxiety in outpatients undergoing gynecologic surgery was unsuccessful simply because of the low levels of preoperative anxiety present.³⁸ Some operations certainly can generate more anxiety than others. Increased anxiety has been noted in females, in those accompanied by a friend or relative to the preoperative holding area, in patients undergoing mutilating surgery or surgery for malignancy, in those undergoing surgery for the first time, in young patients, and in those with a previous bad anesthetic experience. The need to remove dentures is also associated with increased preoperative stress. Some patients worry more about their family than themselves immediately before surgery. If in doubt about patient anxiety, ask: predictive accuracy in determining whether patients are anxious increases when they are asked.³⁹

Figure 46-3. Mean scores for the State-Trait Anxiety Inventory (STAI), which were obtained daily beginning 4 days before surgery, at home, at the time of admission to the hospital, and up to 35 days after surgery (at this time, most patients had been discharged). “Op” indicates day of surgery. The level of anxiety was high not only before surgery but also at 2 days after surgery. (Reprinted with permission from Johnston M: Anxiety in surgical patients. *Psychol Med* 10:145, 1980.)

Like adults, children should have some idea of what to expect during a procedure. But much of a child's anxiety before surgery concerns separation from parent(s). A child is more likely to demonstrate problematic behavior from the time of separation from parents to induction of anesthesia if a procedure has not been explained preoperatively. Similarly, extreme anxiety during the induction of anesthesia is associated with increased occurrence of postoperative negative behavioral changes, such as bad dreams/waking up crying, disobeying parents, separation anxiety, and temper tantrums.⁴⁰ Both parents and children need to be involved in preoperative discussions so that the anxiety of the parents is not transmitted to the child. The transmission of anxiety is at least as problematic as is the separation itself (e.g., experiences of children being left with baby-sitters). If the parents are calm and can effectively manage the physical transfer to a warm and playful anesthesiologist or nurse, premedication is not necessary. Semisedation may be awkward and recovery after premedication may be prolonged. Nonetheless, at least in one study, both parental and child anxiety around the time of induction was better managed with oral midazolam rather than by having the parents present.⁴¹

Although historically many classes of drugs (e.g., barbiturates and antihistamines) have been used to reduce anxiety and to induce sedation, benzodiazepines are at present the drugs most commonly used. Oral transmucosal fentanyl may be useful for reducing anxiety in children. Propofol also has some anxiety-reduction properties.

Benzodiazepines

Midazolam is the benzodiazepine most commonly used preoperatively. It is water-soluble with an initial distribution half-life of 7.2 minutes and an elimination half-life of 2.5 hours (range 2.1–3.4 hr), which increases to 5.6 hours in the elderly and to 8.4 hours in obese patients.⁴² Fifty percent of an orally administered dose undergoes first-pass metabolism in the liver, and extrahepatic metabolism may also occur. The metabolites of midazolam have negligible soporific effects. Although midazolam does not produce thrombosis or thrombophlebitis, it may cause nausea occasionally. The drug's dose should be decreased with increasing age (Fig. 46-4).⁴³ A dose of midazolam of $0.1 \text{ mg} \cdot \text{kg}^{-1}$ iv in a 60-year-old patient would be equivalent to a dose of $0.03 \text{ mg} \cdot \text{kg}^{-1}$ iv in a 90-year-old patient and a dose of $0.15 \text{ mg} \cdot \text{kg}^{-1}$ in a 20-year-old patient. Midazolam $0.07 \text{ mg} \cdot \text{kg}^{-1}$ iv given to 40 elderly patients for sedation before endoscopy of the esophagus, stomach, and duodenum was effective based on time to achieve sedation, adequacy of sedation, and absence of gagging during the procedure.⁴⁴ In a 20-year-old, effective sedation for 20–40 minutes is usually provided at doses of 0.07 – $0.15 \text{ mg} \cdot \text{kg}^{-1}$. Cardiovascular, respiratory, and psychomotor depression are adverse effects of midazolam.

Figure 46-4. The mean dose (\pm SD) of iv midazolam required to produce adequate sedation before upper gastrointestinal endoscopy decreases with age. (Reprinted with permission from Bell GD, Spickett GP, Reeve PA *et al*: Intravenous midazolam for upper gastrointestinal endoscopy: A study of 800 consecutive cases relating dose to age and sex of patient. *Br J Clin Pharmacol* 23:241, 1987.)

Oral midazolam is a useful premedicant for children. The U.S. Food and Drug Administration (FDA) approved an oral formulation of midazolam in October 1998. Oral midazolam in a dose of $0.5 \text{ mg} \cdot \text{kg}^{-1}$ produces effective sedation and reduces anxiety. With this dose, children can be effectively separated from their parents after 10 minutes.⁴⁵ When midazolam is given before procedures lasting about 30 minutes with a halothane anesthetic, recovery is not prolonged (Fig. 46-5).⁴⁶ Initial recovery after shorter acting anesthetics, e.g., sevoflurane or desflurane, may be prolonged; discharge time, however, is not affected. With the antifungal agents itraconazole or ketoconazole, serum concentrations of midazolam are increased, thereby increasing the potential for intense and prolonged sedation as well as respiratory depression.

Figure 46-5. Recovery is not affected by the preoperative use of midazolam (*black* = surgery to PACU; *stippled* = PACU to eye opening; *gray* = PACU to discharge). (Reprinted with permission from McMillan CO, Spahr-Schopfer IA, Sikich N *et al*: Premedication of children with oral midazolam. *Can J Anaesth* 39:545, 1992.)

Diazepam is recommended for oral use by patients who are identified as anxious before coming for ambulatory surgery. Orally administered diazepam is well absorbed from the intestine. Plasma levels peak 60 minutes after ingestion, when anxiolytic effects are measurable. The drug is effective for several hours. Dose requirements decrease approximately 10% per decade of patient age. We prescribe diazepam in a dose of 2–5 mg · 70 kg⁻¹ adult. Its metabolite, desmethyldiazepam, has pharmacologic properties similar to those of the parent drug; concentrations can be detected after 2 hours and decrease only after 36 hours. The elimination half-life of diazepam and desmethyldiazepam is longer in older subjects than in young ones. The activity of this drug, however, does not depend on plasma concentration alone. When younger and older patients with equal plasma levels of diazepam are compared, the central nervous system of elderly patients is more sensitive to the depressant effects.

At proper doses, midazolam places patients at no additional risk for cardiovascular and respiratory depression than does diazepam. Decrease in blood pressure in healthy individuals with the benzodiazepines is trivial (10%); but in older patients, particularly those with heart disease, decreases may range from 20% to 35% and may be associated with apnea.⁴⁷ A decrease in blood pressure is greater when other drugs, such as fentanyl, propofol, or thiopental, are coadministered. Decreased oxygen saturation has also been reported after injection of midazolam. In 100 patients undergoing endoscopy, average baseline oxygen saturation of 95% decreased to 92% after iv administration of midazolam and to 89% during endoscopy (Fig. 46-6).⁴⁸ Oxygen saturation was below 80% in 7% of patients. Routine administration of supplemental oxygen with or without continuous monitoring of arterial oxygenation is recommended whenever benzodiazepines are given intravenously. This precaution is important not only when midazolam is given as a premedicant, but also when it is used alone or with other drugs for conscious sedation.

Figure 46-6. Oxygen saturation and chest wall movements decreased in a patient after injection of midazolam during gastroscopy. After introduction of the gastroscope, the patient coughed and oxygen saturation decreased even more. (Reprinted with permission from Bell GD, Reeve PA, Moshiri M *et al*: Intravenous midazolam: A study of the degree of oxygen desaturation occurring during upper gastrointestinal endoscopy. *Br J Clin Pharmacol* 23:703, 1987.)

Fatigue associated with the effects of anxiolytics may delay or prevent the discharge of patients on the day of surgery, although more frequently patients are not discharged because of the effects of the operation. With regard to anesthesia effects, patients normally stay in the hospital not because they are too sleepy but because they are nauseous.

The potential for amnesia after premedication is another concern, especially for patients undergoing ambulatory surgery. Anterograde amnesia occurs, yet no controlled studies have shown that retrograde amnesia has occurred in patients given midazolam or diazepam. In one study, 42% of patients given a placebo, but only 2.8% of patients given midazolam (0.1 mg · kg⁻¹ im), could remember induction of anesthesia for cervical dilation and uterine curettage ($p < 0.0001$).⁴⁹ It is noteworthy, however, that so many patients given placebo could not remember induction.

Opioids and Nonsteroidal Analgesics

Opioids can be administered preoperatively to sedate patients, to control hypertension during tracheal intubation, and to decrease pain before surgery. Meperidine (but not morphine or fentanyl) is sometimes helpful in controlling shivering in the operating room or postanesthesia care unit (PACU), although treatment is usually instituted at the time of shivering and not in anticipation of the event. The effectiveness of opioids in relieving anxiety is controversial and probably nonexistent, particularly in adults. In children, a lozenge form of fentanyl (oral transmucosal fentanyl citrate) reduced anxiety, increased sedation, and improved quality of induction.⁵⁰ Like all opioids, fentanyl in this form can decrease respiratory rate and oxygen saturation.⁵¹ This effect usually can be reversed by having the child breathe deeply or take a big breath. Oxygen saturation should be monitored, particularly when the drug is used in this form. Pruritus, nausea, and vomiting can also be problematic. Droperidol, 50 µg · kg⁻¹, given to 2- to 8-year-olds, did not reduce the incidence of vomiting.⁵¹ With fentanyl, PACU stay is not prolonged and postoperative analgesia requirements are less, although if children are required to drink fluids before they can be discharged, vomiting may delay their release. In adults, as in children, postoperative analgesia requirements are decreased, but the nausea that may accompany opioids can be problematic.

Opioids are useful in controlling hypertension during tracheal intubation. Opioid premedication prevents increases in systolic pressure in a dose-dependent fashion. After tracheal intubation, however, systolic, diastolic, and mean arterial blood pressures sometimes decrease below baseline values.

Preoperative administration of opioids or nonsteroidal anti-inflammatory drugs is also useful for controlling pain in the early postoperative period. Patients undergoing laparoscopy received ketorolac 60 mg, dezocine 6 mg, or fentanyl 100 µg before the start of operation.⁵² In the PACU 61% of patients who received fentanyl needed supplemental analgesia compared with 34% who received ketorolac and 25% who received dezocine; the amount of narcotic required was also less in the ketorolac and dezocine groups. Nausea was greatest after dezocine. In other studies, preoperative administration of diclofenac or naproxen to patients who underwent laparoscopy significantly reduced postoperative pain as well as the need for supplemental analgesia. Ibuprofen, an anti-inflammatory drug with analgesic action, can be given rectally to children preoperatively.

Propofol

Propofol is used for sedation, induction, and maintenance of anesthesia; the drug is discussed more completely in the section on General Anesthesia. However, propofol has other properties, such as anxiety reduction. When patients could administer propofol in 0.7-mg · kg⁻¹ boluses to themselves during different ambulatory surgical procedures, they described a feeling of well-being and relaxation.⁵³ Anxiety reduction and sedation were similar when propofol was compared with midazolam and methohexital for sedation for retrobulbar and peribulbar ocular block.⁵⁴ Of patients who received either propofol or thiopental for induction and then enflurane, nitrous oxide, and oxygen for maintenance of anesthesia, anxiety increased postoperatively only in the thiopental group.⁵⁵

Preoperative sedation is not needed for every patient. The following is our practice when patients require drugs to relieve anxiety. For the patient who has been seen at least 24 hours before a scheduled procedure and expresses a desire for medication to relieve anxiety or has anxiety that cannot be relieved with comforting, oral diazepam, 2–5 mg · 70 kg⁻¹ body weight, is prescribed for the night before and at 6:00 A.M. on the day of surgery (even if surgery is scheduled for 1:00 P.M. or later).

For patients seen for the first time in the preoperative holding area who seem to need medication, midazolam, $0.03 \text{ mg} \cdot \text{kg}^{-1}$, is administered iv, or the patient is brought into the operating room and propofol, $0.7 \text{ mg} \cdot \text{kg}^{-1}$, is injected iv. For children, when necessary, oral midazolam, $0.5 \text{ mg} \cdot \text{kg}^{-1}$ is administered in the preoperative holding area.

Controlling the Risk of Aspiration

Patients who undergo ambulatory surgery may be at some small risk for aspiration of gastric contents, although this risk is no greater than for inpatients. At greater risk for aspiration are pregnant or morbidly obese patients or patients with hiatal hernia. Preoperative anxiety probably has no effect on gastric acidity for individuals without a history of duodenal ulcer.

H₂ Receptor Antagonists

Cimetidine and ranitidine antagonize the action of histamine on H₂ receptors, causing a reduction in concentration of hydrogen ions; they also decrease gastric volume. The effect of cimetidine begins 60–90 minutes after administration and lasts for at least 3 hours. Ranitidine is 4–6 times as potent as cimetidine, yet the elimination half-lives are similar (2–3 hours).⁵⁶ Famotidine and nizatidine, two new H₂ receptor antagonists, are similar to cimetidine and ranitidine. On an equimolar basis, famotidine is ~7.5 times more potent than ranitidine and 20 times more potent than cimetidine. Cimetidine inhibits metabolism of drugs dependent on biotransformation by cytochrome P-450. Cimetidine also decreases blood flow in the liver by 25% if administered acutely to a fasting patient and by 33% if administered chronically. Thus, drugs such as propranolol, which depend on blood flow in the liver for hepatic elimination, are eliminated from the body more slowly when given in conjunction with cimetidine. Cimetidine sometimes causes mental confusion, particularly in elderly patients,⁵⁷ and usually within 48 hours of the first dose. This syndrome is associated with trough concentrations of $2.0 \text{ mg} \cdot \text{ml}^{-1}$.

Omeprazole

Omeprazole is a substituted benzimidazole that inhibits the gastric enzyme, hydrogen-potassium-adenosine-triphosphatase (ATPase), which mediates the production of hydrochloric acid in the gastric parietal cell. The half-life of omeprazole ranges from 0.3 to 2.5 hours.⁵⁸ Its metabolite is also active and binds irreversibly to gastric hydrogen-potassium-ATPase. Like cimetidine, omeprazole inhibits cytochrome P-450, and therefore reduces the metabolism of drugs depending on cytochrome P-450 systems. When omeprazole, 80 mg, was given to ambulatory patients the night before surgery, gastric volume was unchanged and gastric pH was increased.⁵⁹

Sodium Citrate

Soluble antacids such as sodium citrate or Bicitra are useful because if aspirated, they produce less severe hypoxia and lung abnormalities than do nonabsorbable antacids, such as Mylanta. Customary doses (30 ml) of soluble antacids raise gastric pH but can also increase gastric volume. Very small doses of sodium bicarbonate (1.6 ml) can increase gastric pH without affecting gastric volume.⁶⁰

Metoclopramide

Metoclopramide is a dopamine antagonist that increases the pressure of the lower esophageal sphincter, speeds gastric emptying, and prevents or alleviates nausea and vomiting. To reduce gastric volume even more, metoclopramide is combined with other drugs. For example, the combination of cimetidine and metoclopramide given to ambulatory patients during the preinduction phase was better than either drug alone for increasing gastric pH and decreasing gastric volume.⁶¹ Metoclopramide is also an effective antiemetic. Patients given metoclopramide before surgery may experience less nausea and vomiting not only during, but also after surgery. However, the duration of action of metoclopramide is relatively brief, and its antiemetic effectiveness may be negligible with doses that are too low. Oral doses of $0.15\text{--}0.3 \text{ mg} \cdot \text{kg}^{-1}$, typical for patients undergoing anesthesia, were not effective in preventing emesis induced by cisplatin, an antineoplastic drug given to cancer patients, whereas iv doses of $2 \text{ mg} \cdot \text{kg}^{-1}$ were effective.⁶² These higher doses, however, have not been used perioperatively.

In our practice, sodium citrate and metoclopramide or an H₂ receptor antagonist is routinely administered to patients at risk for acid aspiration, particularly those with hiatal hernia, the morbidly obese, parturients, and those with a history of duodenal ulcer.

Controlling Postoperative Nausea Preoperatively

Nausea, with or without vomiting, is probably the most important factor contributing to a delay in discharge of patients and an increase in unanticipated admissions of both children and adults after ambulatory surgery (Fig. 46-7).⁶³ Women, especially those who are pregnant, have a higher incidence of postoperative nausea and vomiting. Other risk factors include a previous history of motion sickness or postanesthetic emesis; surgery within 1–7 days of the menstrual cycle; and procedures such as laparoscopy; lithotripsy; and ear, nose, or throat surgery. Narcotics given for premedication may exacerbate the problem of postoperative nausea and vomiting. Other drugs such as metoclopramide may help alleviate this condition.

Figure 46-7. Time to home-readiness (mean \pm SD) in nauseated versus non-nauseated patients. Home-readiness is significantly delayed ($p < 0.001$) if a patient is nauseous. (Reprinted with permission from Green G, Jonsson L: Nausea: The most important factor determining length of stay after ambulatory anaesthesia. A comparative study of isoflurane and/or propofol techniques. *Acta Anaesthesiol Scand* 37:742, 1993.)

Droperidol

Droperidol has been variably successful as an antiemetic in patients undergoing surgery. Lower doses ($0.25\text{--}0.5 \text{ mg}$) seem to be more effective than higher doses and recovery after anesthesia is not delayed.^{64,65} The use of doses as low as 1.25 mg can produce untoward effects in the postoperative period (e.g., restlessness).⁶⁶ In children, $50\text{--}75 \mu\text{g} \cdot \text{kg}^{-1}$ is useful to control postoperative nausea, although this dose is also associated with a delay in discharge. When propofol and droperidol were compared, postoperative nausea in patients was similar, but droperidol patients were fit for discharge 1 hour later.⁶⁷

Promethazine

Promethazine is the most common phenothiazine derivative used in children to control postoperative nausea and vomiting. The usual dose is $0.5\text{--}1.0 \text{ mg} \cdot \text{kg}^{-1}$. In patients undergoing strabismus surgery, promethazine, $0.5 \text{ mg} \cdot \text{kg}^{-1}$ iv and im, was significantly more effective than droperidol in controlling overall postoperative vomiting, particularly vomiting that occurred after the children left the hospital.⁶⁸

Serotonin Antagonists

Ondansetron is the most studied drug in this class. It has a half-life that is approximately 3.5 hours in adults but shorter in children and longer in the elderly (mean 7.9 hr).⁶⁹ The primary adverse effect it produces is headache, although patients may also have diarrhea, constipation, sedation, and transient minor elevations in liver function tests. The drug is not associated with extrapyramidal reactions. Studies of patients undergoing anesthesia showed that doses of $4\text{--}8 \text{ mg}$ were very effective

antiemetics, although 4 mg was not less effective than 8 mg (Fig. 46-8).⁷⁰ Ondansetron, 4 mg, was superior to metoclopramide for control of postoperative nausea or vomiting.⁷¹ An 8-mg dose was superior to droperidol, 1.25 mg, and metoclopramide, 10 mg.⁷² In children, ondansetron, 100 μg , was more effective than droperidol, 75 $\mu\text{g} \cdot \text{kg}^{-1}$, or placebo.⁷³ In another study that compared ondansetron to placebo followed by a “rescue” antiemetic of 20 mg of iv metoclopramide and 25 mg of iv hydroxyzine, reduction of postoperative nausea in patients was similar.⁷⁴ Overall, though, ondansetron is most effective when given at the end of surgery.⁷⁵

Figure 46-8. Nausea and vomiting were significantly less in ambulatory surgery patients with 4 or 8 mg ondansetron given before induction of anesthesia compared with placebo or 1 mg ondansetron. (Reprinted with permission from Pearman MH: Single dose intravenous ondansetron in the prevention of postoperative nausea and vomiting. *Anaesthesia* 49[suppl]:11, 1994.)

Acupressure

Acupressure may also decrease postoperative nausea and vomiting. Acupressure bands that were placed preoperatively and removed 6 hr postoperatively reduced nausea and vomiting by 50% (Fig. 46-9).⁷⁶ The pressure bands cost just \$8.00 and are reusable.

Figure 46-9. The treatment point P.6 is located on the anterior surface of the forearm, 2 inches proximal to the distal wrist crease between the tendons of musculus flexor carpi radialis and musculus palmaris longus. The forearm of the patient from the transverse crease of the wrist to the cubital crease is measured as 12 inches, or one-sixth of the forearm. (Reprinted with permission from Fan C, Tanhui E, Joshi S *et al*: Acupressure treatment for prevention of postoperative nausea and vomiting. *Anesth Analg* 84:821, 1997.)

The routine use of antiemetics is controversial, given that a large percentage of patients do not experience postoperative nausea and vomiting. We use propofol for induction (see below), and then metoclopramide and a low dose of droperidol early in the case. If, despite this regimen, patients are nauseous or vomiting in the PACU, we use ondansetron. For children at risk for emesis, after an inhalation induction, we convert to an infusion of propofol.

Fluid Administration Before Surgery

Generally, before they are brought to the operating room, all patients have an intravenous catheter inserted with fluids infusing. Exceptions are children or adults afraid of needles or those who do not have a vein that can be easily accessed. Once the intravenous catheter has been inserted, we give an initial fluid bolus of 10 ml \cdot kg⁻¹. Patients who received 10 ml \cdot kg⁻¹ of fluid in an initial bolus preoperatively were less thirsty, drowsy, and dizzy postoperatively than patients who were given 2 ml \cdot kg⁻¹ of fluid.⁷⁷

INTRAOPERATIVE MANAGEMENT: CHOICE OF ANESTHETIC METHOD

There are several choices among anesthetic methods: general anesthesia or regional or local anesthesia with or without sedation. Except for obstetric cases for which regional anesthesia may be safer than general anesthesia, both are otherwise equally safe. However, even for experienced anesthesiologists, there is a failure rate associated with regional anesthesia. Certainly, some procedures are possible only with a general anesthetic. For others the preference of patients, surgeons, or anesthesiologists may determine selection. Cost may be a factor: the cost of sedation is usually less than the cost of a general anesthetic. Time to recovery may also influence the choice of anesthetic method. Of 1180 ambulatory surgery patients, two-thirds of whom had general anesthesia for their procedures while the remainder had a local anesthetic supplemented by iv sedation, the three patients who required admission on the day of surgery had undergone general anesthesia.⁷⁸ The incidence of postoperative nausea and vomiting in the recovery room after local anesthesia and sedation was 6% compared with 14% after general anesthesia. Recovery times were also shorter after local anesthesia and sedation. In a study comparing regional anesthesia and sedation with general anesthesia for abortion, patients' blood pressures and pulse rates tended to be higher with the former (Fig. 46-10).⁷⁹ In that study, during local block with sedation, patients had more perioperative complaints, although few recalled any discomfort, presumably because of amnesia caused by benzodiazepines. Also, time spent in the operating room was longer with regional anesthesia because more time was needed to institute the block than the general anesthetic; however, time in the PACU was shorter because patients were more alert and in less pain. In a similar study of 136 patients undergoing arthroscopy, intra-articular bleeding and onset time were less, and the success rate was much higher after general anesthesia than local anesthesia: for 16 of 66 patients who received local anesthesia it was either partially successful or unsatisfactory, whereas general anesthesia was successful for all procedures.⁸⁰ Another study of patients undergoing minor gynecologic procedures showed an advantage of general anesthesia. Oxygen saturation was normal in all the patients who received general anesthesia, whereas sedated patients had significant oxygen desaturation.⁸¹ Some of the sedated patients made movements that interfered with surgery, and 6% of sedated patients were switched to a general anesthetic.

Figure 46-10. Heart rate and blood pressure were higher with regional anesthesia and sedation than with general anesthesia. (Reprinted with permission from Raeder

One adverse effect associated with spinal anesthesia is headache, but headaches are also experienced by patients after general anesthesia. Especially when smaller spinal needles are used, the incidence of headache after either technique may be similar. In one study, after either method of anesthesia, incidence of headache ranged between 11% and 15%.⁸² In that study, backache was higher (26%) after spinal anesthesia than general anesthesia (4%). However, incidence of sore throat (24%) and nausea (22%) was higher after general anesthesia than spinal anesthesia (6% for both). For some procedures (e.g., immersion lithotripsy), iv sedation techniques may reduce preparation and recovery time and the need for invasive monitors (e.g., Foley catheter) when compared with regional techniques.⁸³ More large studies of patients undergoing ambulatory surgery are needed, particularly with some of the newer drugs used for both sedation and general anesthesia (e.g., propofol, desflurane, and mivacurium) and some newer techniques (e.g., spinal anesthesia with Sprotte needles), to show that regional anesthesia is better than general anesthesia or that general anesthesia is better than conscious sedation.

Regional Techniques

Local anesthesia and regional anesthesia have long been used for ambulatory surgery. As early as 1963, for example, 56% of ambulatory procedures were performed with the use of these techniques.⁸⁴ Regional techniques commonly used for ambulatory surgery, in addition to spinal and epidural anesthesia, include local infiltration, brachial plexus and other peripheral nerve blocks, and iv regional anesthesia. General anesthesia can also be supplemented with regional nerve blocks. Performing a block takes longer than inducing general anesthesia and the incidence of failure is higher. Unnecessary delays can be obviated by performing the block beforehand in a preoperative holding area. Because the duration of effect of the newer general anesthetics and muscle relaxants is very short, recovery after a regional technique may take longer than after a general anesthetic. An occasional patient may experience syncope when the needle for the regional block is inserted. In the experience of oral and maxillofacial surgeons in Massachusetts in the late 1980s, 1 of 228 patients fainted when local anesthesia was injected.⁸⁵ The incidence was reduced by a factor 2 when parenteral sedation was also provided (see monitored anesthesia care below). Patients usually experience less pain when local or regional anesthesia has been used. Patients might still have a numb extremity (e.g., after a brachial plexus block) but otherwise might meet all criteria for discharge. In such instances, the extremity must be well protected with a sling and patients must be cautioned to protect against injury because they are without normal sensations that would warn them of vulnerability. Reassurance that sensation will return should be provided.

Spinal Anesthesia

Spinal anesthesia is useful for ambulatory procedures in children who were born prematurely. The procedure is best performed with the child in the sitting position, head supported and somewhat extended, to prevent occlusion of the airway. Tetracaine, 0.8 mg · kg⁻¹, mixed with an equal volume of 10% dextrose, is injected into the L4–5 interspace with a 22-gauge Quincke needle 3.75 cm long. Since a leg raised may drive the spinal higher, the child must be kept flat when, for example, the Bovie pad is placed on the back. Hypotension is less common after spinal anesthesia in infants than adults, although it occurs when the spinal is very high. An iv line can be started in a lower extremity after the spinal is in place, the extremity is anesthetized, and vasodilatation is present.

The use of spinal needles with pencil-point noncutting tips has prompted a resurgence of spinal anesthesia for ambulatory surgery in adults. Epidural or spinal anesthesia is suitable for pelvic, lower abdominal, and lower extremity surgery but not for laparoscopic procedures because most people have difficulty breathing in the head-down position with the abdomen distended with air. Motor block of the legs with either technique may delay a patient's ability to walk; however, the use of a short-acting local anesthetic through an epidural catheter, for example, will minimize this problem while allowing the duration of anesthesia to match the sometimes unpredictable duration of surgery. Nausea is much less frequent after epidural or spinal anesthesia than after general anesthesia.

Different drugs and drug concentrations have been used for spinal anesthesia. Lidocaine and mepivacaine are ideal for ambulatory surgery because of their short duration of action, although lidocaine use has been problematic because of transient neurologic symptoms. In one study comparing patients who underwent knee arthroscopy with either 45 mg 1.5% mepivacaine or 60 mg 2% lidocaine, 22% of patients who received lidocaine had transient neurologic symptoms (back pain or dysesthesia). The symptoms were treated by NSAIDs and resolved within 5 days; no patients who received mepivacaine developed transient neurologic symptoms.⁸⁶

For spinal anesthesia, needle size and shape are important to reduce the incidence of postdural puncture headache. The Sprotte and Whitacre needles are less traumatic to the lumbar dura mater than are Quincke needles. Incidence of postdural puncture headache with pencil-point Sprotte and Whitacre needles was 1–4% in one study,⁸⁷ but failure of anesthesia was higher when a Sprotte needle was used. In that study, spinal anesthetic required supplementation with additional parenteral drugs for 17% of patients with use of the Sprotte needle and for only 3% with the Whitacre needle. The position of the needle tip and the need to insert the Sprotte needle a little farther once cerebral spinal fluid is identified may have been factors. Rates of failed block have been shown to be higher with smaller gauge needles and are similar with Quincke and Whitacre needles. In some studies, incidence of postdural puncture headache after use of needles with a cutting tip, such as the Quincke 25–27 gauge, was higher than with the Sprotte needle. When same size Whitacre and Quincke needles were compared, the incidence of postdural puncture headache was higher with the Quincke (8.5%) than with the Whitacre needle (3%).⁸⁸ Another study reported incidence of headache with 25-gauge Quincke needles at 15% and with 22-gauge Whitacre needles at 6%.⁸⁹

Smaller gauge needles result in a lower incidence of postdural puncture headache. With 25-gauge needles, the incidence of postdural puncture headache reported was four times that with 26-gauge needles; with 26-gauge needles, it was 9.6%; and with 27-gauge needles, it was 1.5%.^{90,91} Needles of 27 gauge are associated with increasingly difficult insertion, a higher rate of failed block, and the risk of a spinal anesthetic with the use of the introducer. The incidence of postspinal headache is higher in younger individuals, particularly in women.⁹² Backaches can be problematic after spinal anesthesia, especially when more than two attempts have been made to insert a spinal needle.⁹³ Women also tend to have more complaints of backache than do men.⁹⁴

For those patients who do receive spinal anesthesia, it is incumbent upon the anesthesiologist and the facility to have follow-up with telephone calls to ensure that no disabling symptoms of headache have developed. If the headache does not respond to bed rest, analgesics, and oral hydration, the patient must return to the hospital for a course of caffeine iv therapy or an immediate epidural blood patch.

Spinal anesthesia should not be avoided in ambulatory surgery patients simply because they may be more active postoperatively than inpatients. Bed rest does not reduce the frequency of headache.⁹⁵ Early ambulation may decrease the incidence.⁹⁶ Further study is needed to assess the relative risk–benefit ratio of spinal anesthesia as a technique for the ambulatory surgery patient.

Epidural and Caudal Anesthesia

Epidural anesthesia takes longer to perform than spinal anesthesia. Onset with spinal anesthesia is more rapid, although recovery may be the same with either technique. Some studies suggest that bicarbonate can be added to solutions for faster onset of epidural anesthesia. An advantage of the epidural block is that it can be performed outside the operating room, and after the surgical procedure is completed, the problem of postdural puncture headache is usually avoided. In one study of 682 patients, 90% were discharged within 5 hours of the operation.⁹⁷ Two patients in that series required a blood patch, and the overall incidence of backache was 9.3%.

Caudal anesthesia is a form of epidural anesthesia commonly used in children before surgery below the umbilicus as a supplement to general anesthesia and to control postoperative pain. Bupivacaine, 0.175–0.25%, in a volume of 0.5–1.0 ml · kg⁻¹ may be used. The block may be more difficult in children, particularly those who weigh more than 10 kg and are obese, if landmarks for the block are difficult to locate. The block is usually administered while the child is anesthetized. After injection, the depth of general anesthesia can be reduced. Because of better pain control after a caudal block, children can usually ambulate earlier and be discharged sooner than without a caudal block. In one study, patients who received a dose of 0.175% bupivacaine for caudal block went home more than 1 hour before patients who received higher or lower concentrations of drug.⁹⁸ Pain control and discharge times were no different whether the caudal block had been placed before surgery or after it was completed.⁹⁹

Nerve Blocks

Among the different nerve blocks, the axillary nerve block is popular for hand surgery, particularly useful in an ambulatory setting because postoperative nausea, vomiting, and pain are less. An interscalene block is useful for shoulder surgery. To decrease pain after inguinal hernia repair in children or adults, an ilio-inguinal-hypogastric nerve block is often successful. A femoral nerve block with genitofemoral nerve infiltration is useful for procedures that require saphenous vein stripping. In one study that compared femoral nerve block to spinal anesthesia for vein stripping surgery, femoral nerve block resulted in a shorter hospital stay and less postoperative pain (both in the PACU and at home), backache, and headache; furthermore, patient satisfaction was greater with the nerve block.¹⁰⁰

Sedation and Analgesia

Many patients who undergo surgery with local or regional anesthesia prefer to be sedated and to have no recollection of the procedure. Sedation is important, in part, because injection with local anesthetics can be painful, and lying on a hard operating room table for any time can be uncomfortable. Levels of sedation vary from light, during which a patient's consciousness is minimally depressed, to very deep, in which protective reflexes are partially blocked and response to physical stimulation or verbal command may not be appropriate. When patients are unsuitable for outpatient general anesthesia, surgery can often be performed if local or regional anesthesia is supplemented with conscious sedation. In such cases, however, patients may be at much greater risk for complications after conscious sedation. In one study of approximately 100,000 anesthetics, monitored anesthesia care was associated with the highest rate of mortality (209 deaths per 10,000 anesthetic episodes).¹⁰¹ Children who have surgery usually will not remain immobile unless they are deeply sedated or receive general anesthesia.

During conscious sedation, medication is administered to provide amnesia and sedation, to reduce anxiety, and to control pain. Agents commonly used in adults for sedation include benzodiazepines for anxiety reduction and amnesia, opioids to control pain, and low doses of iv or inhalation anesthetics to provide sedation. Benzodiazepines, such as midazolam, or the iv anesthetic propofol may be used alone because both reduce anxiety and cause amnesia. For more painful procedures, or when a block does not seem to be working well, opioids (e.g., fentanyl, $25\text{--}50\ \mu\text{g} \cdot \text{kg}^{-1}$) are usually added. Nonsteroidal analgesics such as ketorolac are also useful.

For adults, the iv route of administration is the most popular. Drugs are often titrated to effect, although bolus dosing may produce a faster effect. The challenge lies in selecting appropriate drugs and titrating their doses. Usually, drugs from the sedative-hypnotic and analgesic classes are administered. Propofol is particularly useful because during low-dose infusions, degree of sedation can be adjusted precisely. Infusion rates between 25 and $100\ \text{mg} \cdot \text{hr}^{-1}$ produce dose-dependent levels of sedation (Fig. 46-11).¹⁰² Fentanyl with or without an NSAID is often used for analgesia.

Figure 46-11. Sedation produced by increasing propofol dose in patients with spinal anesthesia. Group 1 = propofol $0.2\ \text{mg} \cdot \text{kg}^{-1}$ bolus and $0.5\ \text{mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$; Group 2 = propofol $0.4\ \text{mg} \cdot \text{kg}^{-1}$ bolus and $1\ \text{mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$; Group 3 = propofol $0.5\ \text{mg} \cdot \text{kg}^{-1}$ bolus and $2\ \text{mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$; Group 4 = propofol $0.7\ \text{mg} \cdot \text{kg}^{-1}$ bolus and $4\ \text{mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$. Mean values \pm SEM; * $p < 0.05$ from lowest dose group. (Reprinted with permission from Smith I, Monk TG, White PF, Ding Y: Propofol infusion during regional anesthesia: Sedative, amnestic and anxiolytic properties. *Anesth Analg* 79:313, 1994.)

In children multiple drug combinations are used to achieve sedation. One combination often given is im meperidine ($2\ \text{mg} \cdot \text{kg}^{-1}$), promethazine ($1\ \text{mg} \cdot \text{kg}^{-1}$), and chlorpromazine ($1\ \text{mg} \cdot \text{kg}^{-1}$). With this combination, sedation is long-lasting for painful procedures. In one study of 63 patients, the onset time for sedation was 27 minutes, and the children were sitting upright after the procedure in ~ 100 minutes.¹⁰³ Rectal thiopental is also used for sedation; however, children particularly dislike shots or rectal injections. Chloral hydrate, not as useful for painful procedures, is given in a dose of $20\text{--}100\ \text{mg} \cdot \text{kg}^{-1}$ orally or rectally and onset time occurs after ~ 1 hour. Other popular drugs for sedation include oral midazolam, pentobarbital ($5\text{--}7\ \text{mg} \cdot \text{kg}^{-1}$), and a combination of oral meperidine ($2\ \text{mg} \cdot \text{kg}^{-1}$) and promethazine ($0.5\ \text{mg} \cdot \text{kg}^{-1}$). Unfortunately, chloral hydrate is bitter. Oral transmucosal fentanyl citrate (described above) may be a more readily accepted alternative. Ketamine, which provides analgesia, amnesia, and sedation, can be given intravenously, orally, rectally, or intramuscularly. It is commonly used in the operating room to sedate children who have become uncontrollable and refuse to inhale anything after an attempt at induction with an inhalation anesthetic has failed. A dose of $2\ \text{mg} \cdot \text{kg}^{-1}$ im is usually adequate.¹⁰⁴ For oral doses, $5\ \text{mg} \cdot \text{kg}^{-1}$ resulted in onset of action after 20 minutes, similar to that with oral midazolam, although patients who received midazolam were discharged from the hospital sooner.¹⁰⁵ Nitrous oxide can also be used, but achieving sedation may be difficult when nitrous oxide is not supplemented with other agents.

In one survey of 89 pediatric residency programs, the most popular method for sedating children for medical procedures was use of chloral hydrate; a combination of parenteral meperidine, promethazine, and chlorpromazine was second; and pentobarbital was third.¹⁰⁶ Those sedation regimens were associated with few serious adverse effects, except for two deaths reported in infants with congenital heart disease who were sedated with a combination of meperidine, promethazine, and chlorpromazine.

For adults, the proper dose might be selected by having the patient control dosage, as has been successful with postoperative analgesia. When anesthetist versus patient control of sedation with midazolam was compared during bilateral extraction of third molar teeth, the total dose of midazolam administered was similar, $5.0\text{--}5.3$ mg, but 67% of patients reported that they could sedate themselves better than the anesthetist could.¹⁰⁷ Equal numbers preferred either one or the other technique and overall satisfaction with both techniques was high. In a similar study in which patient-controlled sedation with propofol was compared with anesthetist-administered midazolam and fentanyl for third molar tooth extraction, satisfaction was higher with patient-controlled sedation for both subjective intraoperative feelings and willingness to have the procedure again.¹⁰⁸ When using such techniques, though, it is important to adjust dose for patient variables, such as patient age. In a study of 30 patients, aged 26–72 years, who received a fixed propofol dose of $0.7\ \text{mg} \cdot \text{kg}^{-1}$ when they pressed a button, older age was significantly correlated with a deeper maximum level of sedation.⁵³ When a drug is administered by an anesthetist or anesthesiologist for sedation, the amount needed may be unclear. Eye signs and verbal responses from the patient are important monitors. To determine an adequate amount of midazolam, good patient markers are ptosis, with the eyelid halfway across the pupil, or a loss of interest in maintaining conversation with a tendency toward monosyllabic replies. The latter marker is associated with a shorter duration of amnesia after a procedure; the former, with more intense amnesia during the procedure.¹⁰⁹ During patient-controlled administration of propofol, sedation no deeper than full eyelid closure with prompt response to verbal command was reported.⁵³ In summary, patient-controlled sedation may or may not be associated with equal or less drug administered. The patient, though, has some control over medication, which produces a positive psychological response.

As with any other instance in which the potential exists for complete loss of consciousness, appropriate monitoring and availability of resuscitation equipment are essential. The monitoring standards for general anesthesia also apply for monitored sedation. A member of the anesthesia care team must be continuously present and an anesthesiologist must be immediately available. Cardiac and respiratory monitoring is required. Pulse oximetry is essential and oxygen, if necessary, should be provided. Capnography is also invaluable, even when a nasal cannula is used to administer oxygen (Fig. 46-12).¹¹⁰ All drugs used during conscious sedation can cause hypoxia, and oxygen should be routinely used (see Fig. 46-6). Monitoring patient awareness or level of consciousness by speaking to the patient frequently is also an important component of this type of anesthetic. The patient must be reassured, particularly during times of distress or discomfort, and, if necessary, given additional medication. The patient must also be warned of stimulating events about to take place (e.g., injection of local anesthetic, laparoscope insertion, tourniquet inflation). An expected event is less stimulating than an unanticipated one. Conversation is also important because some drugs, e.g., the benzodiazepines, which normally reduce anxiety, may, in some individuals, increase it. A patient may appear sleepy but not calm or, conversely, calm but not sleepy. Conversation with the patient may better determine how the patient is really feeling. An excellent review of this topic is provided by Sá Rêgo *et al.*¹¹¹

(Reprinted with permission from Prstojevic SJ, Sabol SR, Goldwasser MS, Johnson C: Utility of capnography in predicting venous carbon dioxide partial pressure in sedated patients during outpatient oral surgery. *J Oral Maxillofac Surg* 50:37, 1992.)

General Anesthesia

The drugs selected for general anesthesia determine how long patients stay in the postanesthesia recovery unit after surgery, and for some patients, whether or not they can be discharged to go home. Some of the pertinent issues, *i.e.*, problems with nausea and vomiting and drowsiness, have already been discussed in the premedication section (Managing the Anesthetic: Premedication).

Induction

Since its introduction, propofol has almost become the induction agent of choice for patients undergoing ambulatory surgery. This fact in part relates to its half-life: the elimination half-life of propofol is 1–3 hours, shorter than that of methohexital (6–8 hr) or thiopental (10–12 hr). Although the effect of drugs given for induction seems to be transient, these drugs can depress psychomotor performance for several hours. When induction doses of propofol and thiopental were compared, psychomotor impairment in patients was evident for up to 5 hours after thiopental, but only for 1 hour after propofol (Fig. 46-13).¹¹² When a volatile anesthetic is used after induction with propofol, recovery is much more rapid than after induction with thiopental, methohexital, or etomidate. For arthroscopic surgery lasting 30–40 minutes, patients who received isoflurane for maintenance of anesthesia recovered 1 hour sooner with propofol induction than with thiopental.¹¹³ The differences in recovery are also apparent in children. In a study of children who received propofol, halothane, or thiopental for induction, recovery was associated with less nausea and discharge home was much more rapid after propofol.¹¹⁴ Postoperatively patients have much less nausea and vomiting after an induction with propofol; such a reduction is even more apparent when propofol is also used for maintenance of anesthesia.

Figure 46-13. Performance on the digit symbol substitution test after either propofol 2.5 mg · kg⁻¹, then 1 mg · kg⁻¹ (diamonds); thiopental 5 mg · kg⁻¹, then 2.0 mg · kg⁻¹ (filled squares); or control (open squares) in 12 healthy volunteers (**p* < 0.05, ****p* < 0.001 vs. control; • *p* < 0.05, ••• *p* < 0.001 vs. propofol). (Reprinted with permission from Korttila K, Nuotto EJ, Lichtor L *et al*: Clinical recovery and psychomotor function after brief anesthesia with propofol or thiopental. *Anesthesiology* 76:676, 1992.)

Pain on injection can be a problem with propofol. Pain is more likely on injection into dorsal hand veins and is minimized if forearm or larger antecubital veins are used. Some individuals, though, experience pain if the drug is injected into proximal larger veins. Nonetheless, thrombophlebitis does not appear to be a problem after iv administration of this agent. The addition of 1 ml lidocaine (1%) to 19 ml propofol significantly reduced the incidence and severity of pain on injection (Fig. 46-14).¹¹⁵ Lidocaine injected immediately before propofol only partially reduced the incidence.

Figure 46-14. Pain on injection of propofol with and without lidocaine. Median, interquartile range and 90th percentile are illustrated. (Reprinted with permission from Helbo-Hansen S, Westergaard V, Krogh BL, Svendsen HP: The reduction of pain on injection of propofol. The effect of lignocaine. *Acta Anesthesiol Scand* 32:502, 1988.)

Most children and some adults prefer not to have an intravenous catheter inserted before the start of anesthesia. Sevoflurane has a relatively low blood-gas partition coefficient and the speed of induction is similar to, albeit somewhat slower than, that of propofol. In one study of 146 adults, when sevoflurane with nitrous oxide and fentanyl for induction was compared with propofol, fentanyl, and nitrous oxide, induction with sevoflurane was approximately 60 sec longer than with propofol; sevoflurane for induction and maintenance was associated with a higher incidence of postoperative emetic sequelae compared with propofol.¹¹⁶ Yet, when a vital capacity inhaled induction with sevoflurane was compared with an iv induction with propofol for ambulatory surgery in adults, sevoflurane resulted in a faster loss of consciousness (30 sec). Adverse effects, recovery times, and patient satisfaction were similar to those after a propofol induction.¹¹⁷ When sevoflurane was compared to halothane for induction of anesthesia in children, induction times were not clinically different.

Parental presence is becoming more accepted during induction of anesthesia in children, even though scientific evidence of its advantages is not conclusive. Some studies show that children are less upset and have fewer behavioral changes after surgery if a parent is present during induction. Others have suggested that parents can become upset when they see their anesthetized child, who appears to be dead, albeit breathing and with a beating heart. Separation anxiety on the part of the parents is probably no different if the child is awake or asleep.

For short procedures, some patients may not require neuromuscular blocking drugs; others may need an ultra-short-acting agent to facilitate tracheal intubation or a

muscle relaxant during the procedure. Succinylcholine, a depolarizing relaxant, is used to facilitate tracheal intubation and to provide a short period of profound relaxation. Skeletal muscle aches and pains can be problematic with the drug. Myalgia may occur up to the fourth postoperative day and be more painful than the surgery itself. The incidence of myalgia was significantly higher in patients who walked shortly after surgery (66%) than in inpatients who remained resting in bed (13.9%); the pain can persist for 2–3 days.¹¹⁸ Pretreatment with a variety of drugs (*d*-tubocurarine, 0.05 mg · kg⁻¹; diazepam, 0.05 mg · kg⁻¹; calcium gluconate, 1000 mg; succinylcholine, 10 mg) has been reported to lessen and even eliminate the myalgia that occurs after administration of succinylcholine. Succinylcholine should be used with caution in children because of the possibility of cardiac arrest related to malignant hyperthermia or unsuspected muscular dystrophy, particularly Duchenne's disease.

Nondepolarizing drugs such as rapacuronium or rocuronium have rapid onset times that are similar to those with succinylcholine. Rapacuronium's duration of action is similar to duration with succinylcholine. In one study, onset time was 67 sec for succinylcholine vs. 83 sec for rapacuronium, and conditions for endotracheal intubation were similar.¹¹⁹ Times until clinically sufficient recovery from neuromuscular block induced after succinylcholine (time until T₁ = 90%) was 10.6 min and after rapacuronium was 11.6 min with reversal by neostigmine. Not all anesthesiologists have found that intubating conditions are as good after rapacuronium as after succinylcholine. Rapid recovery from block is a desired characteristic if, for example, tracheal intubation is not possible. In one study, when 0.07 mg neostigmine was given 2 minutes after rapacuronium administration, the time to 25% T₁ twitch recovery decreased from 16 minutes in control patients to 8–10 minutes.¹²⁰ When rocuronium and succinylcholine were compared, 1 mg · kg⁻¹ of succinylcholine had an onset time (as measured by suppression of twitch tension to 5% of control value) of 0.8 minutes, and 0.6 mg · kg⁻¹ rocuronium had an onset time of 1.2 minutes.¹²¹ The time to recovery of twitch was of the same order of magnitude as time with vecuronium. The nondepolarizing drugs are useful because they are not associated with postoperative muscle pain. Postoperative nausea may be less, in particular with rapacuronium, because reversal of the drug (after single injection) with neostigmine may not be necessary. Priming doses can also accelerate onset time. A priming dose of mivacurium, for example, can reduce the time for onset of action of the drug. When mivacurium was given in a bolus dose of 0.15 mg · kg⁻¹, onset time was 3.5 minutes; onset time was reduced to 2 minutes when a priming dose was used, longer by 1.5 minutes compared with onset time of succinylcholine.¹²² If a higher dose of nondepolarizing drugs is used, onset time should be shorter, particularly when a priming dose is also used. Certainly, other longer-acting, nondepolarizing drugs can also be used for tracheal intubation of ambulatory surgical patients. Tracheal intubation can also be performed without the use of muscle paralytics. Combinations of alfentanil and propofol have been described. Nonetheless, succinylcholine provides the most rapid onset of paralysis, which is particularly useful when there is a risk of aspiration or hypoxia.

Maintenance

Although many factors affect the choice of agents for maintenance of anesthesia, one primary consideration for ambulatory anesthesia is speed of wake-up. Time to recovery may be measured by various criteria; however, for an ambulatory center, a patient may be considered awake when able to leave the center. Actual discharge from an ambulatory center, though, may depend on administrative issues, such as a written order from a surgeon or anesthesiologist. The time necessary before a patient can be taken from the operating room after completion of surgery, or a patient's ability to skip the post-anesthesia care unit and go directly to a step-down unit may be directly related to the anesthetic and result in cost savings for an institution. Does choice of maintenance agent affect recovery after anesthesia? The relatively new drugs, propofol, desflurane, and sevoflurane, have characteristics that make them ideal for maintenance of anesthesia for ambulatory surgery. Propofol has a short half-life, and when used as a maintenance agent, results in rapid recovery and few side effects. Desflurane and sevoflurane, halogenated ether anesthetics with low blood-gas partition coefficients, seem to be ideal for general anesthesia for ambulatory surgery. Sevoflurane, unlike desflurane, facilitates a smooth inhalation induction of anesthesia, the preferred technique to ensure rapid recovery of children in ambulatory surgery centers. For children who receive either sevoflurane or halothane, or halothane and then desflurane for induction and maintenance of anesthesia, recovery times are significantly shorter after sevoflurane or desflurane. Studies with desflurane and sevoflurane have shown that recovery afterward, even by comparison with that after propofol for maintenance, is rapid. In one study of laparoscopic surgery, patients emerged from anesthesia with desflurane and nitrous oxide significantly faster than after propofol or sevoflurane and nitrous oxide, although the ability to sit up, stand, and tolerate fluids and the time to fitness for discharge were no different (Fig. 46-15).¹²³ On arrival in the PACU, a significantly higher percentage of patients who had received desflurane or sevoflurane were eligible to skip the PACU for recovery. Nausea was greater, albeit not significantly, when desflurane was used for maintenance. Other studies have shown relatively equal times to discharge with propofol, desflurane, and enflurane; propofol for maintenance of anesthesia resulted in less nausea and vomiting than did the two inhalation anesthetics. When propofol was used for induction, and maintenance was with halothane, enflurane, isoflurane, or propofol, no differences were readily apparent among the four agents 4 hours after the end of anesthesia when the patient was discharged.¹²⁴ Children who received desflurane or halothane to maintain anesthesia for ambulatory surgery (induction was with halothane after premedication with midazolam), awakened more rapidly after desflurane (10 min vs. 21 min).¹²⁵ The desflurane group was in the PACU 8 fewer minutes, although discharge times were unaffected. Desflurane is not recommended for induction in children because it causes a high incidence of coughing and laryngospasm. In one study, halothane was used first, and then children received desflurane, after which no airway irritability was reported.¹²⁵

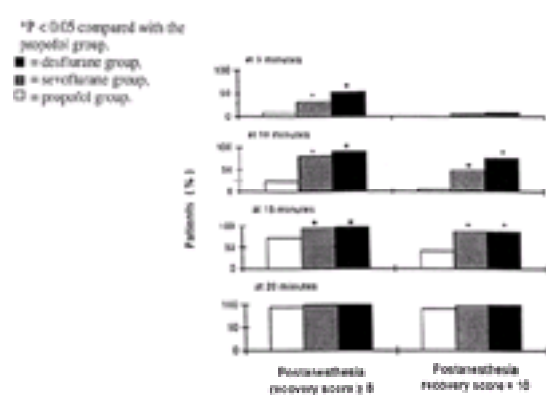

Figure 46-15. Percentage of patients receiving a modified Aldrete score ³8 of a possible 10 points at various times after discontinuation of anesthesia. The Aldrete score is a measure of postanesthetic recovery that includes consciousness, activity, respiration, and blood pressure level. (Reprinted with permission from Song D, Joshi G, White PF: Fast-track eligibility after ambulatory anesthesia: A comparison of desflurane, sevoflurane and propofol. *Anesth Analg* 86:267, 1998.)

Desflurane can be problematic in individuals with hypertension when the concentration of the drug is increased rapidly. Rapid changes in concentration of isoflurane or desflurane were associated with sympathetic and renin-angiotensin system activity and with transient increases in arterial blood pressure and heart rate.¹²⁶ Increases were greater in patients who received desflurane. These patients also had a transient increase in plasma vasopressin concentration. This response can be avoided if the concentration is increased more slowly or if other drugs that attenuate the sympathetic response, such as opioids, are also administered.

The use of nitrous oxide for ambulatory anesthesia is an issue because the incidence of emesis may be greater after nitrous oxide than after other inhalation agents. Yet many studies have shown that nitrous oxide can be used successfully for ambulatory anesthesia. A meta-analysis, designed to determine if nitrous oxide significantly reduced the odds of postoperative nausea and vomiting (PONV) included 26 trials from 24 studies.¹²⁷ Overall, the use of nitrous oxide increased the risk of PONV by 28% (Fig. 46-16). The maximal benefit of nitrous oxide avoidance was seen in females (46%).

Figure 46-16. Meta-analysis of randomized trials comparing incidence of PONV with or without the use of nitrous oxide.¹²⁷ The odds ratios (OR) are plotted on the x-axis using a logarithmic scale. The position of each solid square represents the OR of each trial. The horizontal line indicates the 95% confidence interval. In each trial, squares to the left of unity (OR = 1) imply that omission of nitrous oxide reduced the incidence of nausea and vomiting; conversely, squares to the right of unity signify the omission of nitrous oxide increased the likelihood of nausea and vomiting. (Reprinted with permission from Divatia JV, Vaidya JS, Badwe RA, Hawaldar RW:

Propofol is better than some other agents for ambulatory anesthesia because it is associated with less nausea. When patients undergoing laparoscopy or arthroscopy received either propofol or isoflurane for maintenance, initial recovery was faster after isoflurane, although nausea was much less in the group who received propofol.⁶³ After outpatient restorative dental surgery lasting 2–4 hours, patients who received propofol went home sooner than those who received isoflurane, primarily because of less nausea.¹²⁸ Less postoperative nausea after propofol has been reported when it was compared with enflurane, isoflurane, or desflurane. Despite the greater initial cost of propofol, overall costs may be less because treatment for nausea and vomiting is eliminated. In one study of patients undergoing office-based surgical procedures, patients received either propofol or sevoflurane for induction and maintenance.¹²⁹ Costs of drugs used for anesthesia were the same; yet, when wasted propofol was also considered, propofol costs were greater by approximately \$5.00. Overall, though, average cost per patient was lowest when propofol was used for both induction and maintenance, primarily because of the costs of treating nausea and vomiting (\$46 propofol induction and maintenance; \$63 propofol induction and sevoflurane maintenance; \$72 sevoflurane induction and maintenance).

Muscle relaxation for ambulatory anesthesia extends beyond the time of relaxation for intubation, particularly when nondepolarizing drugs have been used. The clinical effect of the nondepolarizing agent mivacurium, given as a bolus injection to 25% recovery, lasts 12–18 minutes, the shortest duration of effect for the neuromuscular blockers. The duration of action of rocuronium, vecuronium, rapacurium, and atracurium ranges from 25 to 40 minutes. Because mivacurium is dependent on plasma cholinesterase for metabolism, recovery can be prolonged in the presence of atypical plasma cholinesterase. In patients with normal plasma cholinesterase levels, postoperative vomiting might be reduced if mivacurium does not have to be reversed. Reversal agents must be used unless there is no doubt that muscle relaxation has been fully reversed. When an ambulatory surgery case is expected to last more than 30 minutes, mivacurium may not be indicated. Particularly for children, in whom muscle relaxants generally have decreased potency, thereby enabling more rapid recovery, longer-acting drugs, such as pancuronium, may be used without sequelae. When residual muscle paralysis was examined in children undergoing ambulatory surgery who had received pancuronium, atracurium, or vecuronium, no postoperative weakness could be observed in the PACU.¹³⁰

Opioids, when given intraoperatively, are useful to supplement both intraoperative and postoperative analgesia. Fentanyl is probably the most popular drug, although all other available narcotics have been tried. All narcotics can cause nausea, sedation and dizziness, which can delay a patient's discharge. Nonsteroidal analgesics are not effective as supplements during general anesthesia, although they are useful in controlling postoperative pain, particularly when given before skin incision. For example, in a study of patients undergoing breast biopsy, patients received intravenous tenoxicam (20 mg) either 30 min before surgery (37 patients) or after incision (40 patients); tenoxicam given before surgery resulted in lower postoperative pain scores, a longer time before additional postoperative analgesia was needed, and lesser amounts of postoperative pain medications than tenoxicam administered after incision.¹³¹ Nerve blocks can also be used in conjunction with general anesthesia, both to decrease intraoperative anesthesia requirement and to effectively reduce postoperative pain.

Certain devices or equipment are commonly used during anesthesia for inpatients. The usefulness of forced-air warmers for the ambulatory surgery patient has been questioned. Patients undergoing general anesthesia for arthroscopic surgery were warmed either with blankets or with a forced-air warmer. Those warmed with forced air were initially 0.4°C warmer in the PACU and 0.6°C warmer after 1 hour, but shivering rates were not different (about 35%) and discharge rates were the same.¹³² Routine aspiration of gastric contents to decrease postoperative nausea and vomiting is probably unwarranted, except for laparoscopic surgery. Despite what is commonly stated, insertion of an orogastric tube was associated with an increased incidence of nausea and vomiting (incidence for both was doubled) in ambulatory surgery patients.¹³³ Bispectral index (BIS) monitors are thought to decrease anesthesia requirement without sacrificing amnesia during general anesthesia. One group found that for ambulatory patients, inhalation anesthetic requirement was reduced with the BIS monitor. However, paralytic use increased to prevent coughing or bucking, and discharge times were no different with or without the use of the BIS monitor.¹³⁴

Using a laryngeal mask airway (LMA) provides several advantages for allowing a patient to return to baseline status quickly. Muscle relaxants required for intubation can be avoided. Coughing is less than with tracheal intubation. Anesthetic requirements are reduced. Hoarseness and sore throat are also reduced. Overall, cost savings result with the use of LMAs. Because of gastric insufflation, though, nausea and vomiting may be greater. The use of the LMA has been described for laparoscopic procedures, although the potential for aspiration exists because of an inflated abdomen during laparoscopy.

MANAGEMENT OF POSTANESTHESIA CARE

Many recovery issues are part of patient selection and perioperative management and must be considered before the patient enters the PACU. Managing common problems in the PACU quickly and effectively is as important as appropriate patient selection and choice of anesthetic technique if the patient is to return home on the day of surgery. The three most common reasons for delay in patient discharge from the PACU are drowsiness, nausea and vomiting, and pain. All three are a function of intraoperative management; but nausea, vomiting, and pain also can be treated in the PACU.

Reversal of Drug Effects

Reversal of muscle relaxants is not unique to the ambulatory surgery patient and will not be discussed here. Reversal of opioids may sometimes be necessary. However, to prevent pain postoperatively, longer-acting drugs, such as morphine, may be used. Flumazenil, a benzodiazepine receptor antagonist, has primarily been used to reverse the effects of sedation after endoscopy and spinal anesthesia. Reversal of psychomotor impairment with flumazenil is not complete, and the subjective experience of sedation is not necessarily attenuated.^{135,136} After 1 hour there was usually no difference in psychomotor performance from control (Fig. 46-17).¹³⁶ Even patients who appeared awake still suffered some psychomotor impairment.¹³⁵ Reversal of amnesia with flumazenil is only partial, and the duration of the reversal effect may not be long enough to be clinically significant. Flumazenil should not be used routinely as a benzodiazepine antagonist, but only when sedation appears to be excessive. In addition, reversal of benzodiazepine-induced sedation by flumazenil should not replace appropriate ventilatory assistance and, if necessary, placement of an endotracheal tube.

Midazolam-saline (MS) (●), midazolam-flumazenil (MF) (■) and propofol (P) (▲) groups. P < 0.05 compared with: *group P; § group MS; † preoperative baseline.

Figure 46-17. Time to perform the serial 7s test (reverse counting aloud from 100 to 44 in steps of 7) after midazolam alone, midazolam and then flumazenil given 60 min after the operation, or propofol. Performance initially improved after flumazenil, but 2 hr after the operation, performance in the two midazolam groups was similarly impaired compared to performance after propofol. (Reprinted with permission from Kestin IG, Harvey PB, Nixon C: Psychomotor recovery after three methods of sedation during spinal anaesthesia. *Br J Anaesth* 64:675, 1990.)

Nausea and Vomiting

Nausea and vomiting are the most common reasons both children and adults have protracted stays in the PACU or unexpected hospital admission. Nausea and vomiting are also the most common adverse effect in patients in the PACU.¹³⁷ Much research has been undertaken to study prophylactic treatment of this problem before surgery and the practice techniques in the operating room that can minimize nausea and vomiting in the PACU. The treatment of this problem, once it occurs in the PACU, has not received as much study. Drugs that are useful for this problem include metoclopramide 20 mg, hydroxyzine 25 mg, or droperidol 0.625–1.25 mg. Metoclopramide, 0.15 mg · kg⁻¹, is useful for children.¹³⁸ Ondansetron and propofol have also been shown to be effective. In a study of the treatment of nausea and vomiting after ambulatory surgery in more than 500 patients at 10 medical centers, ondansetron doses of 1, 4, and 8 mg were found to be equally effective.¹³⁹ Ondansetron 8 mg was similarly effective against nausea or vomiting after laparoscopy.⁷³ Propofol, 10 mg, prevented nausea with an 81% success rate (vs. 35% with placebo) in the PACU.¹⁴⁰ A dose of 0.5 mg · kg⁻¹, given at the end of an inhalation anesthetic, prolonged awakening time but reduced emesis, request for antiemetic

rescue, and time to home readiness by at least 30 minutes.¹⁴¹ Propofol also can be infused at low doses (8–12 μg after a loading dose of 10 mg) for 2 hr.¹⁴² Because anxiety may be associated with persistent nausea and vomiting, midazolam also has been used for treatment.¹⁴³ Because pain may be associated with nausea, treatment of pain frequently decreases nausea.

Pain

Postsurgical pain must be treated quickly and effectively. It is important for the practitioner to differentiate postsurgical pain from the discomfort of hypoxemia, hypercapnia, or a full bladder. Factors that correlate with greater postoperative pain are younger age of patient, less serious illness, greater body mass index; operative site, and duration of surgery.¹⁴⁴ Medications for pain control should be given in small iv doses (e.g., 1–3 mg \cdot 70 kg^{-1} morphine or 10–25 μg \cdot 70⁻¹ kg fentanyl). Intramuscular injection of opioid for pain control in the PACU is probably not necessary. Onset of action of drugs is faster after intravenous than after oral administration. Control of postoperative pain may include administration of opioid analgesics or nonsteroidal anti-inflammatory agents, which are not associated with respiratory depression, nausea, or vomiting. Fentanyl is the narcotic frequently used to control postoperative pain, although the effects of morphine last longer. Patients who received fentanyl for pain control required additional injections and went home no sooner compared to patients who received morphine.¹⁴⁵ Patients given ketorolac both iv in the PACU and then orally for up to 6 days postoperatively had less somnolence and earlier return of bowel function than those who received fentanyl in the PACU and codeine with aspirin afterward.¹⁴⁶ In another study, ibuprofen controlled postoperative pain, gave pain relief for a longer period than fentanyl, and was associated with less nausea and vomiting (Fig. 46-18).¹⁴⁷ The effects of iv ketorolac lasted longer than the effects of oral ibuprofen or aspirin.¹⁴⁸ Nonsteroidal anti-inflammatory drugs (NSAIDs) can increase bleeding, although there is no evidence at this time of such a danger for most ambulatory surgery procedures. When swelling and pain are problematic postoperatively, e.g., tooth extraction, NSAIDs can be more effective than opioids in relieving both.¹⁴⁹ Particularly for operations associated with moderate pain, butorphanol, in a nasal spray for delivery, may afford satisfactory relief. Onset of action is rapid (2–3 minutes), and the effects last for 4–5 hours. Because the spray can be taken home for pain treatment, this method of delivery seems ideal for patients undergoing ambulatory surgery. This method is also ideal for children, particularly when no iv is used for (painful) surgery, e.g., myringotomy. Butorphanol is lipophilic, quickly absorbed, and has no vasoactive effects.

Figure 46-18. Pain and nausea were much less in the same-day surgery stepdown unit, during the ride home, and after arrival home with ibuprofen when either ibuprofen or fentanyl was given preoperatively to patients undergoing laparoscopic surgery. (Reprinted with permission from Rosenblum M, Weller RS, Conard PL *et al*: Ibuprofen provides longer lasting analgesia than fentanyl after laparoscopic surgery. *Anesth Analg* 73: 255, 1991.)

We manage pain in both adults and children initially either with a short-acting opioid analgesic, e.g., fentanyl (25 μg \cdot 70 kg^{-1}), or with an injection of ketorolac 60 mg \cdot 70⁻¹ kg im or iv. Fentanyl is repeated at 5-minute intervals until pain is controlled. For children, we also use an elixir of acetaminophen containing codeine (120 mg acetaminophen, 12 mg codeine, in each 5 ml of solution). Five milliliters is administered to children between the ages of 3 and 6, and 10 ml to children between the ages of 7 and 12. Children are returned to parental care as soon as they are awake. We find frequently that infants younger than 6 months of age usually need to be reunited with their mothers for nursing (or bottle feeding) after a procedure not associated with severe pain. For older infants and young children in the PACU, acetaminophen, 60 mg per year of age (given orally or rectally), is commonly used to relieve mild pain. Intravenous fentanyl (up to a dose of 2 μg \cdot kg^{-1} is preferred for more severe pain). Meperidine (0.5 mg \cdot kg^{-1}) and codeine (1–1.5 mg \cdot kg^{-1}) can be given im if an iv route has not been established.

Preparation for Discharging the Patient

In addition to the PACU, many ambulatory surgery centers in the United States have another area, often known as a Phase II recovery room, where patients may stay until they are able to tolerate liquids, walk, and/or void. With the anesthetics that are typically used in ambulatory surgery ORs, patients who are awakened in the OR and are evaluated as 9 or 10 according to the modified Aldrete scoring system may be transferred directly to Phase II recovery from the OR. Some criteria for discharge from the Phase II recovery, however, have been created without scientific basis. One criterion is the ability to tolerate liquids before being discharged. When this criterion was applied to patients 1–18 years of age, incidence of postoperative nausea was greater and hospital stay was 20 minutes longer than in the control groups (Fig. 46-19).¹⁵⁰ Patients who were not required to drink were not readmitted because of dehydration. Similar results have been found in adults.¹⁵¹ Even though it is warranted after spinal or epidural anesthesia, some data suggest that requiring low-risk patients to void before discharge may be unduly conservative if patients are willing to return to a medical facility if they are unable to void.¹⁵² Perhaps some patients do not need to go to the PACU before going to the Phase II recovery area. We frequently transfer all patients who have had sedation and some patients who have had a general anesthetic directly to the Phase II recovery area if they can tolerate sitting in a chair in the operating room and can breathe comfortably. Practical criteria for patient discharge from the operating room, from the PACU, and from the Phase II recovery area are needed that in no way compromise patient safety. The value of psychomotor tests to measure different phases of recovery (except for research purposes) is questionable.

Figure 46-19. The incidence of vomiting in the day surgery unit was significantly less in those individuals who were allowed to drink electively compared with those who were required to drink prior to discharge. (Reprinted with permission from Schreiner MS, Triebwasser A, Keon TP: Ingestion of liquids compared with preoperative fasting in pediatric outpatients. *Anesthesiology* 72:593, 1990.)

Scoring systems have been developed to guide transfer from the PACU to the Phase II recovery room and from Phase II recovery to home (Table 46-2).¹⁵³ These criteria do little to test higher levels of function, such as the ability to use one's hands, to drive a car, or to remain alert for long enough to drive. Patients may feel fine after they leave the hospital, but they should be advised against driving for at least 24 hours after a procedure. Patients and responsible parties should be reminded that the patient should not operate power tools or be involved in major business decisions for up to 24 hours. Once the patient leaves the medical facility, supervision may not be as good as it was in the hospital. Therefore, before a patient is discharged, dressings should be checked. It is wise to include the responsible person in all discharge instructions, which are best made available on printed forms.

|------------------------------|---|
| Vital signs | |
| 2 | = within 20% of preoperative value |
| 1 | = 20-40% of preoperative value |
| 0 | = 40% of preoperative value |
| Ambulation and mental status | |
| 2 | = oriented \times 3 and has a steady gait |
| 1 | = oriented \times 3 or has a steady gait |
| 0 | = neither |
| Pain or nausea | |
| 2 | = minimal |
| 1 | = moderate |
| 0 | = severe |
| Surgical bleeding | |
| 2 | = minimal |
| 1 | = moderate |
| 0 | = severe |
| Intake and output | |
| 2 | = has had po fluids and has voided |
| 1 | = has had po fluids or has voided |
| 0 | = neither |

* The total score is 16; if the patient's score is 9, then the patient is fit for discharge. Reprinted with permission from Chung F, Anz: Discharge criteria changing? J Clin Anesth 5:645, 1993.

Table 46-2. REPRESENTATIVE SURGICAL PROCEDURES APPROPRIATE FOR SPINAL ANESTHESIA

Patients should also be informed that they may experience pain, headache, nausea, vomiting, or dizziness and, if succinylcholine was used, muscle aches and pains apart from the incision for at least 24 hours. A patient will be less stressed if the described symptoms are expected in the course of a normal recovery. Written instructions are important. In 100 consecutive outpatients who were given no written instructions at discharge, despite oral instructions to the contrary, 31% of patients went home unaccompanied by a responsible adult; 73% of car owners drove within 24 hours of surgery (30% within 12 hours); 9% of patients drove themselves home; and a bus driver returned to work on the same day, to drive a busload of passengers a distance of 95 miles.¹⁵⁴ The addition of written and oral education techniques at discharge has a significant impact on improving compliance.

For patients with a language barrier (e.g., in a population with a high percentage of immigrants), consent forms, procedural explanation, and discharge information may have to be written in languages other than English and the services of an interpreter may be necessary. Nursing staff should assess the adult who will take the patient home to determine whether he or she is in fact a responsible person. A responsible person is someone who is physically and intellectually able to take care of the patient at home. Facilities should develop a method of follow-up after the patient has been discharged. At some facilities staff members telephone the patient the next day to determine the progress of recovery; others use follow-up postcards.

Whenever we become innovative in the management of our outpatients, we must assess how a cost-effective "no frills" approach to care affects patient safety. We must determine what we can do for the patient who lives alone, the patient whose responsible person is unable to manage his or her needs, the patient without means of transportation, and the patient with limited insurance coverage. Hospital beds can be set aside for patients who require observation. Patients in these beds after an ambulatory surgical procedure are still considered outpatients. They are charged for the hours spent in the observation area. Some hospitals have joined with management firms to build a hospital hotel or medical motel close to the hospital itself. The hotel, usually a nonmedical facility, offers the outpatient a comfortable, inexpensive, and convenient place to recuperate while being cared for by family or nurses. Home health care nursing may be appropriate after surgical procedures such as reduction mammoplasty, abdominoplasty, vaginal hysterectomy, and major open ligament repairs of the knee. The various services for outpatient observation and home health care stand today where outpatient surgery stood in the health care delivery system 20 years ago. Prospective studies are needed to assess the quality of care and the effect these innovative approaches have on patient safety.

Patient, procedure, availability and quality of aftercare, and anesthetic technique must be individually and collectively assessed to determine acceptability for ambulatory surgery. A delicate balance must be maintained between the physical status of patient, the proposed surgical procedure, and the appropriate anesthetic technique, to which must be added the expertise level of the anesthesiologist caring for a patient.

Anesthesia for ambulatory surgery is a rapidly evolving specialty. Patients once thought unsuitable for ambulatory surgery are now considered to be appropriate candidates. Operations once thought unsuitable for outpatients are now routinely performed in the morning so that the patient can be discharged in the afternoon or evening. The appropriate anesthetic management before these patients come to the operating room, during their operation, and then afterwards is the key to success. The availability of both shorter-acting anesthetics and longer-acting analgesics and antiemetics enables us to care for patients in ambulatory centers effectively.

Monitored anesthesia care is usually provided to patients undergoing therapeutic or diagnostic procedures that would otherwise be unacceptably uncomfortable or unsafe without the continuous attention of an anesthesiologist who is solely dedicated to optimizing the patient's comfort and safety. Monitored anesthesia care commonly, but not necessarily, involves the administration of drugs with anxiolytic, hypnotic, analgesic, and amnestic properties, either alone or as a supplement to a local or regional technique.

TERMINOLOGY

It is important to distinguish between “monitored anesthesia care” and “sedation/analgesia.” *Sedation/analgesia*, which has replaced the previously used term “conscious sedation,” is the term currently used by the American Society of Anesthesiologists (ASA) in their recently published Practice Guidelines for Sedation and Analgesia by Non-anesthesiologists.¹ *Conscious sedation*, a term first introduced by the American Dental Association (ADA), described the level of sedation provided to patients during dental procedures.² The ADA defined conscious sedation as “a depressed level of consciousness that allows the patient the ability to independently and continuously maintain an airway and respond appropriately to physical stimulation and verbal command.” The current ASA definition of sedation/analgesia is “a state which allows patients to tolerate unpleasant procedures while maintaining adequate cardiorespiratory function and the ability to respond purposefully to verbal command or tactile stimulation.” Thus, conscious sedation or sedation/analgesia is intended to be a lighter level of sedation than may be encountered during monitored anesthesia care. The term sedation/analgesia is used most frequently in the context of care provided by nonanesthesiologists, and implies a level of vigilance that is less than that required for general anesthesia.³ The ASA specifically states that those patients whose only response is reflex withdrawal from a painful stimulus are sedated to greater degree than encompassed by the term sedation/analgesia. Significant inter-patient variability in dose response will cause some patients intended to receive sedation/analgesia to be rapidly sedated to a level much deeper than intended. Indeed, some patients may have no movement in response to painful stimulus (general anesthesia). This situation compromises patient safety and may increase morbidity and mortality. Education of nonanesthesiologist providers as described by the ASA practice guidelines is intended to reduce the likelihood of such outcomes. *Monitored anesthesia care* implies the potential for a deeper level of sedation than that provided by sedation/analgesia and is always administered by an anesthesiologist provider. The standards for preoperative evaluation, intraoperative monitoring, continuous presence of a member of the anesthesia care team, etc. are no different from those for general or regional anesthesia.⁴

Conceptually, monitored anesthesia care is attractive because it should invoke less physiologic disturbance and allow a more rapid recovery than general anesthesia. It is instructive to review the ASA position statement approved by the House of Delegates in 1986 and last amended in 1998.⁴ The ASA definition of monitored anesthesia care is as follows:

Monitored anesthesia care is a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.

Monitored anesthesia care includes all aspects of anesthesia care—a preprocedure visit, intraoperative care and postprocedure anesthesia management.

During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, including but not limited to:

Monitoring of vital signs, maintenance of the patient's airway and continual evaluation of vital functions

Diagnosis and treatment of clinical problems which occur during the procedure

Administration of sedatives, analgesics, hypnotics, anesthetic agents or other medications as necessary to ensure patient safety and comfort

Provision of other medical services as needed to accomplish the safe completion of the procedure

Monitored anesthesia care often includes the administration of doses of medications for which the loss of normal protective reflexes or loss of consciousness is likely. Monitored anesthesia care refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure. If, for an extended period of time, the patient is rendered unconscious and/or loses normal protective reflexes, then anesthesia care shall be considered a general anesthetic.

Because monitored anesthesia care is a physician service provided to an individual patient and is based on medical necessity, it should be subject to the same level of reimbursement as general or regional anesthesia. Accordingly, the ASA Relative Value Guide provides for the use of proper basic procedural units, time units and age and risk modifier units as the basis for determining reimbursement.

The ASA also states that monitored anesthesia care should be requested by the attending physician and be made known to the patient, in accordance with accepted procedures of the institution. In addition, the ASA states that the service must include the following:

1. Performance of a preanesthetic examination and evaluation.
2. Prescription of anesthetic care.
3. Personal participation in, or medical direction of, the entire plan of care.

4. Continuous physical presence of the anesthesiologist or, in the case of medical direction, of the resident or nurse anesthetist being medically directed.
5. Proximate presence, or in the case of medical direction, availability of the anesthesiologist for diagnosis and treatment of emergencies.

Furthermore, the ASA states that all institutional regulations pertaining to anesthesia services shall be observed, and all the usual services performed by the anesthesiologist shall be furnished, including but not limited to:

1. Usual noninvasive cardiocirculatory and respiratory monitoring.
2. Oxygen administration, when indicated.
3. Administration of sedatives, tranquilizers, antiemetics, narcotics, other analgesics, beta-blockers, vasopressors, bronchodilators, antihypertensives, or other pharmacologic therapy as may be required in the judgment of the anesthesiologist.

From the statements above it is apparent that monitored anesthesia care always involves preoperative assessment and evaluation and intraoperative monitoring but does not necessarily involve the administration of sedative drugs. It should be self-evident that whenever monitored anesthesia care is planned, the facilities and expertise to secure the airway and provide general anesthesia should be immediately available.

PREOPERATIVE ASSESSMENT

The preoperative evaluation is an essential prerequisite to monitored anesthesia care and should be as comprehensive as that performed prior to any general or regional anesthetic (see [Chapter 18](#)). However, in addition to the usual evaluation for the patient who is planned to undergo general anesthesia, there are additional considerations unique to monitored anesthesia care that may ultimately determine the success or failure of the procedure. Because the patient will be conscious during monitored anesthesia care, it is important to evaluate the patient's ability to remain motionless and, if necessary, actively cooperate throughout the procedure. Thus, it is important to evaluate the patient's psychological preparation for the planned procedure. It is also important to elicit the presence of coexisting sensorineural or cognitive deficits. These factors or the inability to communicate with the patient may on occasion make general anesthesia a more appropriate alternative. Verbal communication between physician and patient is very important for three reasons: (1) as a monitor of the level of sedation and cardiorespiratory function, (2) as a means of explanation and reassurance for the patient, and (3) as a mechanism of communication when the patient is required to actively cooperate. Although cardiorespiratory disease is often an indication to perform a procedure using monitored anesthesia care rather than general anesthesia, there are occasions when cardiorespiratory disease may reduce the utility of monitored anesthesia care. For example, the presence of a persistent cough may make it very difficult for the patient to remain immobile, which can be particularly dangerous during ophthalmologic or awake neurosurgical procedures. Attempts to attenuate coughing with sedation techniques are likely to be unsuccessful and potentially harmful, as a significant level of anesthesia is required to abolish the cough reflex. Similarly, some patients with significant cardiovascular disease may experience orthopnea and be unable to lie flat for an extended period.

SEDATION TECHNIQUES FOR MONITORED ANESTHESIA CARE

Sedative hypnotics are commonly administered intravenously during monitored anesthesia care. The desired endpoint is to provide patient comfort, maintain cardiorespiratory stability, improve operating conditions, and to prevent recall of unpleasant perioperative events. It is helpful to delineate and individualize the goals of the sedation technique in each patient in order to formulate an appropriate regimen. The ideal sedation technique involves the administration of either individual or combinations of analgesic, amnestic, and hypnotic drugs. There should be a minimal incidence of side-effects, such as cardio-respiratory depression, nausea and vomiting, delayed emergence, and dysphoria. There should be a rapid and complete recovery after completion of the procedure. Ideally, the sedation technique will allow the patient to be able to communicate during the procedure. Experience shows that this level of sedation is optimal for the patient's comfort and safety. If the level of sedation is deepened to the extent that verbal communication is lost, most of the advantages of sedation/analgesia are lost and the risks of the technique approximate those of general anesthesia with an unprotected and uncontrolled airway ([Table 47-1](#)). Monitored anesthesia care may or may not involve the provision of sedation. However, because monitored anesthesia care is provided by anesthesiologists, the range of sedation can safely be expanded to include significantly deeper sedation techniques than those provided by nonanesthesiologists during sedation/analgesia.

| Sedation/Analgesia | Deep Sedation or General Anesthesia with an Unprotected Airway |
|------------------------------------|--|
| Verbal communication possible | Verbal communication impossible |
| Patient cooperation possible | Patient cooperation impossible |
| Patient reassurance possible | Patient reassurance impossible |
| Airway reflexes intact | Airway reflexes attenuated |
| Apnea unlikely | Apnea possible |
| Airway dilator muscles functional | Airway dilator muscles dysfunctional |
| Obstruction unlikely | Obstruction likely |
| Work of breathing normal | Work of breathing increased |
| Respiratory control intact | Respiratory control impaired |
| Hyperventilation unlikely | Hyperventilation likely |
| Airway intervention unlikely | Airway intervention likely |
| Unplanned intubation unlikely | Unplanned intubation likely |
| Respiratory complications unlikely | Respiratory complications likely |
| | Apnea |
| | Obstruction |
| | Post-obstructive edema |
| | Hypoxia/hypercarbia |
| | Hypoxic neurologic injury |

Table 47-1. COMPARISON OF THE IMPORTANT FEATURES OF A SEDATION/ANALGESIA TECHNIQUE AND A DEEP SEDATION TECHNIQUE

The word "sedation" is derived from the Latin *sedatus*, meaning composed or calm. However, in current anesthetic practice "sedation" is often used loosely to describe analgesia, anxiolysis, and hypnosis, either individually or in combination.^{5,6} Ideally, any sedation technique should strive to identify specific causes of and provide specific therapy for pain, anxiety, and agitation. Pain may be treated by local or regional analgesia, systemic analgesics, or removal of the painful stimulus. Anxiety may be reduced by the use of an anxiolytic such as a benzodiazepine and reassurance by the anesthesiologist. Patient agitation may be a result of pain or anxiety, but it is also vitally important to eliminate life-threatening factors such as hypoxia, hypercarbia, impending local anesthetic toxicity, and cerebral hypoperfusion. Other, less ominous, but often overlooked, causes of discomfort and agitation include a distended bladder, hypothermia, hyperthermia, pruritus, nausea, positional discomfort, uncomfortable oxygen masks and nasal cannulae, iv cannulation site infiltration, a member of the surgical team leaning on the patient, and prolonged pneumatic tourniquet inflation.

Pharmacologic Basis of Conscious Sedation Techniques—Optimizing Drug Administration

During conscious sedation, drugs are administered in the expectation that the desired therapeutic effects will result. Ideally, the therapeutic effects are as predicted. Occasionally, however, the result can depart significantly from expected, leading to an adverse effect upon patient comfort and safety. The ability to predict the effects of the drugs in our armamentarium demands an understanding of their pharmacokinetic and pharmacodynamic properties. This understanding is a fundamental prerequisite for the design of an effective sedation regimen and greatly increases the probability of producing the desired therapeutic effect. Context-sensitive half-time, effect-site equilibration time, and quantification of anesthetic/sedative drug interactions are all recently introduced concepts that are particularly useful in the context of conscious sedation and will be discussed in some detail.

The ultimate objective of any dosing regimen is to deliver a therapeutic concentration of drug to its site of action. The concentration of drug that is achieved as a result of a drug administration regimen is determined by the unique pharmacokinetic properties of that drug in that particular patient. The therapeutic response to a particular drug concentration is described by the pharmacodynamics of that particular patient-drug combination. There is a large degree of pharmacokinetic and pharmacodynamic variability, producing a significant variability in the dose-response relationship in clinical practice. Variability in drug response is an especially important consideration during MAC because these patients have unprotected airways. Excessive sedation may result in cardiac or respiratory depression. Inadequate sedation may result in patient discomfort and potential morbidity due to lack of cooperation. As a general principle, to avoid excessive levels of sedation, drugs should be titrated in small increments or by adjustable infusions rather than administered in larger doses according to predetermined notions of efficacy. In an ideal dosing regimen, an effective concentration of drug is achieved and then adjusted according to the magnitude of the noxious stimulus. If the noxious stimulus is increased or decreased, the concentration is increased or decreased accordingly. By the end of the procedure, the drug concentration should have decreased to a level compatible with rapid recovery. This approach requires the use of drugs that are easily titratable, such as propofol. When using drugs such as propofol, adjustable-rate continuous infusions are the most logical method of maintaining a desired therapeutic concentration. When the traditional method of intermittent bolus administration is used, significant fluctuations in drug concentration occur. Under these circumstances, the plasma concentrations are either above or below the desired therapeutic range for a significant proportion of the procedure ([Fig. 47-1](#)). Continuous infusions are superior to intermittent bolus dosing because they produce less fluctuation in drug concentration, thus reducing the number of episodes of inadequate or excessive sedation. Administration of drugs by continuous infusion rather than by intermittent dosing also reduces the total amount of drug administered and facilitates a more prompt recovery.⁷

Figure 47-1. The changes in drug concentration during differing administration techniques. The heavy line represents a continuous infusion of a drug. In this situation the drug is maintained within the therapeutic range for most of the procedure. The lighter line represents the drug concentration resulting from intermittent bolus administration. The drug concentration is significantly above or below the desired therapeutic level for most of the procedure.

Distribution, Elimination, Accumulation, and Duration of Action

Following the administration of iv anesthetic drugs, the immediate distribution phase causes a brisk decrease in plasma levels as the drug is transported to the rapidly equilibrating vessel-rich group of tissues. There is a simultaneously occurring distribution of drug to the less well perfused tissues such as muscle and skin. Over time, the drug is also distributed to the poorly perfused tissues such as bone and fat. Although the latter compartments are poorly perfused, they may accumulate significant amounts of lipophilic drugs over the course of prolonged drug administration. This peripheral depot of drug may contribute to a delayed recovery when it is eventually released back into the central compartment after its administration is discontinued. These redistributive factors are extremely important determinants of drug effect and may increase or decrease the plasma concentration of a drug in a time-dependent fashion.

The Elimination Half-Life

Until recently, the elimination half-time was the predominant pharmacokinetic parameter utilized as the predictor of an anesthetic drug's duration of action. In everyday clinical practice, however, this parameter has not greatly enhanced our ability to predict anesthetic drug disposition. Only in single-compartment models does the elimination half-time actually represent the time required for a drug to reach half of its initial concentration after administration. This is because in a single-compartment model elimination is the only process that can alter drug concentration. Intercompartmental distribution cannot occur because there are no other compartments for the drug to be distributed to and from. Most drugs in the anesthesiologist's armamentarium are lipophilic and are therefore more suited to multicompartmental modeling than single-compartment modeling. Similarly, other pharmacokinetic parameters, such as distribution half-time, distribution volume, intercompartmental rate constants, and so forth, do not provide us with a practical means of predicting drug disposition. In multicompartmental models, the metabolism and excretion of some iv anesthetic drugs may have only a minor contribution to changes in plasma concentration when compared with the effects of intercompartmental distribution.

Context-Sensitive Half-Time

In order to improve the description and understanding of anesthetic drug disposition, the concept of context-sensitive half-time has been developed.⁸ This concept has greatly improved our understanding of anesthetic drug disposition and is clinically applicable. The effect of distribution upon plasma drug concentration varies in magnitude and direction over time and is dependent upon the drug concentration gradients that exist between the various compartments. For example, during the early part of an infusion of a lipophilic drug, distributive factors will tend to decrease plasma concentrations as the drug is transported to the unsaturated peripheral tissues. Later, after the infusion is discontinued, drug will return from the peripheral tissues and re-enter the central circulation. The relative effect on plasma concentrations of distributive processes versus elimination varies over time and from drug to drug. The context-sensitive half-time describes the time required for the plasma drug concentration to decline by 50% after terminating an infusion of a particular duration. This parameter is calculated by utilizing computer simulation of multicompartmental models of drug disposition (Fig. 47-2). The context-sensitive half-time reflects the combined effects of distribution and metabolism on drug disposition. There are several interesting aspects of these data. First, the data confirm the clinical impression that as the infusion duration increases, the context-sensitive half-time of all the drugs increases; this phenomenon is not described in any way by the elimination half-life. The increase in context-sensitive half-time is particularly marked with fentanyl and thiopental. In the case of fentanyl, drug that is irreversibly eliminated from the plasma by hepatic clearance is immediately replaced by drug returning from the peripheral compartments. Thus, although fentanyl has a shorter elimination half-life than that of sufentanil (462 vs. 577 min), its context-sensitive half-time is much greater than that of sufentanil after an infusion of duration longer than 2 hours. The storage and later release of fentanyl from peripheral binding sites delays the decline in plasma concentration that would otherwise occur. The context-sensitive half-times of all the drugs bear no constant relationship to their elimination half-times. Note also that the context-sensitive half-time of propofol is short compared with that of thiopental. Although the context-sensitive half-times of propofol and thiopental are comparable following a brief infusion, the context-sensitive half-time of thiopental increases rapidly following all but the shortest infusions. This finding confirms the clinical impression that thiopental is not an ideal drug for continuous infusion during ambulatory procedures. The context-sensitive half-time of propofol is prolonged to a minimal extent as the infusion duration increases. After an infusion of propofol, the drug that returns to the plasma from the peripheral compartments is rapidly cleared by metabolic processes and is therefore not available to retard the decay in plasma levels. This difference between thiopental and propofol is attributable to (1) the high metabolic clearance of propofol compared to thiopental and (2) the relatively slow rate at which propofol returns to the plasma from peripheral compartments.

Figure 47-2. Context-sensitive half-times as a function of infusion duration. These data were generated from the computer model of Hughes *et al.*⁸ It can be seen that the context-sensitive half-time of propofol demonstrates a minimal increase as the duration of the infusion increases. Also note that for infusions of short duration sufentanil has a shorter half-time than alfentanil. (Reproduced with permission from Hughes MA, Glass PSA, Jacobs JR: Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology* 76:334, 1992.)

Alfentanil is the opioid that has, until recently, been most frequently studied, described, and promoted in the context of ambulatory techniques. This is because alfentanil has a very short elimination half-time, one-fifth that of sufentanil (111 vs. 577 min). However, despite sufentanil's short elimination half-time, its context-sensitive half-time is actually less than that of alfentanil for infusions up to 8 hours in duration. This phenomenon is explained in part by the huge distribution volume of sufentanil. After termination of a sufentanil infusion, the decay in plasma drug concentrations is accelerated not only by elimination but also by the continued redistribution of sufentanil into peripheral compartments. On the other hand, the small distribution volume of alfentanil equilibrates rapidly; therefore, peripheral distribution of drug away from the plasma is not a significant contributor to the decay in plasma concentration after an infusion. The data derived from computer simulation by Hughes *et al.*⁸ show that the plasma decay of alfentanil is slower than that of sufentanil following infusions of similar duration to those used during conscious sedation. Thus, despite its short elimination half-time, alfentanil may not necessarily be superior to sufentanil for ambulatory sedation techniques.

How Does the Context-Sensitive Half-Time Relate to the Time to Recovery? Although the context-sensitive half-time represents a significant advance in our ability to describe drug disposition, this parameter does not directly describe how long it will take the patient to recover from conscious sedation. The context-sensitive half-time merely describes how long it will take for the plasma concentration of the drug to decrease by 50%. The time to recovery is dependent upon other additional factors. The difference between the plasma concentration at the end of the infusion and the plasma concentration below which awakening can be expected is an

obvious factor in determining time to recovery. For example, if the drug concentration is maintained at a level just above that required for awakening, the time to recovery will be more rapid than after an infusion during which the drug concentration is much greater than that required for awakening (Fig. 47-3). Furthermore, although context-sensitive half-time is a reflection of plasma drug decay, awakening from anesthesia is actually a function of effect-site (*i.e.*, brain) concentration decay. Changes in effect-site concentration demonstrate a variable time lag behind changes in plasma drug concentration. Effect-site equilibration is a concept that is particularly relevant to iv sedation. When a drug is administered iv by bolus or infused rapidly, there is a delay before the onset of clinical effect. This delay occurs because the plasma is not usually the site of action but is merely the route by which the drug reaches its effect site. If some parameter of drug effect can be measured (*e.g.*, power spectrum electroencephalographic [EEG] analysis in the case of opioids), the half-time of equilibration between drug concentration in the blood and the drug effect can then be determined.⁹ This parameter is abbreviated $t_{1/2}^{ke0}$. Drugs with a short $t_{1/2}^{ke0}$ will equilibrate rapidly with the brain and have a shorter delay in onset than drugs that have a longer $t_{1/2}^{ke0}$. Thiopental, propofol, and alfentanil have short $t_{1/2}^{ke0}$ values compared with midazolam, sufentanil, and fentanyl. The $t_{1/2}^{ke0}$ allows predictions to be made of the time course of equilibration of the drug between the blood and the brain. A distinct time lag between the peak serum fentanyl concentration and the peak EEG slowing can be seen. In contrast, following alfentanil administration, the EEG changes closely parallel serum concentrations. The $t_{1/2}^{ke0}$ for fentanyl is 6.4 minutes compared with a $t_{1/2}^{ke0}$ of 1.1 minutes for alfentanil. If an opioid is required to blunt the response to a single brief stimulus, alfentanil might represent a logical choice over fentanyl. The $t_{1/2}^{ke0}$ is an important determinant of bolus spacing when titrating drugs to clinical effect. In the case of drugs like midazolam, which have a relatively long equilibration time (midazolam $t_{1/2}^{ke0} = 0.97\text{--}5.6$ min), boluses of drug should be spaced far enough apart to allow the full peak effect to be clinically appreciated before further drug administration in order to avoid inadvertent overdosing.^{10,11} For example, even if the shortest quoted equilibration half-time for midazolam (0.9 min) is used, it will take 2.7 minutes for effect-site concentrations to be 87.5% equilibrated. Other factors are also important determinants of bolus size and spacing. For example, a low cardiac output will markedly delay drug arrival at the site of action. If sufficient time is not given for the drug to take effect before giving additional drug increments, significant cardiorespiratory compromise may occur. Furthermore, the effects of initial doses of most drugs in anesthetic practice are terminated by redistribution, which is dependent upon blood flow to redistribution sites. If there is reduced blood flow to redistribution sites because of pre-existing and iatrogenic decreases in cardiac output, the dangerous adverse effects of these drugs are likely to be markedly prolonged. An example of the above scenario is the patient with a hemodynamically compromising cardiac tachydysrhythmia that requires sedation for cardioversion. Careful, well-spaced, small boluses of drug should be given to induce the appropriate level of sedation, bearing in mind that it may take several minutes for the full effect of a small bolus dose to become apparent.

Figure 47-3. The context-sensitive half-time is not the sole determinant of the time it takes for the patient to awaken. This parameter merely reflects the time taken for the plasma concentration of a drug to decrease by 50%. The time to awakening is determined in addition by the difference in concentration at the end of the procedure and the concentration below which awakening will occur.

DRUG INTERACTIONS IN CONSCIOUS SEDATION

At the present time, no one inhaled or iv drug can provide all the components of conscious sedation (*i.e.*, analgesia, anxiolysis, and hypnosis) with an acceptable margin of safety or ease of titratability. Therefore, patient comfort is usually maintained with a combination of drugs. Combinations of drugs should theoretically enable reductions in the dose requirements of individual drugs, thereby resulting in a reduction in adverse drug effects. For example, during general anesthesia, the combination of propofol and fentanyl by infusion has been shown to produce a more rapid recovery and better stress response abolition than the use of propofol alone.¹² Under most circumstances, the hypnotic effect of combinations of barbiturates or propofol with either opioids or benzodiazepines is synergistic. However, the decision whether to use a particular drug combination depends upon to what extent the synergistic interaction also extends to the undesirable nonhypnotic interactions of the drugs such as cardiorespiratory depression.

Drug interactions may have both a pharmacodynamic and a pharmacokinetic basis and may vary depending on the combination of drugs being coadministered, the dose range over which these drugs are administered, and the specific clinical effect that is measured. For example, because fentanyl is primarily an analgesic rather than a hypnotic, it reduces propofol requirements for suppression of response to skin incision to a much greater degree than it reduces propofol requirements for induction of anesthesia.¹³ On the other hand, because midazolam has significant hypnotic properties, it displays significant synergism with propofol or thiopental when used to induce hypnosis.^{14,15}

The plasma concentration of a drug at steady state that is required to abolish purposeful movement at skin incision in 50% of patients ($C_{p_{ss}50}$) is a measure of potency that is analogous to the familiar parameter of minimum alveolar concentration (MAC) of the volatile inhaled anesthetics. Intravenous anesthetic interactions may be evaluated by their effect upon the $C_{p_{ss}50}$ in a manner analogous to the expression of the effects of opioids on volatile anesthetic requirements in terms of MAC reduction. For example, during general anesthesia, opioid requirements to suppress the responses to noxious stimuli are 10-fold higher when used as the sole agent compared to when they are used in conjunction with a nitrous oxide/potent inhaled vapor technique. This interaction is likely to persist at the lighter levels of anesthesia encountered during conscious sedation. Therefore, in an ambulatory conscious sedation setting, it is likely that a rapid recovery would be facilitated by using opioids in combination with other agents (*e.g.*, propofol/midazolam) rather than as the sole drug.

Drug interactions are dose-dependent. For example, when fentanyl is combined with isoflurane, the greatest reduction in isoflurane MAC occurs within the analgesic concentration range of fentanyl, *i.e.*, $1\text{--}2\text{ ng} \cdot \text{ml}^{-1}$. At a fentanyl concentration of $1.7\text{ ng} \cdot \text{ml}^{-1}$ the minimum alveolar concentration of isoflurane is reduced by 50%.¹⁶ Once the fentanyl concentration is increased beyond $3\text{ ng} \cdot \text{ml}^{-1}$, there appears to be minimal further reduction with a maximum MAC reduction of 80%. Likewise, the MAC of desflurane is reduced by approximately 50% 25 minutes after a $3\text{-mg} \cdot \text{kg}^{-1}$ iv bolus of fentanyl.¹⁷ However, when the fentanyl bolus is increased to $6\text{ mg} \cdot \text{kg}^{-1}$, there is no significant further decrease in the MAC of desflurane. The interactions between propofol and opioids are important because these agents are frequently used during conscious sedation. When analgesic concentrations of fentanyl ($0.6\text{ ng} \cdot \text{ml}^{-1}$) are used in combination with propofol for anesthesia, the $C_{p_{ss}50}$ of propofol is reduced by 50% compared with when propofol is used as the sole agent.¹⁵ However, when the dose of fentanyl is increased, there is no significant further reduction of the $C_{p_{ss}50}$ for propofol beyond a fentanyl concentration of $3\text{ ng} \cdot \text{ml}^{-1}$.

Although the data presented above pertain to patients under general anesthesia, these findings have important implications for monitored anesthesia care. These studies demonstrate that the potentiating effects of opioids upon coadministered sedatives are pronounced within the dose range commonly used during conscious sedation. Furthermore, the data suggest that the dose-response curve is likely to be steep within this dose range, thus supporting the clinical impression that significant increases in depth of sedation can occur with only modest increments in opioid or hypnotic/sedative dosage. The following clinical recommendations can be made: During conscious sedation, the maximum benefit of opioid supplementation, in terms of potentiation of other administered sedatives, will accrue when the opioid is used in the analgesic dose range. Within this dose range there is great potential for adverse cardiorespiratory interaction.

Opioid and benzodiazepine combinations are frequently used to achieve the components of hypnosis, amnesia, and analgesia. The opioid-benzodiazepine combination displays marked synergism in producing hypnosis. Approximately 25% of the ED_{50} for each individual drug is required in combination to induce hypnosis in 50% of patients.¹⁸ If the combination were simply additive, hypnosis would be induced in only approximately 25% of patients. Even subanalgesic doses of alfentanil ($3\text{ mg} \cdot \text{kg}^{-1}$) produce a profound reduction in midazolam requirements for hypnosis.¹⁹ This synergism also extends to the unwanted effects of these drugs, producing the life-threatening complications of respiratory and cardiac depression.²⁰ Several fatalities have been reported after the use of midazolam, the majority of these being related to adverse respiratory events. In many of these cases, midazolam was used in combination with an opioid. The effects of midazolam and fentanyl upon respiratory function in healthy volunteers have been examined by Bailey *et al.*²¹ Whereas midazolam produced no significant respiratory effects alone, and fentanyl alone produced hypoxemia (oxyhemoglobin saturation 95%) in half of the subjects, the combination of midazolam $0.05\text{ mg} \cdot \text{kg}^{-1}$ and fentanyl $2.0\text{ mg} \cdot \text{kg}^{-1}$ resulted in hypoxemia in 11 of 12 subjects and apnea (no spontaneous respiratory effort for 15 seconds) in 6 of 12 subjects. The combination of midazolam and fentanyl places patients at high risk for developing hypoxemia and apnea. The respiratory depressant effects of this drug combination are likely to be even more significant in the patient with coexisting respiratory or CNS disease or at the extremes of age. In clinical practice, the clinical advantages of the synergy between opioids and

benzodiazepines for the maintenance of patient comfort should be carefully weighed against the disadvantages of the potentially adverse effect of this drug combination on the cardiovascular and respiratory systems.

SPECIFIC DRUGS USED FOR CONSCIOUS SEDATION

Propofol

Propofol has many of the ideal properties of a sedative-hypnotic for use in conscious sedation. Its pharmacokinetic profile, *i.e.*, a context-sensitive half-time that remains short even after infusions of prolonged duration and a short effect–site equilibration time, makes it an easily titratable drug with an excellent recovery profile. The quality of recovery and the low incidence of nausea and vomiting make propofol particularly well suited to ambulatory conscious sedation procedures. A significant body of experience with the use of propofol for conscious sedation has emerged. Propofol has significant advantages compared with benzodiazepines when used as the hypnotic component of a conscious sedation technique. Although midazolam has a relatively short elimination half-time, its context-sensitive half-time is approximately twice that of propofol. Whereas propofol is noted for the rapid return to clear-headedness, midazolam is often associated with prolonged postoperative sedation and psychomotor impairment, particularly in the elderly. Propofol in typical conscious sedation doses ($25\text{--}75\text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) has minimal analgesic properties. However, the unique advantages of propofol can be exploited to the maximum when propofol is used to provide sedation when the analgesic component is provided by a local or regional analgesic technique. The use of propofol ($50\text{--}70\text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) to provide sedation (defined as sleep with preservation of the eyelash reflex and purposeful reaction to verbal or mild physical stimulation) as an adjunct to spinal anesthesia for lower limb surgery has been examined.²² After termination of infusions of approximately 100 minutes in duration, patients regained consciousness in approximately 4 minutes. The authors also noted the ease with which general anesthesia could be induced if necessary by increasing the propofol infusion. The same group also compared propofol ($60.5\text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) to midazolam ($4.3\text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) as an adjunct to spinal anesthesia. The propofol group had faster immediate recovery than the midazolam group (2.3 vs. 9.2 min to spontaneous eye opening). Furthermore, psychomotor function was comparable to baseline values following propofol sedation but did not return to baseline until 2 hours after midazolam administration. White and Negus also compared propofol and midazolam sedation for local and regional anesthesia.²³ These investigators examined several recovery parameters and demonstrated that propofol produced less postoperative sedation, drowsiness, confusion, and clumsiness than midazolam but that discharge times were similar. It should be noted that most investigators have shown that propofol does not reliably produce amnesia in subhypnotic doses.²⁴ Although recall of intraoperative events is generally thought to be undesirable, propofol's lack of amnestic properties may be preferable when patients are required to remember important instructions they are given in the postoperative period. Theoretically, a combination of propofol and midazolam could produce reliable amnesia for intraoperative events yet allow a rapid recovery of psychomotor function at the end of the procedure.

The use of propofol for conscious sedation has been examined in several diverse clinical settings, including propofol alone for upper gastrointestinal endoscopy²⁵ and magnetic resonance imaging in children,²⁶ with fentanyl for extracorporeal shock wave lithotripsy,²⁷ and with alfentanil for transvaginal oocyte retrieval.²⁸ The provision of conscious sedation during dental care to the mentally and physically handicapped is a significant anesthetic challenge. Propofol has been used successfully in the mentally and physically handicapped undergoing dental surgery.²⁹ However, the authors of that study expressed concern about the purported proconvulsive properties of propofol, particularly when used in the handicapped population, which has a high prevalence of epilepsy. However, a follow-up study by the same group examined the EEG effects of propofol sedation on epileptic patients undergoing dental surgery and found no increase in EEG or clinical epileptoid activity during propofol sedation.³⁰

There is a general clinical impression that patients recovering from propofol not only recover rapidly but often experience an increased sense of well-being. However, a study specifically addressing the issue of the subjective effects of low-dose propofol in volunteers could find no evidence for a euphoric effect of propofol.³¹ The authors postulate that the sense of well-being arises from the feeling of relief that the procedure is over. This feeling of relief may be inhibited by the prolonged psychomotor impairment that often follows other anesthetic techniques.

General anesthesia with propofol is generally associated with less nausea and vomiting than most other anesthetic techniques. There is now evidence that even subhypnotic doses of propofol (a single 10-mg dose in an adult) also possess direct antiemetic properties.³² Thus, it is likely that the beneficial effects of propofol upon nausea and vomiting will be a feature of conscious sedation techniques using this drug. On the other hand, even during low-dose infusions used for conscious sedation, pain during injection of propofol may be troublesome in 33–50% of patients.^{33,34} Several strategies for reducing the pain of propofol administration are described in [Table 47-2](#).³⁵

Using larger veins in antecubital fossa
 Decreasing the speed of injection
 Injection into a fast-running iv
 Diluting with 5% glucose or 10% intralipid
 Adding lidocaine to propofol
 Pretreating with lidocaine and venous occlusion
 Pretreatment with opioid
 Pretreatment with pentothal
 Cooling to 4°C prior to injection
 Injecting cooled saline (4°C) prior to injection
 Discontinuing iv fluid administration during injection

Table 47-2. PUBLISHED STRATEGIES FOR REDUCING THE PAIN ON IV INJECTION OF PROPOFOL

Benzodiazepines

Benzodiazepines are commonly utilized during conscious sedation for their anxiolytic, amnestic, and hypnotic properties. In the past, diazepam enjoyed great popularity as a major component of conscious sedation techniques. However, midazolam has many advantages and has now displaced diazepam as the most commonly utilized benzodiazepine for conscious sedation. The important differences between midazolam and diazepam are listed in [Table 47-3](#).³⁶ Although midazolam has a short elimination half-time, there is often significant and prolonged psychomotor impairment following conscious sedation techniques using midazolam as a significant component. With the recent availability of propofol, midazolam may be better utilized in a modified role by using lower doses prior to the start of a propofol infusion to provide the specific amnestic and perhaps anxiolytic component of a “balanced” sedation technique rather than as the major hypnotic component.³⁷ This allows the more evanescent and titratable propofol to provide the desired level of conscious sedation in an adjustable manner according to the specific stimulus. The analgesic component, if required, of a balanced conscious sedation technique could be provided by regional/local techniques or opioids. However, when using opioids with benzodiazepines, the potential for significant respiratory impairment should be considered.

| Midazolam | Diazepam |
|---|---|
| Water-soluble, does not require propylene glycol for solubilizing | Lipid-soluble, requires propylene glycol for solubilizing |
| Nonemetic, usually painless | Venous irritant, pain on injection |
| Thrombophlebitis rare | Thrombophlebitis common |
| Short elimination half-time (1–4 hours) | Long elimination half-time (>20 hours) |
| Clearance unaffected by H ₂ antagonists | Clearance reduced by H ₂ antagonists |
| Inactive metabolites (1-hydroxy-midazolam) | Active metabolites (desmethyldiazepam, oxazepam) |
| Reversal unlikely | Reversal more likely |

Table 47-3. COMPARISON OF THE IMPORTANT PROPERTIES OF MIDAZOLAM AND DIAZEPAM

Clinical experience suggests that the dose of a particular benzodiazepine required to reach a desired clinical endpoint is reduced in the elderly compared with younger

patients. This difference in dosing requirements in the elderly is due mainly to pharmacodynamic factors, as evidenced by the 3-fold decrease in steady-state plasma concentration of midazolam at which 50% of patients would be expected not to respond to verbal command (Cp₅₀) in the 80-year-old compared to the 40-year-old (Fig. 47-4).³⁸

Figure 47-4. Midazolam Cp₅₀ (the concentration at which 50% of subjects will fail to respond to a verbal command) as a function of age. There is a marked decrease in midazolam requirements as patient age increases. (Reproduced with permission from Jacobs JR, Reves JG, Marty J *et al*: Aging increases pharmacodynamic sensitivity to the hypnotic effects of midazolam. *Anesth Analg* 80:143,1995.)

Although benzodiazepines are valuable components of conscious sedation techniques because they enhance patient comfort, improve operating conditions, and provide amnesia, recovery of psychomotor and cognitive function may be significantly prolonged following benzodiazepine sedation, especially when compared with sedative-hypnotic techniques utilizing propofol as the major component.³⁹ The recent introduction of a specific benzodiazepine antagonist flumazenil provides the potential to improve the recovery profile of benzodiazepines by permitting the active termination of their sedative and amnestic effects. Several studies have demonstrated that flumazenil facilitates early recovery from benzodiazepine sedation without invoking adverse side-effects. However, the potential for re-sedation remains an obstacle to the routine use of benzodiazepine reversal, particularly in patients undergoing ambulatory procedures. Flumazenil has a very short elimination half-life of only 60 minutes, which is shorter than that of most clinically used benzodiazepines.⁴⁰ Although the more clinically relevant context-sensitive half-times have not been published for flumazenil, it is likely that the plasma concentration of flumazenil following a bolus will decrease by 50% in less than 12 minutes, or in less than 20 minutes in the case of an infusion lasting up to 2 hours (Dr. Steven L. Shafer, Stanford University Department of Anesthesia, personal communication, 1994). By contrast, the plasma concentration of midazolam will decrease by 50% in approximately 40 minutes following a 2-hour infusion.⁸ The effective duration of a dose of flumazenil will depend upon the dose and elimination half-life of the benzodiazepine, the dose of flumazenil, and the time elapsed between benzodiazepine and flumazenil administration.⁴¹ The effects of midazolam may recur up to 90 minutes following the administration of flumazenil.⁴² Thus, it is possible that patients could be discharged prematurely to a less well-monitored area, or even out of the hospital in the case of ambulatory surgery, and later experience recurrence of benzodiazepine effects. An important additional issue is that of cost. The routine use of flumazenil-antagonized benzodiazepine sedation has a significant cost disadvantage. Ghouri *et al*⁴² demonstrated that flumazenil-antagonized midazolam sedation was more expensive than propofol sedation (\$68.67 vs. \$27.80). Typical dose requirements are listed in Table 47-4.

| |
|---|
| Initial recommended dose of 0.2 mg |
| If desired level of consciousness is not achieved in 45 seconds, repeat 0.2-mg dose |
| 0.2-mg doses may need to be repeated every 60 seconds until a maximum of 1 mg is administered |
| Be aware of the potential for re-sedation |

Table 47-4. RECOMMENDED REGIMEN FOR THE USE OF FLUMAZENIL TO ANTAGONIZE BENZODIAZEPINE EFFECTS

Opioids

Opioids are most logically used in the context of conscious sedation to provide the specific analgesic component of a “balanced conscious sedation” technique. With the availability of drugs with specific and potent hypnotic and amnestic properties, such as propofol and midazolam, opioids are no longer required to play a significant role as the sole or major component of a sedation technique. Before the introduction of remifentanyl, the available opioids did not reliably produce a controllable degree of sedation without a significant risk of respiratory depression. Furthermore, the significant increase in the incidence of nausea and vomiting associated with opioid use increased morbidity in ambulatory patients. Opioid analgesics are indicated when regional or local anesthetic techniques are inappropriate or ineffective. Opioids may also play an important role during the initial injection of local anesthetic solution or during other periods of intense patient discomfort. Pain relief may be required for factors other than the procedure itself, such as uncomfortable positioning, propofol injection, pneumatic tourniquet pain, or other pain not relieved by the local anesthetic technique.

A situation in which the patient must cooperate and remain motionless for a brief period is during the placement of a retrobulbar block prior to ophthalmic procedures. Patient movement during block placement may increase the incidence of complications such as brain stem anesthesia and cardiac arrest. Retrobulbar block placement affords an excellent opportunity to study the effects of drugs on the response to a standardized ethically acceptable brief painful stimulus. The ideal drug for block placement would provide a brief period of intense analgesia yet allow the patient to be awake and cooperative without causing cardiorespiratory depression, cause minimal nausea and vomiting, and not significantly prolong recovery.⁴³ Alfentanil (20 mg · kg⁻¹) has a rapid onset and offset of intense analgesia and was compared with methohexital (0.5 mg · kg⁻¹) for retrobulbar block placement.⁴³ Patients receiving methohexital were unresponsive to verbal command at the time of block placement and demonstrated more movement upon injection than those receiving alfentanil, who were mostly (87%) awake and cooperative at the time of injection. The authors note that one elderly patient out of the 15 who received alfentanil became apneic for 30 seconds, and suggested that the dose of opioids be reduced in the elderly. They also noted that the personnel performing the block were accustomed to the patient being “asleep” during methohexital sedation, but took some time to become at ease with the awake yet comfortable and cooperative patient who had received alfentanil.

The well-described phenomenon of patient awareness and subsequent recall of intraoperative events following high-dose opioid anesthesia is taken as evidence that opioids lack significant amnestic properties. However, when the effects of low-dose fentanyl upon memory were specifically examined in volunteers, it was found that although the subjects appeared to be awake during the fentanyl infusion, there was significant memory impairment.⁴⁴ However, the degree of stimulation was probably less than that experienced by a patient undergoing a painful surgical procedure. Recall for a painful stimulus may not be impaired to the same degree as recall for the less noxious stimuli that the subjects of this study experienced.

Alfentanil appears to have a pharmacokinetic advantage for the treatment of discrete stimuli because of its short effect-site equilibration time, which allows rapid access of the drug to the brain and facilitates titration. However, sufentanil may have a more favorable recovery profile when used over a longer period of time because of its shorter context-sensitive half-time. In clinical practice, however, there is a marked interpatient variability in opioid pharmacokinetics and dynamics. This interpatient variability may be more significant than the interdrug differences, making it difficult to predict with any precision the effects of a given drug dose in an individual patient.

Remifentanyl

In the context of monitored anesthesia care, the analgesic properties of opioids are extremely valuable. However, their adverse effects, including respiratory depression, muscle rigidity, and emesis, are undesirable in the spontaneously breathing patient with an unprotected airway and significantly limit our ability to

consistently provide effective analgesic doses. A further complicating issue is that our ability to predict the effect of a given dose of opioid in a particular patient is limited by significant interpatient pharmacokinetic and pharmacodynamic variability. This problem is usually overcome in practice by the cautious incremental administration of small, carefully spaced boluses or by titrating infusions to the desired effect.

Remifentanyl, a recently introduced m-opioid receptor agonist, has pharmacodynamic properties similar to those of other potent m-opioid receptor agonists such as fentanyl and alfentanil. However, unlike previously available opioids, remifentanyl is predominantly metabolized by nonspecific esterases generating an extremely rapid clearance and offset of effect.⁴⁵ The context-sensitive half-time of remifentanyl is consistently short, 3–5 minutes, increasing to a minimal degree with the duration of the infusion. Furthermore, remifentanyl has a comparatively short effect–site equilibration time ($t_{1/2}^{ke0}$) of 1.0–1.5 minutes. This $t_{1/2}^{ke0}$ is slightly longer than that of alfentanil (0.6–1.2 min) but shorter than that of fentanyl (4–5 min) and much shorter than that of morphine (~20 min), and makes the onset of effect after drug administration very rapid. The rapid onset and offset of remifentanyl greatly facilitate titration of effect during MAC.

In clinical practice, remifentanyl has been used successfully as the analgesic component of sedation techniques for regional and local anesthesia. Its unique pharmacokinetic profile makes it well suited for ambulatory sedation/analgesia techniques. Published experience with the use of remifentanyl suggests that it is possible to titrate remifentanyl administration to provide effective analgesia with minimal respiratory depression. The published data can be used to generate some practical clinical guidelines,⁴⁶ which are discussed below.

1. As with other potent opioids used during sedation techniques, the most logical therapeutic endpoint for remifentanyl administration is effective analgesia and patient comfort rather than sedation. When opioids are titrated to preconceived levels of sedation rather than patient comfort, an unacceptable degree of respiratory depression may occur. Drugs such as propofol or midazolam can be used in combination with remifentanyl to provide the hypnotic–anesthetic component of the sedation technique, remembering that the concomitant administration of midazolam decreases remifentanyl dose requirements by up to 50%.⁴⁷
2. Published data suggest that bolus administration of remifentanyl is associated with an increased incidence of respiratory depression and chest wall rigidity. Because these side-effects are likely to be related to high peak concentrations of drugs, it is recommended that remifentanyl boluses be administered slowly (over 30–90 sec) or avoided completely by utilizing a pure infusion technique. Furthermore, the administration of remifentanyl boluses during the concomitant administration of remifentanyl infusions is also associated with an increased incidence of respiratory depression, the most likely mechanism again being excessive peak drug concentrations. These episodes of respiratory depression are of significant concern, particularly in the spontaneously breathing patient with an unprotected airway. However, once they were recognized and the remifentanyl administration was reduced or discontinued, they resolved with a median time of 3 minutes. Thus, despite the pharmacokinetic advantages of remifentanyl, the level of vigilance required for its administration should be no different from that for any other potent opioid. Although the offset time of remifentanyl is rapid, it still requires the recognition of respiratory depression to trigger a downward adjustment in dosage. On the other hand, the short $t_{1/2}^{ke0}$ of remifentanyl suggests that sudden respiratory depression may occur in response to upward adjustments in dosage. Despite the potential for respiratory depression, the efficacy of remifentanyl boluses during MAC has been investigated by several groups. The most logical scenario in which a bolus dose could be utilized is immediately prior to a brief but very painful stimulus, such as placement of a retrobulbar block.⁴⁸ A bolus of 1 mg · kg⁻¹ over 30 seconds was administered 90 seconds prior to block placement. More than three-quarters of patients receiving remifentanyl did not report any pain during subsequent block placement. However, 15% of the patients given a single bolus alone had significant respiratory depression (respiratory rates breaths per minute), and 19% of those given a bolus followed by an infusion had significant respiratory depression.
3. The effects of coadministration of benzodiazepines and opioids are well documented. The addition of midazolam to provide the anxiolytic–sedative and amnestic components of a sedation technique has been shown to increase patient satisfaction and significantly reduce remifentanyl dose requirements. The combination of remifentanyl with midazolam significantly reduces patient anxiety when compared to the use of the opioid alone.⁴⁹ Even relatively low-dose midazolam (2 mg iv) produces significant reductions in remifentanyl requirements and patient anxiety. During breast or lymph node biopsy, remifentanyl infusion requirements were 0.065 mg · kg⁻¹ · min⁻¹ when preceded by midazolam compared to 0.123 mg · kg⁻¹ · min⁻¹ when used alone. The advantages of coadministration of small doses of midazolam include increased patient satisfaction, increased amnesia, decreased nausea and vomiting, and decreased anxiety. The disadvantages include a tendency toward increased respiratory depression, apnea, and excessive sedation.
4. Because most painful stimuli are of unpredictable duration and because the risk of adverse respiratory events is increased following bolus administration, the most logical method for the administration of remifentanyl during MAC is by an adjustable infusion. This should ideally be preceded by a small bolus of midazolam. Most investigators have used infusion rates that start at 0.1 mg · kg⁻¹ · min⁻¹ approximately 5 minutes prior to the first painful stimulus. This initial “loading” infusion is then weaned to approximately 0.05 mg · kg⁻¹ · min⁻¹ to maintain patient comfort. The maintenance infusion is adjusted upward in response to pain or hemodynamic response or downward in response to excessive sedation, respiratory depression, or apnea. A typical incremental change in infusion rate is 0.025 mg · kg⁻¹ · min⁻¹. The use of remifentanyl infusions of 0.2 mg · kg⁻¹ · min⁻¹ is associated with an increased incidence of respiratory depression that is not necessarily associated with superior analgesia. As in the case of propofol administration, inadvertent interruption of remifentanyl administration will result in abrupt offset of effect, which may result in patient discomfort, hemodynamic instability, and even morbidity due to patient movement. It is therefore very important to ensure that the drug delivery system is monitored carefully during the procedure. Remifentanyl is supplied as a powder that must be reconstituted prior to use. It is particularly important when administering this drug to patients with an unsecured airway to ensure that there are no errors in drug dilution that would result in inadvertent dosing errors.

Typical adult dose recommendations for opioids and other drugs discussed in the text are listed in [Table 47-5](#).

| Drug | Typical Adult iv Dose Range (titrated to effect in small increments) |
|--------------------------|--|
| Benzodiazepines | |
| Midazolam | 1–2 mg prior to propofol or remifentanyl infusion |
| Ethiopam | 2–8 mg as major component 2.5–10 mg |
| Opioid analgesics | |
| Alfentanil | 5–30 µg · kg ⁻¹ bolus 2 min prior to stimulus |
| Fentanyl | 0.5–2.0 µg · kg ⁻¹ bolus 2–4 min prior to stimulus |
| Remifentanyl | Infusion 0.1 µg · kg ⁻¹ · min ⁻¹ 5 min prior to stimulus Wean to 0.05 µg · kg ⁻¹ · min ⁻¹ as tolerated Adjust up or down in increments of 0.025 µg · kg ⁻¹ · min ⁻¹ Reduce dose accordingly when coadministered with midazolam or propofol Avoid boluses |

| Propofol | 250–500 µg · kg ⁻¹ boluses 25–75 µg · kg ⁻¹ · min ⁻¹ infusion |

Table 47-5. TYPICAL DOSE RANGES OF SEDATIVE, HYPNOTIC AND ANALGESIC DRUGS

Patient-Controlled Sedation and Analgesia

There is increasing interest in techniques that allow the patient some direct control of the level of sedation. Patient participation in the perioperative process may positively affect patient satisfaction.⁵⁰ The degree of sedation desired by the patient varies significantly and the individual response to drugs is variable. Patient-controlled sedation (PCS) appears to be an attractive solution to this problem. One approach to PCS has been to use a conventional patient-controlled analgesia (PCA) delivery system set to deliver 0.7-mg · kg⁻¹ boluses of propofol with a 3-minute lockout period.⁵¹ Other approaches include fixed-dose combinations of 0.5 mg midazolam and 25 mg fentanyl with a 5-minute lockout interval between doses.⁵² This technique was as safe and effective as anesthesiologist-controlled drug delivery. However, some workers have noted greater post-procedure sedation following self-administration compared to physician controlled sedation.⁵³ The pharmacokinetic profile of alfentanil is ideal for the treatment of short, discrete episodes of pain. These properties have been exploited during vaginal ovum retrieval procedures, when ultrasonically guided needles are passed through the vaginal wall under monitored anesthesia care. Zelcer *et al* utilized a PCA delivery system to allow self-administration of alfentanil during this procedure.⁵⁴ After midazolam premedication and a loading dose of alfentanil, patients received 5-mg · kg⁻¹ boluses of alfentanil via the PCA pump with a mandatory 3-minute lockout period. Patient acceptability, alfentanil dosage, respiratory variables, and pain scores were similar to those obtained with physician-controlled analgesia. From the limited data that are available, intraoperative PCA during monitored anesthesia care appears to be an effective alternative to physician-administered analgesia.

RESPIRATORY FUNCTION AND SEDATIVE–HYPNOTICS

During monitored anesthesia care there is significant potential for respiratory compromise mediated via several important mechanisms. These include adverse effects on respiratory drive, either directly as a result of sedative–hypnotic or opioid administration or indirectly as a consequence of brain stem hypoperfusion resulting from hypotension, such as that occurring during spinal or epidural anesthesia. There may also be a marked increase in the work of breathing due to increased resistance to gas flow in the upper airway.⁵⁵ During sedation it is likely that protective airway reflexes will be attenuated. On the other hand, sedative doses of benzodiazepines appear to have variable effects upon respiratory system mechanics, decreasing, increasing, or having no effect upon functional residual capacity.^{56,57} and ⁵⁸

Sedation and Upper Airway Patency

The upper airway is located outside the thorax. During normal inspiration, the pressure within the upper airway is subatmospheric; thus, there is a tendency for the upper airway to collapse under the influence of the surrounding atmospheric pressure. However, in the normal subject this tendency for airway collapse is opposed by upper airway dilator muscle tone. These muscles probably both increase the diameter and reduce the compliance of the upper airway. An increase in upper airway dilator muscle tone occurs during inspiration, commencing just prior to diaphragmatic contraction.⁵⁹ Several studies have confirmed the importance of coordinated activation of the diaphragmatic and upper airway respiratory muscles in maintaining airway patency. Upper airway dilator muscle control appears to be extremely sensitive to sedative–hypnotic drug administration.⁶⁰ For example, sedative doses of midazolam have been reported to increase inspiratory subglottic airway resistance by 3- to 4-fold.⁶¹ Sedative doses of diazepam selectively suppress genioglossal muscle activity to a greater degree than diaphragmatic activity; furthermore, this effect is exaggerated in the elderly.⁶² In all these examples the increased upper airway resistance markedly increased the work of breathing. The response to this obstruction is a significant increase in intercostal and accessory muscle activity. However, this response is only partially effective because the increase in inspiratory force will further decrease intraluminal upper airway pressure, predisposing to further airway collapse. It is likely that these effects will be of greatest significance in patients with pre-existing respiratory compromise, such as the elderly or those with chronic obstructive pulmonary disease. These patients often have limited respiratory reserve and are unable to increase their respiratory muscle activity in response to the increased work of breathing induced by sedation and may become hypercarbic, acidotic, and hypoxic.

Sedation and Protective Airway Reflexes

Competent laryngeal and upper airway reflexes are required to protect the lower airway from aspiration. It is well documented that protective laryngeal and pharyngeal reflexes are depressed by anesthesia and sedation. Furthermore, it is also well documented that protective airway reflexes are compromised by advanced age and debilitation. Therefore, it is likely that significant depression of airway reflexes could occur during sedation in the elderly or debilitated patient. Aspiration of gastric contents could occur either in the operating room or during recovery, particularly if oral intake is allowed before the return of adequate upper airway protective reflexes. The time required for the return of protective reflexes varies considerably. Complete recovery of the swallowing reflex occurs approximately 15 minutes after the return of consciousness following propofol anesthesia.⁶³ However, the iv administration of 15 mg of diazepam has been shown to depress the swallowing reflex for up to 4 hours.⁶⁴ The swallowing reflex is significantly depressed for up to 2 hours following the administration of midazolam despite the return to a normal state of consciousness.⁶⁵ In otherwise healthy adult male volunteers the inhalation of 50% nitrous oxide was associated with marked depression of the swallowing reflex.⁶⁶

It is apparent from the sources quoted above that the protective airway reflexes alone cannot be relied upon to protect the lower airway from aspiration during sedation. Thus, patients who are deemed to be at risk from aspiration of gastric contents should be maintained at the lightest level of sedation possible. Ideally, the patient should be awake enough to recognize the regurgitation of gastric contents and be able to protect his or her own airway. If the ability of the patient to protect his or her own airway cannot be reliably guaranteed and regurgitation/aspiration is thought to be a significant risk, placement of a cuffed endotracheal tube under general or local anesthesia should be seriously considered.

Sedation and Respiratory Control

Clinical experience would lead most anesthesiologists to predict that the administration of sedative–hypnotic drugs is associated with the depression of respiratory drive. However, the findings of scientific studies in this area are often conflicting and confusing, on occasion finding minimal, if any, effects of sedative drugs upon ventilatory responsiveness. However, it is important to note that in many cases the methods used to measure respiratory drive may affect the outcome of the study by stimulating the subject, thus attenuating the negative effect of the drug upon respiratory drive. In clinical practice it is likely that during regional anesthesia there is a degree of deafferentation that will potentiate the respiratory depressant effects of sedative–hypnotic drugs.⁶⁷ Most studies have demonstrated that opioids depress the ventilatory response to hypercapnia and hypoxia.⁶⁸ Reports of the effects of sedative doses of benzodiazepines upon carbon dioxide responsiveness have shown variable results, including no significant effect⁶⁹ and clinically significant depression.⁷⁰ However, when opioids and benzodiazepines are used in combination, there appears to be a marked negative effect upon respiratory responsiveness.²¹ However, initial clinical investigation examining the combination of propofol and opioids has shown little potentiation of the adverse effects of opioids by sedative doses of propofol.²⁸

SUPPLEMENTAL OXYGEN ADMINISTRATION

Hypoxia as a result of alveolar hypoventilation is a relatively common occurrence following the administration of sedatives, analgesics, and hypnotics. In the absence of significant lung disease, the administration of only modest concentrations of supplemental oxygen is frequently effective in restoring the patient's oxygen saturation to an acceptable level. This concept is well illustrated by reference to the familiar alveolar gas equation. An extreme example illustrates the point: an otherwise healthy adult male breathing room air receives a dose of an opioid that causes marked alveolar hypoventilation such that his alveolar PCO_2 is increased to 80 mm Hg. The alveolar gas equation predicts that his arterial PO_2 will fall to approximately 40 mm Hg as shown below:

$$\begin{aligned} P_{AO_2} &= P_{iO_2} - P_{ACO_2}/R \\ P_{iO_2} &= F_{iO_2} \times (P_B - P_{H_2O}) \\ P_{iO_2} &= 0.21 \times (760 - 47) = 150 \text{ mm Hg} \\ P_{AO_2} &= 150 - 80/0.8 \\ P_{AO_2} &= 50 \text{ mm Hg} \end{aligned}$$

Assuming a normal A–a gradient, his P_{aO_2} will be 40 mm Hg, corresponding to an arterial oxygen saturation of 75%. If while initiating definitive therapy for hypoventilation this patient were to receive only a modest increase in inspired oxygen, a marked improvement in arterial saturation would be achieved:

$$\begin{aligned} F_{iO_2} &\text{ increased to 28\%} \\ P_{iO_2} &= 0.28 \times (760 - 47) = 200 \text{ mm Hg} \\ P_{AO_2} &= 200 - 80/0.8 \\ P_{AO_2} &= 100 \text{ mm Hg} \end{aligned}$$

This theoretical example serves to highlight several points. First, in isolated hypoventilation modest increases in inspired oxygen are remarkably effective at restoring oxygen saturation to acceptable levels. However, a patient who is receiving minimal supplemental oxygen and has an acceptable oxygen saturation may have significant undetected alveolar hypoventilation. Therefore, before making the decision to discharge patients to a less well monitored environment without supplemental oxygen, it is useful to measure their oxygen saturation while breathing room air.

MONITORING DURING MONITORED ANESTHESIA CARE

ASA Standards

The ASA standards for basic anesthetic monitoring are applicable to all levels of anesthesia care, including monitored anesthesia care. It is useful to review the components of the ASA standards that are pertinent to monitored anesthesia care as approved by the house of delegates on October 21, 1986 and subsequently amended on October 21, 1998.⁷¹ (See Chapter 2, [Table 2-1](#), for the current ASA standards.)

Communication and Observation

A conscientious and well-trained anesthesia caregiver is the single most vital monitor in the operating room. However, his or her effectiveness will be markedly enhanced by the use of the basic quantitative and qualitative monitoring devices, which should be readily available in all operating rooms. It is important that the anesthesiologist continually evaluate the patient's response to verbal stimulation to effectively titrate the level of sedation and to allow the earlier detection of neurologic or cardiorespiratory dysfunction. Continuous visual, tactile, and auditory assessment of physiologic function should include observation of the rate, depth, and pattern of

respiration; palpation of the arterial pulse; and assessment of peripheral perfusion by extremity temperature and capillary refill. In addition, the patient should be continually observed for diaphoresis, pallor, shivering, cyanosis, and acute changes in neurologic status.

Auscultation

Auscultation of heart and breath sounds has long been a vital component of monitoring during anesthesia. Placement of a precordial stethoscope near the sternal notch of a nonintubated patient provides important information concerning upper airway patency as well as a continuous monitor of heart sounds and ventilation. Continuous precordial auscultation is an inexpensive, effective, and essentially risk-free process that serves an additional important purpose by bringing the anesthesia care provider closer to the patient. If access to the patient is limited during the procedure, FM wireless or infrared remote transmission systems are now commercially available.

Pulse Oximetry

No monitor of oxygen transport has had a greater impact on the practice of anesthesiology than the pulse oximeter.⁷² Despite occasional mechanical interference due to limb movement, this technology is readily applied and is positively indicated in the context of monitored anesthesia care. Pulse oximetry is noninvasive, safe, and comfortable to the awake patient; it is also technically simple to apply and interpret, and allows continuous real-time monitoring of arterial oxygenation. The use of a quantitative measure of oxygenation is specifically mandated by the ASA standards for intraoperative monitoring. The important mechanisms whereby respiratory function may be compromised during monitored anesthesia care include the effects of sedatives and opioids upon respiratory drive, upper airway patency, and protective airway reflexes. Additional important risk factors for arterial desaturation include obesity, pre-existing upper airway obstruction and respiratory disease, the extremes of age, and the lithotomy position.⁷³ The fundamental importance of monitoring oxygenation during monitored anesthesia care can be appreciated from the closed-claim study of Caplan *et al.*,⁶⁷ who examined 14 cases of sudden cardiac arrest in otherwise healthy patients who received spinal anesthesia. These major anesthetic mishaps occurred before the routine adoption of pulse oximetry. One of the major findings of this study was that cyanosis frequently heralded the onset of cardiac arrest, suggesting that unappreciated respiratory insufficiency may have played an important role. Further support for the use of pulse oximetry comes from the ASA Committee on Professional Liability analysis of closed anesthesia claims. Examination of the data from the closed-claims project reveals that respiratory events constitute the single largest source of adverse outcome. Furthermore, review of these cases suggests that pulse oximetry in combination with capnometry would have prevented the adverse outcome in the vast majority of cases. During monitored anesthesia care, patient movement can occasionally interfere with effective pulse oximetry. One solution to this problem has been developed by Nellcor Inc. (Hayward, CA). This company has developed a system whereby the pulse oximeter compares the pulsatile absorbance signal with the simultaneous electrocardiogram (ECG) waveform.⁷² Absorbance pulsations that are not synchronous with an ECG complex are rejected. This system (C-Lock[®], Nellcor Inc.) is generally effective but requires a clean ECG signal, which can also be adversely affected by patient movement. On the other hand, pulse oximeter artifacts due to shivering have proved to be a difficult problem to overcome, further emphasizing the need to monitor and maintain body temperature during monitored anesthesia care.⁷⁴

Capnography

Although capnography is most effective in the intubated patient, some useful information may be obtained from a spontaneously breathing, nonintubated patient. Sidestream capnographs have been adapted for use with facemasks, nasal airways, and nasal cannulae and have been used successfully during monitored anesthesia care.^{75,76,77} and ⁷⁸ Nasal cannulae for oxygen delivery have been modified to provide an integral port for respiratory gas sampling and are available commercially. Alternatively, capnograph sampling lines can be attached to shortened iv catheters and inserted inside nasal oxygen probes.

Cardiovascular System

At a minimum, the ECG must be continually displayed and the blood pressure measured and recorded at least every 5 minutes during monitored anesthesia care. The pulse should be monitored by palpation, oximetry, or auscultation. The selection of additional hemodynamic monitoring is usually determined more by the cardiovascular status of the patient than the magnitude of the procedure. Most procedures performed under monitored anesthesia care do not involve major hemorrhage, fluid shifts, or major physiologic trespass. Decisions concerning choice of monitoring for myocardial ischemia and other adverse hemodynamic events will need to be individualized on a case-by-case basis. Monitoring modalities that may be considered include automated ECG ischemia detection, invasive arterial pressure monitoring, central venous and pulmonary artery catheters, urinary catheterization, and transesophageal echocardiography (very uncomfortable in the awake patient).

Temperature Monitoring and Management During Monitored Anesthesia Care

The value of temperature monitoring is well established during general anesthesia, the perioperative period being frequently complicated by hypothermia and hyperthermia. Although sedation techniques used during monitored anesthesia care do not generally trigger malignant hyperthermia, there is potential for significant inadvertent hypothermia, particularly during neuraxial anesthesia. Even monitored anesthesia care techniques unaccompanied by regional anesthesia are associated with hypothermia at the extremes of age, both the old and very young having impaired thermoregulatory mechanisms. The elderly also have markedly reduced muscle mass and therefore basal heat production. Although the anesthesiologist may be able to exert some control over the ambient temperature in the operating room, he or she may be unable to influence the temperature at remote anesthetizing locations. Radiology suites are often maintained at lower temperatures to accommodate the computer systems that are used to reconstruct images. Radiant heating lamps, forced-air heaters, fluid warmers, or warming blankets, all common items in operating rooms, may be unavailable and unsuitable for use at remote locations. Forced-air heating has been shown to be an effective means of maintaining normothermia, and can be combined with iv fluid warming.⁷⁹ Even mild perioperative hypothermia (*i.e.*, 1–2°C) accompanying general anesthesia is associated with adverse myocardial outcomes, increased bleeding tendency and transfusion requirements, wound infections, and delayed wound healing and hospital discharge.⁸⁰ There is no evidence suggesting that the morbidity associated with perioperative hypothermia is any less during monitored anesthesia care than during general anesthesia. The morbidity associated with perioperative hypothermia is well described in high-risk patients; this is a group of patients that are very likely to undergo procedures under monitored anesthesia care. When hypothermia is significant, shivering may interfere with the planned procedure and markedly increase oxygen requirements and predispose susceptible patients to myocardial ischemia or respiratory insufficiency. The major thermoregulatory defenses against hypothermia include vasoconstriction, shivering, and behavior. Vasoconstriction and shivering are impaired during major conduction anesthesia. Behavioral thermoregulation is impaired even in the conscious patient. The patient undergoing a procedure is immobile, unable to move to a warmer environment, or put on warmer clothes. Furthermore, neuraxial or regional techniques and the presence of impaired consciousness will impair the patients' ability to perceive that they are hypothermic. Regional anesthesia has major effects on thermoregulation.⁸¹ Lower extremity vasodilatation causes central cooling *via* a redistribution of heat from the core to the periphery. Afferent input to the hypothalamus from the warm peripheral compartment counteracts conflicting input from the cooling central compartment, thus delaying the initiation of compensatory thermoregulation. In the absence of reliable temperature monitoring it is possible that the first indication of hypothermia would be the onset of shivering, by which time considerable central cooling may have occurred.

Frank and co-workers have examined the issue of temperature monitoring and management during neuraxial anesthesia and found that temperature monitoring is significantly underutilized, only one-third of patients being monitored.⁸² Furthermore, the method that was most frequently used to monitor temperature may not accurately reflect core temperature, the most important determinant of thermoregulatory response and perioperative morbidity. Forehead skin surface was the most commonly monitored site followed by the axilla. Forehead skin surface monitoring usually utilizes liquid crystal thermometry. This site is chosen for convenience, accessibility, minimal forehead subcutaneous insulation, and because the site has few arteriovenous shunts. However, forehead skin surface temperature is significantly dependant upon vasomotor tone and the ambient temperature. The commercially available liquid crystal devices supplied for this purpose usually incorporate a 2–3°C offset to account for the difference between skin and core temperature under normal conditions. The accuracy of these devices for perioperative temperature monitoring remains controversial; they do not reliably detect malignant hyperthermia and are not sufficiently accurate for fever screening purposes in children.⁸³ Sessler recommends the use of a properly positioned axillary probe or intermittent oral temperature monitoring during neuraxial anesthetics.⁸¹

Some of the more accurate methods of measuring core temperature—pulmonary artery, distal esophagus, and nasopharynx—are clearly not well tolerated in the awake patient. However, other sites such as tympanic membrane, urinary bladder (with neuraxial techniques), and rectum can provide accurate indications of core temperature. Sessler notes the important distinction between properly positioned tympanic membrane thermocouples and infrared aural canal thermocouples, the accuracy and precision of the latter being clearly inferior.⁸¹

Patients will frequently complain of feeling too warm when covered by heavy drapes. Although malignant hyperthermia is rare during monitored anesthesia care because the common triggering agents are rarely used, hyperthermia is still possible as a result of thyroid storm or malignant neuroleptic syndrome. The subjective sensation of hyperthermia may also be the first indicator of important adverse events in evolution such as hypoxia, hypercarbia, cerebral ischemia, local anesthetic toxicity, and myocardial ischemia.

Bispectral Index Monitoring During Monitored Anesthesia Care

The bispectral index (BIS) is a processed EEG parameter that was developed specifically to evaluate patient response during drug-induced anesthesia and sedation. Sedation monitoring is attractive because of the potential to titrate drugs more accurately, avoiding the adverse effects of both over and under dosing. BIS monitoring

has some potential advantages over conventional intermittent techniques of patient assessment. Conventional assessment involves patient stimulation at frequent intervals to determine the level of consciousness, requires patient cooperation, and is subject to testing fatigue. An example of a conventional assessment tool is the Observer's Assessment of Alertness/Sedation Scale (OAA/S; see [Table 47-6](#)).⁸⁴ The bispectral index has been shown to be a useful monitor of drug-induced sedation and recall in volunteers and has been shown to correlate with OAA/S scores during propofol-induced sedation in patients undergoing surgery with regional anesthesia.⁸⁵ An increasing depth of sedation was associated with a predictable decrease in the BIS index. Absence of recall was associated with BIS values below 80. These findings correspond with those of Kearse *et al*, who found no intraoperative recall at BIS values below 79 during midazolam-, isoflurane-, and propofol-induced sedation.⁸⁶ However, the inability to recall a non-noxious stimulus such as a picture, as used in the above studies, may not necessarily correspond to amnesia to noxious events such as surgical stimulation. Despite this caveat, Liu and co-workers suggest that using a combination of propofol and midazolam to achieve a BIS value below 80 will minimize the possibility of intraoperative recall.⁸⁵ Although the use of BIS to monitor sedation is appealing, conventional assessment of sedation is an important mechanism whereby continuous patient contact is maintained. Ideally, BIS monitoring will be employed in the future as an adjunct to clinical evaluation rather than as the primary monitor of consciousness.

| Responsiveness | Speech | Facial Expression | Eyes | Composite Score |
|---|--------------------------------|------------------------------|--|-----------------|
| Responds readily to name spoken in normal tone | Normal | Normal | Clear, no gross | 5 (awake) |
| Largely responsive to name spoken in normal tone | Mild slowing or thickening | Mild relaxation | Clouded or mild ptosis (less than half the eye) | 4 |
| Responds only after name is called loudly or repeatedly | Slurring or pronounced slowing | Marked relaxation (lack jaw) | Clouded and marked ptosis (half the eye or more) | 3 |
| Responds only after mild prodding or shaking | Very recognizable words | | | 2 |
| Does not respond to mild prodding or shaking | | | | 1 (asleep) |

Table 47-6. OBSERVER'S ASSESSMENT OF ALERTNESS/SEDATION SCALE^{84,85}

Preparedness to Recognize and Treat Local Anesthetic Toxicity

Monitored anesthesia care is often provided in the context of regional or local anesthetic techniques. It is vitally important that the anesthesiologist responsible for the patient have a high index of suspicion and be fully prepared to recognize and treat local anesthetic toxicity immediately (see [Chapter 17](#)). This point deserves special emphasis, particularly in view of the fact that monitored anesthesia care is often provided to the elderly or debilitated patient who has been deemed “unfit” for general anesthesia; these are the patients most likely to suffer adverse reactions to local anesthetic drugs. Even if the anesthesiologist does not perform the block personally, he or she is in a unique position to fulfill an important “preventive” role by advising the surgeon about the most appropriate volume, concentration, and type of local anesthetic drug or technique to be used.

Systemic local anesthetic toxicity occurs when plasma concentrations of drug are excessively high. Plasma concentrations will increase when the rate of entry of drug into the circulation exceeds the rate of drug clearance from the circulation. The clinically recognizable effects of local anesthetics on the central nervous system are concentration-dependent. At low concentrations, sedation and numbness of the tongue and circumoral tissues and a metallic taste are prominent features. As concentrations increase, restlessness, vertigo, tinnitus, and difficulty of focusing may occur. Higher concentrations result in slurred speech and skeletal muscle twitching, which often herald the onset of tonic-clonic seizures.

The conduct of monitored anesthesia care may modify the individual's response to the potentially toxic effects of local anesthetic administration and adversely affect the margin of safety of a regional or local technique. For example, a patient with compromised cardiovascular function may experience a further decline in cardiac output during sedation. The resultant reduction in hepatic blood flow will reduce the clearance of local anesthetics that are metabolized by the liver and have a high hepatic extraction ratio, thereby increasing the likelihood of achieving toxic plasma concentrations. A patient receiving sedation may experience respiratory depression and a subsequent increase in arterial carbon dioxide concentration. Hypercarbia adversely affects the margin of safety in several ways. By increasing cerebral blood flow, hypercarbia will increase the amount of local anesthetic that is delivered to the brain, thereby increasing the potential for neurotoxicity. By reducing neuronal axoplasmic pH, hypercarbia increases the intracellular concentration of the charged, active form of local anesthetic, thus also increasing its toxicity. In addition, hypercarbia, acidosis, and hypoxia all markedly potentiate the cardiovascular toxicity of local anesthetics. Furthermore, the administration of sedative-hypnotic drugs may interfere with the patient's ability to communicate the symptoms of impending neurotoxicity. However, the anticonvulsant properties of benzodiazepines and barbiturates may attenuate the seizures associated with neurotoxicity. In both of the above circumstances, it is possible that the symptoms of cardiotoxicity will be the first evidence that an adverse reaction has occurred. Thus, appropriate treatment is delayed or inadvertent intravascular injection is continued because of the absence of any clinical evidence of neurotoxicity. Cardiovascular toxicity usually occurs at a higher plasma concentration than neurotoxicity, but when it does occur, it is usually much more difficult to manage than neurotoxicity. Although cardiotoxicity is usually preceded by neurotoxicity, it may occur *de novo* when bupivacaine is being used.

Regional anesthetic techniques may have adverse effects upon respiratory function. The effects of clinically relevant concentrations of local anesthetics on respiratory control have been examined in two studies. In one of these studies, lidocaine was found to depress the ventilatory response to hypoxia.⁸⁷ The authors postulate that patients with carbon dioxide retention whose resting ventilation depends upon hypoxic drive may be at risk for ventilatory failure when lidocaine is administered (such as for arrhythmia control or regional anesthesia). However, lidocaine and bupivacaine have both been shown to increase the ventilatory response to carbon dioxide.^{88,89} There appear to be few data concerning the combined effects of local anesthetics and sedative-hypnotics on respiratory control.

Sedation and Analgesia by Nonanesthesiologists

Although anesthesiologists have specific training and expertise to provide sedation and analgesia, in clinical practice these services are frequently provided by nonanesthesiologists. The specific reasons for nonanesthesiologist involvement differ from institution to institution and from case to case. Putative causes include: convenience, availability, and scheduling issues; perceived lack of anesthesiologist enthusiasm; perceived cost issues; and a perceived lack of benefit concerning patient satisfaction and safety when sedation/analgesia is provided by anesthesiologists. Despite our frequent noninvolvement in these cases, anesthesiologists can be indirectly involved in the care of these patients by participating in the development of institutional policies and procedures for analgesia and sedation. To assist anesthesiologists in this process, an ASA task force has developed practice guidelines for sedation and analgesia by nonanesthesiologists.¹ Practice guidelines are recommendations that can be adopted, modified, exceeded, or rejected according to local institutional demands and resources.

The ASA practice guidelines define specifically the desired level of sedation that should be achieved by nonanesthesiologist providers. The term “sedation and analgesia” is used in preference to “conscious sedation”: “Sedation and analgesia describes a state that allows patients to tolerate unpleasant procedures while maintaining adequate cardiorespiratory function and the ability to respond purposefully to verbal command and/or tactile stimulation.” The practice guidelines specifically state that the patient whose only response is reflex withdrawal is sedated to a greater degree than defined by the term “sedation and analgesia.” Excessive sedation may result in cardiorespiratory compromise. If cardiorespiratory compromise is not immediately diagnosed and treated appropriately, hypoxic brain damage or death may occur.

The guidelines emphasize the importance of preprocedure patient evaluation, patient preparation, and appropriate fasting periods. The importance of continuous patient monitoring is discussed: in particular, the response of the patient to commands as a guide to the level of consciousness. The appropriate monitoring of pulmonary ventilation, oxygenation, and hemodynamics is also discussed and recommendations are made for the contemporaneous recording of these parameters. The task force strongly suggests that an individual other than the person performing the procedure be available to monitor the patient's comfort and physiologic status. Education and training of providers is recommended. Specific educational objectives include: the potentiation of sedative-induced respiratory depression by concomitantly administered opioids, adequate time intervals between doses of sedative/analgesics to avoid cumulative overdosage, and familiarity with sedative/analgesic antagonists. The routine administration of supplemental oxygen is recommended. At least one person with advanced life support skills should be present during the procedure. This individual should have the ability to recognize airway obstruction, establish an airway, and maintain oxygenation and ventilation. The practice guidelines recommend that appropriate patient size emergency equipment be readily available, specifically including equipment for establishing an airway and delivering positive pressure ventilation with supplemental oxygen, emergency resuscitation drugs, and a working defibrillator. As discussed earlier in this chapter, the use of drug combinations may be more effective than using single agents to achieve adequate sedation/analgesia. However, in the context of nonanesthesiologist-provided sedation/analgesia it is important that the potential adverse effects on ventilatory function of drug combinations be well understood. When using combinations of drugs, the importance of careful individual drug titration rather than the use of fixed-dose combinations is emphasized. The presence of reliable intravenous access until the patient is no longer at risk for cardiorespiratory depression will improve safety. Adequate post-procedure recovery care with appropriate monitoring must be provided until discharge. Certain high-risk patient groups (e.g., uncooperative patients, extremes of age, severe cardiac, pulmonary, hepatic, renal,

or central nervous system disease, morbid obesity, sleep apnea, pregnancy, drug or alcohol abuse) will be encountered. The guidelines recommend that preprocedure consultation with cardiologists, pulmonologists, and so forth be performed *before* administration of analgesia/sedation by nonanesthesiologists.

CONCLUSION

Through the use of monitored anesthesia care and conscious sedation, an often terrifying and painful procedure can be made safe and comfortable for the patient. Monitored anesthesia care presents an opportunity for our patients to observe us at work. For the anesthesiologist, monitored anesthesia care presents an opportunity to provide a more prolonged and intimate level of care and reassurance to our patients that is in contrast to the more limited exposure that occurs during and after general anesthesia. Our airway management skills and our daily practice of applied pharmacology make us uniquely qualified to provide this service. Monitored anesthesia care presents us with an opportunity to display these skills and increase our recognition in areas outside the operating room. The availability of drugs with a more favorable pharmacologic profile allows us to tailor our techniques to provide the specific components of analgesia, sedation, anxiolysis, and amnesia with minimal morbidity and to facilitate a prompt recovery. As the population ages, increasing numbers of patients will become candidates for monitored anesthesia care. Significant advances in nonsurgical fields, *e.g.*, interventional radiology, will increase the number of procedures that are ideally performed under monitored anesthesia care. It is our responsibility to clearly demonstrate to our nonanesthesia colleagues that anesthesiologist-provided monitored anesthesia care contributes to the best outcome for our patients. If anesthesiologists are not willing or able to provide these services, others, who are less well qualified, are prepared to assume that role.

Injuries are the most common cause of death in Americans between the ages of 1 and 45 years; more than 50% of all deaths in people between 5 and 34 years of age result from trauma.¹ Although the proportionate mortality rate from trauma (6.3%) is far less than those of heart disease (31.5%) and cancer (23.3%), these are most often diseases of older people.¹ Thus, injuries remain the largest contributor (34%) to the 13.6 million years of productive life lost annually in the population younger than 75 years of age. As of 1996, years of productive life lost from trauma were 4.6 million; malignancy, 4.4 million; heart disease, 3.5 million; and human immunodeficiency virus infection, 1.1 million.¹

In the United States, deaths from unintentional injuries are most often the result of motor vehicle accidents, falls, poisoning, fires, or drowning.¹ In the last few years, although the number of deaths from unintentional injuries has been stable at approximately 92,000 per year, the per capita mortality rate has been decreasing because the population has been increasing.¹ However, this improvement has been thwarted by an alarming increase in violent injuries, especially in inner cities, mostly caused by firearms, and usually affecting young men of minority groups.^{2,3} In 1996, the death toll from homicide was 20,971 and from suicide 30,903, a total intentional injury mortality of approximately 52,000.

Although the time of death after trauma may be influenced by the type and severity of injury and the effectiveness of prehospital and hospital care, existing data suggest that between 34 and 76% of trauma deaths occur immediately at the scene of the accident or during transport to the hospital.^{4,5} and ⁶ Central nervous system (CNS) injuries, exsanguination, or both are responsible for 90% of these deaths;⁶ hypoxia as a result of airway obstruction, aspiration of gastric contents, or pneumothorax may also contribute. Any improvement in prehospital care is unlikely to better the outcome of these unsalvageable patients.

Approximately 75% of the hospital mortality from trauma occurs within 48 hours after admission,^{4,6,7} most commonly from thoracic, abdominal or retroperitoneal, vascular, or CNS injuries.^{6,7} Hypoxia, systemic air embolism, and cardiac failure may also be direct or contributing factors.⁶ Approximately one third of these patients die within the first 4 hours after admission, representing most of operating room trauma deaths.^{4,5} Of the remaining 25% of hospital deaths, 5–10% occur between the third and seventh day of admission, usually from CNS injuries,^{4,5} and ⁷ and the rest in subsequent weeks, most commonly as a result of multiorgan failure.⁶ Pulmonary thromboembolism and infectious complications may also contribute to mortality during this phase.^{6,7} The quality of life may also be affected; approximately 80% of survivors of major trauma have significant functional limitation at 12 and 18 months after injury.⁸

TRAUMA CENTERS

The American College of Surgeons (ACS) has published guidelines for the organization of centers structured to care for injuries of various grades of severity.⁹ A Level I trauma center must manage at least 1200 patients annually, 20% of whom should have injury severity scores of 15 or greater.⁹ Other requirements include around-the-clock coverage in a fully staffed emergency department by a physician experienced in management of injuries, with continuous availability of a surgeon, a neurosurgeon, and other consultants who can be present within a short time. There should always be an operating room prepared and staffed, along with available anesthesia personnel, an intensive care unit (ICU), a fully equipped laboratory and blood bank, and a radiology facility that can perform portable chest radiographs, computed tomography (CT), angiography, and ultrasound studies. Level I and II trauma centers must have anesthesia services available in-house 24 hours a day.⁹ Preferably, anesthesia care in a Level I or II trauma center should be controlled by an anesthesiologist interested and experienced in the care of the injured.⁹ In Level I and II trauma centers, senior anesthesia residents (chief residents as described in the ACS manual) or certified registered nurse anesthetists (CRNA) experienced in trauma care can initiate emergency care, including surgical anesthesia, as long as an attending physician is notified and can arrive promptly.⁹ In Level III trauma centers, a CRNA may provide initial care, as long as an anesthesiologist is immediately available, or in the worst circumstances, the CRNA is supervised by a physician skilled in airway management.⁹ Approximately 12% of injured patients require Level I care.¹⁰

Unfortunately, the changing demographics of trauma victims has put severe financial pressure on designated trauma centers. As discussed previously, in some areas the previously predominant population of blunt trauma victims, more than 70% of whom are insured and, proportional to their injury severity, generate significant profit to the institution,¹¹ is being replaced by an increasing number of people injured by firearms, who are mostly underinsured or uninsured, and whose medical expenses are either covered by public funds or written off as bad debt. In a population-based study in California, annual medical charges for 9193 hospitalized firearm injuries were \$164 million. Seventy-five percent of these patients were either uninsured or had publicly financed health insurance.¹² This is part of the reason that 66 of 600 designated trauma centers closed between 1983 and 1992.¹³ This trend has been reversed since 1992 by the passage of the Trauma Care Systems Planning and Development Act of 1990 (Public Law 101-590). Under this law, in 1993 development grants were given to 19 states for initiation of trauma systems, while an additional 16 states received funds to improve their existing programs.¹⁴

The economic impact of trauma on society is enormous. In 1998, the estimated total cost of unintentional injuries alone exceeded \$500 billion, including wage and productivity losses of \$246 billion and medical expenses of \$76 billion, in addition to other costs.¹

INITIAL EVALUATION AND RESUSCITATION

The Advanced Trauma Life Support (ATLS) Course developed by the Committee on Trauma of the ACS provides the trauma team with a common base of clinical knowledge and skills that facilitates coordination and clear, rapid, and accurate communication during the initial phase of treatment.¹⁵ The main emphasis in the ATLS Course is on the recognition of clinical priorities that proceed in a stepwise fashion to assess and treat injuries in order from the most to the least life threatening. Although this vertical or sequential care design is safe and frequently practiced in centers with limited manpower, in hospitals where personnel from various clinical disciplines can readily form a multidisciplinary team, a horizontal or simultaneous approach is used. In this manner, each group of physicians carries out its role in

resuscitation, coordinated by a team leader who applies the same priority-oriented care principles.⁹ As part of the team, the anesthesiologist, aside from managing the airway, contributes to evaluation and resuscitation while gathering information needed for possible future anesthetic management.

The clinical strategy of initial management can be defined as a continuous, priority-driven process of patient assessment, resuscitation, and reassessment. The general approach to evaluation of the acute trauma victim has three sequential components: rapid overview, primary survey, and secondary survey¹⁵ (Fig. 48-1). Resuscitation is initiated, if needed, at any time during this continuum. *Rapid overview* takes only a few seconds and is used to determine whether the patient is stable, unstable, dead, or dying. The *primary survey* involves rapid evaluation of functions that are crucial to survival. The “ABCs” of airway patency, breathing, and circulation are assessed. Then a brief neurologic examination is performed and the patient is examined for injuries that might have been overlooked.

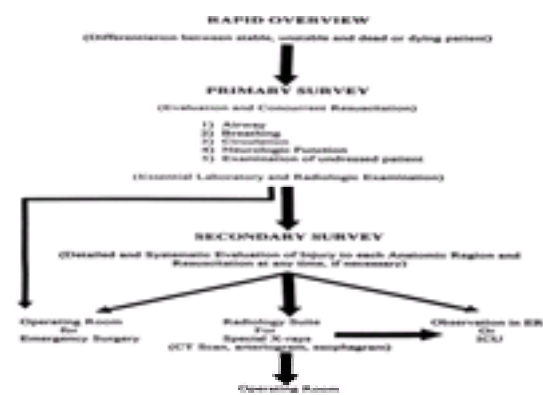

Figure 48-1. Clinical sequence followed during initial management of the major trauma patient.

The *secondary survey* involves a more elaborate systematic examination of the entire body to identify additional injuries. Radiographic and other diagnostic procedures may also be performed if the stability of the patient permits. Within this general framework, the anesthesiologist identifies injuries, pre-existing conditions, and any resulting functional abnormalities that require either immediate treatment or provision for resuscitative and anesthetic management.

An important issue should be emphasized at this time. Many trauma victims are carriers of hepatitis B, hepatitis C, tuberculosis, or human immunodeficiency virus.^{16,17} and ¹⁸ Universal infection control precautions are the standard and must be used during every stage of management of these patients.

It is possible that injuries may be missed during initial evaluation and even during emergency surgery. An Australian study demonstrated that many clinically significant injuries were undiagnosed, resulting in significant pain, complications, residual disability, delay of treatment, or death.¹⁹ Examples of missed diagnoses included cervical spine, thoracoabdominal, pelvic, nerve, and external soft tissue injuries, and extremity fractures. Some of these injuries may present during anesthesia, such as spinal cord damage during airway management in a patient with unrecognized cervical spine injury, massive intraoperative bleeding from an unrecognized thoracoabdominal injury during extremity surgery, or sudden intraoperative hypoxemia in a patient with unrecognized pneumothorax. A *tertiary survey* within the first 24 hours after admission (that may include a period of anesthesia), which involves repeating the primary and secondary examinations and reviewing the radiologic and laboratory results, has been shown to diagnose 90% of clinically significant injuries missed during initial evaluation.¹⁹

Airway Evaluation and Intervention

Airway evaluation (see also [Chapter 23](#)) involves the diagnosis of any trauma to the airway or surrounding tissues, recognition and anticipation of the respiratory consequences of these injuries, and prediction of the potential for exacerbation of these or other injuries by any contemplated airway management maneuvers. Although nontraumatic causes of airway difficulty, such as pre-existing factors, may be present, only the management of trauma-related problems is discussed in this section.

Asphyxia or Hypoxia

Airway obstruction, hypopnea or apnea, thoracic trauma, inhalation injury, and pulmonary embolism (PE; air, fat, or thrombus) are the most frequent causes of this complication. Rapid intervention is required to restore airway patency, administer oxygen, establish ventilation, and ultimately secure the airway. Hypoxia may be difficult to recognize in the severely injured patient; its symptoms may be masked or attributed to other causes. For example, cyanosis may be undetectable in the presence of coexisting anemia, a low-flow state, or dark skin pigmentation. Apprehension and restlessness may be attributed to fear and anxiety rather than to hypoxia. If the patient can talk, serious airway obstruction is unlikely, although inability to respond verbally may also be caused by respiratory or CNS dysfunction.

Airway obstruction is probably the most frequent cause of asphyxia, and may result from posteriorly displaced or lacerated pharyngeal soft tissues, hematoma, bleeding, secretions, foreign bodies, or displaced bone or cartilage fragments. Bleeding into the cervical region may produce airway obstruction not only because of direct airway occlusion by the hematoma but from venous congestion and upper airway edema as a result of compression of neck veins.²⁰ Signs of upper and lower airway obstruction include dyspnea, hoarseness, stridor, dysphonia, subcutaneous emphysema, and hemoptysis. Cervical deformity, edema, crepitation, tracheal deviation, or jugular venous distention may be present before appearance of these symptoms and may help to indicate that specialized airway management techniques are required.

The initial steps in airway management are chin lift, jaw thrust, clearing of the oropharyngeal cavity, placement of an oropharyngeal or nasopharyngeal airway, and in inadequately breathing patients, ventilation with a self-inflating bag. These measures should follow immobilization of the cervical spine and should include administration of oxygen. Blind passage of a nasopharyngeal airway on a nasogastric or nasotracheal tube should be avoided if a basilar skull fracture is suspected; it may enter the anterior cranial fossa.²¹ A cuffed oropharyngeal airway (COPA) with a standard connector may permit ventilation by a self-inflating bag, although it provides no protection against aspiration of gastric contents. If these measures do not provide adequate ventilation, the trachea must be intubated immediately using either direct laryngoscopy or a cricothyroidotomy, depending on the results of airway assessment. Whenever possible, the airway should be secured only after adequate ventilation and oxygenation are provided by mask. Maxillofacial, neck, and chest injuries and cervicofacial burns are the most common trauma-related causes of difficult tracheal intubation. Appropriate personnel and equipment must be ready to establish an emergency surgical airway in case attempts at direct laryngoscopy fail. Airway assessment should therefore include a rapid examination of the anterior neck for the feasibility of access to the cricothyroid membrane. Tracheostomy is not desirable during initial management because it takes longer to perform than a cricothyroidotomy and requires neck extension, which may cause or exacerbate cord trauma in cervical spine-injured patients. Conversion to a tracheostomy should be considered to prevent laryngeal damage if a cricothyroidotomy will be in place for more than 2–3 days. Possible contraindications to cricothyroidotomy include age younger than 12 years and suspected laryngeal trauma; laryngeal damage may result in the former and uncorrectable airway obstruction may occur in the latter situation.

A high rate of success in prehospital airway management by paramedics is possible using the laryngeal mask airway (LMA), esophageal–tracheal combitube, tracheal intubation under direct laryngoscopy with or without rapid-sequence induction, and surgical cricothyroidotomy.^{22,23} and ²⁴ Proper placement of these devices should be confirmed, preferably with capnography, as soon as possible. Esophageal lacerations presenting as subcutaneous emphysema, pneumomediastinum, or pneumoperitoneum have been described secondary to esophageal–tracheal combitube use.^{25,26}

Full Stomach

A full stomach is a background condition in acute trauma; the urgency of securing the airway most often does not permit adequate time for pharmacologic measures to reduce gastric volume and acidity. Thus, rather than relying on these agents, the emphasis should be placed on selection of a safe technique for securing the airway when necessary: rapid-sequence induction with cricoid pressure for those patients without serious airway problems, and awake intubation with sedation and topical anesthesia, if possible, for those patients who may present with serious airway difficulties. Excessive cricoid pressure is unnecessary and may increase the likelihood of a reduction in expired tidal volume, an increase in peak airway pressure, and even complete airway obstruction.²⁷ Posterior displacement of a vertebral bone fragment, with potential damage to the spinal cord, may also occur when cricoid pressure and manual inline stabilization (MIS) are applied to cervical spine-injured patients.²⁸ Modifying this technique by supporting the back of the neck with another hand may alleviate this problem.²⁷

The probability of a full stomach precludes the use of an LMA or any other device that does not protect the trachea as a definitive airway in trauma patients. However, there are some potential benefits to using this device. It can serve as a bridge for a brief period to re-establish airway patency or to facilitate intubation aided by a

flexible fiberoptic bronchoscope. In patients with maxillofacial injuries, aspiration of pharyngeal blood or secretions is more likely than aspiration of gastric contents.²⁹ If it can be inserted in these circumstances, an LMA may protect the lungs. Positive-pressure ventilation may be used with the LMA provided that peak airway pressures do not exceed 25 cm H₂O.²⁷ However, trauma patients with pulmonary contusion, edema, or aspiration may be difficult to ventilate with this device. Difficulty may also be encountered when inserting an LMA in the presence of cricoid pressure and MIS of the cervical spine.^{27,30} These problems may be somewhat circumvented with the intubating laryngeal mask (ILM); adequate ventilation is more likely, blind tracheal intubation is more successful, and an endotracheal tube up to 8 mm can be placed by ILM, as opposed to the maximum of 6 mm that can be passed through an LMA.^{31,32} An important disadvantage of the ILM is that its metal part may exert considerable pressure against cervical vertebrae, potentially exacerbating an unstable injury in this region.³³

The selection of an airway management technique in the trauma patient is affected by his or her hemodynamic condition. The presence of uncorrectable hypotension from hemorrhage, hypovolemia, or pericardial tamponade may necessitate omitting intravenous (iv) anesthetics from the rapid-sequence technique. Muscle relaxants alone may be sufficient. If only a mild to moderate degree of hypovolemia is present, reduced doses (30–50%) of iv anesthetics should be administered.³⁴ Although there is no evidence that the choice of iv agent affects outcome, ketamine and etomidate may confer advantages over thiopental and propofol. In equipotent doses, in normovolemic patients, they have less cardiovascular depressant effects. The resulting better muscle perfusion promotes increased drug delivery to the neuromuscular junction, accelerating the onset time of muscle relaxants.³⁵ Although succinylcholine, with its short onset time and duration, is still the muscle relaxant of choice for rapid-sequence induction, the nondepolarizing relaxants rocuronium (0.9–1.2 mg · kg⁻¹) and rapacuronium³⁶ (1.5–2.5 mg · kg⁻¹) have onset times almost comparable with that of succinylcholine and do not have the undesirable side effects associated with succinylcholine (e.g., increased intragastric, intraocular, and intracranial pressure, and potassium release in patients with burns and neurologic diseases).^{37,38} Bradycardia, dysrhythmias, and cardiac arrest have been described after succinylcholine in the presence of hypoxia and hypercarbia; however, these complications may also follow apparently uneventful intubation performed without succinylcholine.

There is no consensus about the extent of the airway that can be safely anesthetized with topical agents to facilitate awake tracheal intubation in the trauma patient. Anesthesia of the entire pharynx, larynx, and trachea clearly provides the most optimal conditions. Avoiding transtracheal and superior laryngeal nerve blockade helps to preserve glottic and cough reflexes, although tracheal intubation is technically more difficult. Another approach is to block the superior laryngeal nerves in addition to topically anesthetizing the mouth and pharynx, using the rationale that even in the absence of glottic closure, an intact cough reflex will cause the expulsion of aspirated material. To our knowledge, there are no data to verify which method is superior.

Agitated and uncooperative patients present a difficult situation. Topical anesthesia of the airway may be impossible, whereas administration of sedative agents may result in apnea or airway obstruction, with an increased risk of aspiration of gastric contents and inadequate conditions for tracheal intubation. After locating the cricothyroid membrane and denitrogenating the lungs, a rapid-sequence induction may be used to permit securing the airway with direct laryngoscopy or, if necessary, with immediate cricothyroidotomy. Personnel and material necessary to perform translaryngeal ventilation or cricothyroidotomy must be secured before induction of general anesthesia.³⁹

Head, Open Eye, and Contained Major Vessel Injuries

The principles of tracheal intubation are similar for all of these injuries. Apart from the need to ensure adequate oxygenation and ventilation, these patients require deep anesthesia and profound muscle relaxation before airway manipulation. This helps to prevent hypertension, coughing, and bucking, and thereby minimizes intracranial, intraocular, or intravascular pressure elevation, which can result in herniation of the brain, extrusion of eye contents, or dislodgment of a hemostatic clot from an injured vessel, respectively. The preferred anesthetic sequence to achieve this goal includes preoxygenation and opioid loading followed by relatively large doses of an iv anesthetic and muscle relaxant. Because of its rapid onset and short duration, remifentanyl has been considered for opioid loading; a 1 µg · kg⁻¹ bolus with or without a 0.5 µg · kg⁻¹ infusion can attenuate the pressor response to laryngoscopy and intubation.^{40,41} In one study, however, almost one half of the patients had hypotension and bradycardia unless glycopyrrolate was also given.⁴¹ Hemodynamic responses to the opioid should be carefully monitored and promptly corrected. Systemic hypotension, intracranial pressure (ICP) elevation, and decreased cerebral perfusion pressure (CPP) may occur whether cerebral autoregulation is present or absent, and if untreated can produce secondary ischemic insults.⁴² Ketamine is probably contraindicated in patients with head and vascular injuries because it may increase both intracranial^{43,44} and systemic vascular pressures; however, no significant increase in intraocular pressure (IOP) has been documented.⁴⁵ Any muscle relaxant, including succinylcholine, may be used as long as the fasciculations produced by this agent are inhibited by prior administration of an adequate dose of a nondepolarizing muscle relaxant.⁴⁶ Alternatively, rocuronium can be administered; intubating conditions may be achieved within 60 seconds with a dose of 1.6–2.0 mg · kg⁻¹, although the neuromuscular blockade produced by this dose lasts approximately 2 hours.⁴⁷ Intravenous lidocaine may be used although its attenuating effect on the pressor response to airway instrumentation is mild and unpredictable. Of course, neither muscle relaxants nor iv anesthetics are indicated when initial assessment suggests a difficult airway. If the patient is hypotensive, the same precautions used during intubation in any other trauma victim apply: little or no iv anesthetic is administered.

Cervical Spine Injury

Cervical spine injury may be present in any trauma patient, but it is more likely in those sustaining high-velocity blunt injuries, especially above the clavicle. Evidence of a serious new spinal cord injury or accentuation of existing neurologic abnormalities has been documented after intubation of patients with unsuspected cervical spine injuries.^{48,49} Immobilization of the neck in a neutral position is indicated in all unconscious patients, in conscious patients with cervical pain or tenderness, and whenever the pain of other injuries is likely to mask neck pain.⁵⁰ The combined use of a semirigid collar, sandbags placed on both sides of the head and neck, bindings, and a backboard provides the most reliable immobilization.⁵⁰ For airway management purposes, however, MIS, with assistants holding the head and torso of the patient, is a practical and safe method if the neck is not otherwise reliably stabilized.⁵⁰ A semirigid neck collar alone does not provide reliable protection. Of course, the airway must be evaluated before administration of any anesthetics or muscle relaxants. The anterior part of the cervical collar can be removed for this purpose. Protection of the neck should be maintained after tracheal intubation until a cervical spine injury has been ruled out.

Nasotracheal intubation carries the risks of epistaxis, failure of intubation, and the possibility of entry of the endotracheal tube into the cranial vault or the orbit if there is damage to the cranial base or the maxillofacial complex. Absence of the usual signs of cranial base fracture (Battle sign, raccoon eyes, or bleeding from the ear or the nose) cannot be relied on to exclude the possibility of its occurrence because with rapid prehospital transport, these signs may not be immediately apparent. Thus, nasotracheal intubation cannot be routinely recommended for the early phase of trauma management. Orotracheal intubation with direct laryngoscopy is more desirable, although stabilization of the neck, which limits head extension, may make glottic visualization difficult. The incidence of inadequate exposure of the larynx increases from less than 3% in the general population to approximately 10% with immobilization of the neck.^{51,52}

A variety of devices and techniques, including the McCoy laryngoscope, rigid fiberoptic laryngoscopes (Bullard or WuScope), flexible fiberoptic endoscope, light-wand, translaryngeal (retrograde) intubation, and cricothyroidotomy, can be used to secure the airway in patients requiring cervical spine immobilization.²⁷ In most instances, successful, safe, and rapid tracheal intubation can be achieved with a conventional laryngoscope in spite of limited visualization of the larynx.⁵³ The McCoy laryngoscope with its flexible tip is able to lift the epiglottis and improve the laryngeal view without adding to the time and complexity of the procedure.²⁷ A gum-elastic bougie passed through the endotracheal tube, or a satin-sheathed stylet placed through its Murphy aperture may also be helpful because they can be inserted through the larynx more easily than the tube itself; their small diameter does not block the view of the glottis during direct laryngoscopy.⁵⁴ Other specialized techniques require operator experience and a longer preparation and performance time; thus, they should probably be used in cervical spine-stabilized patients only when tracheal intubation is suspected or proven to be impossible. Of these, the WuScope provides a consistently good laryngeal view with a high success rate of intubation and minimal neck movement.⁵⁵ The Bullard scope is also considered useful, although there have been no studies comparing it with the WuScope.⁵¹

Although flexible fiberoptic laryngoscopy and translaryngeal guided intubation (see [Maxillofacial Injuries](#)) cause almost no neck movement, the presence of blood or secretions in the airway, a long preparation time, and difficulty in their use in comatose, uncooperative, or anesthetized patients reduce their utility during initial management.

Direct Airway Injuries

Direct airway damage can occur anywhere between the nasopharynx and the bronchi; sometimes more than one site may be involved, resulting in persistent airway dysfunction after one of the problems is corrected.⁵⁶ The clinical presentation and management of airway compromise resulting from direct trauma are determined by the type of injury and its location.

Maxillofacial Injuries. In addition to soft tissue edema of the pharynx and peripharyngeal hematoma, blood or debris in the oropharyngeal cavity may be responsible for partial or complete airway obstruction in the acute stage of these injuries. Occasionally teeth or foreign bodies in the pharynx may be aspirated into the airway, causing some degree of obstruction, which may occur or be recognized only during attempts at tracheal intubation. Another problem is the dynamic nature of soft tissue injuries in this region. A hematoma or edema in the head or neck may expand during the 6–12 hours after injury and ultimately occlude the airway.⁵⁷ Serious airway compromise may develop within a few hours in up to 50% of patients with major penetrating facial injuries or multiple trauma as a result of progressive

inflammation or edema resulting from liberal administration of fluids.^{58,59} Prophylactic intubation of the trachea or very close and repeated examination of the upper airway may help detect the potential for airway compromise before its occurrence.

Certain facial fractures may also produce airway compromise. In bilateral parasymphseal fractures of the mandible, a posteriorly shifted bone fragment may encroach on the pharynx and the larynx; traction on this fragment with the hand or a clamp can relieve the airway obstruction. Bilateral, but not unilateral, mandibular condyle fractures may prevent adequate mouth opening, thus causing problems with laryngoscopy. In the midface, trimalar fractures can cause the free fragment of the zygoma to descend in front of the coronoid process of the mandible and interfere with mouth opening. These mechanical problems should be differentiated from the limitation of jaw movement produced by pain and trismus. Fentanyl in titrated doses of up to 2–4 $\mu\text{g} \cdot \text{kg}^{-1}$ over a period of 10–20 minutes may produce an improvement in the patient's ability to open the mouth in the latter case.

LeFort fractures of the midface are the most severe types of facial trauma. Of these, LeFort 1 involves the maxilla and the maxillary sinus. Airway management is easy in these patients because the fracture mobilizes the upper jaw, leaving more maneuvering room for the laryngoscope. Both LeFort 2 and LeFort 3 fractures involve the thick portion of the nasal bone; LeFort 2 extends to the medial side of the orbit, whereas the LeFort 3 involves the orbit laterally and extends toward the temporal bone. From the airway management standpoint, the degree of posterior extension of these fractures is important. The pterygoid plate, an inferior process of the sphenoid bone, is the only buttress that prevents the midface from shifting posteriorly. In LeFort 2 and 3 fractures, the pterygoid plate is fractured at its base, often in combination with the cranial base, including the cribriform plate. With disruption of the posterior buttress, the entire midface of the patient with one of these fractures moves backward and may encroach on the pharynx⁶⁰ (Fig. 48-2).

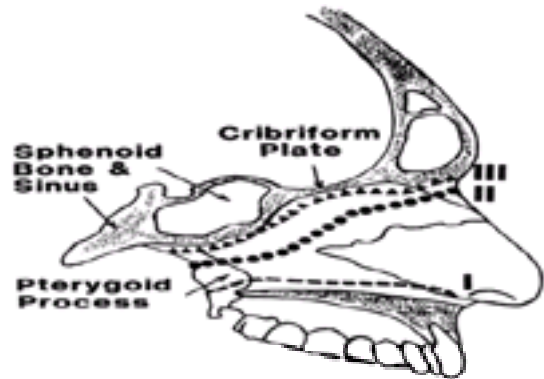

Figure 48-2. Anteroposterior fracture lines of LeFort 1 (I), LeFort 2 (II) and LeFort 3 (III) injuries. Note that in LeFort 3 fracture the pterygoid process, the only facial buttress posteriorly, is injured from its base, allowing the entire midface to shift posteriorly. In this injury, the cribriform plate may also be fractured. (Reprinted by permission from Capan LM, Miller, SM, Glickmann R: Management of facial injuries. In Capan LM, Miller SM, Turndorf H [eds]: Trauma: Anesthesia and Intensive Care, p 383. Philadelphia, JB Lippincott, 1991.)

The selection of an airway management technique in the presence of a maxillofacial fracture is based on the presenting condition. Most patients with isolated facial injury do not require emergency tracheal intubation. Surgery for facial injuries may be delayed for approximately a week without adverse effect on the repair. Patients who present with airway compromise may be intubated using direct laryngoscopy; the use of anesthetics and muscle relaxants is based on the results of airway evaluation. When there is bleeding into the oropharynx, a flexible fiberoptic laryngoscope may be useless because of obstruction of the view. A retrograde technique, using a wire or epidural catheter passed through a 14-gauge catheter introduced into the trachea through the cricothyroid membrane, may be used if the patient can open his or her mouth. A surgical airway is indicated when there is airway compromise, when direct laryngoscopy has failed or is considered impossible, when the jaws will be wired, or when a tracheostomy tube will be placed anyway after definitive repair of the fracture. Nasogastric or nasotracheal intubation should be avoided when basilar skull or maxillary fracture is suspected because of the possibility that the tube may enter the cranium or the orbital fossa. Cranial and cervical spine injuries are commonly associated with midface fractures; the airway management must be tailored accordingly.⁶¹ The likelihood of cranial injury increases in midface fractures involving the frontal sinus and the orbitozygomatic and orbitoethmoid complexes.⁶²

Cervical Airway Injuries. Injury to the cervical air passages can result from blunt or penetrating trauma. In the latter category, stab wounds are usually easier to manage than gunshot wounds. Clinical signs such as escape of air, hemoptysis, and coughing are present in almost all patients with penetrating injuries, facilitating the diagnosis. In contrast, major blunt laryngotracheal damage may be missed, either because the patient is asymptomatic or unresponsive, or because suggestive signs and symptoms are missed in the initial evaluation.⁵⁶ The typical presentation includes hoarseness, muffled voice, dyspnea, stridor, dysphagia, odynophagia, cervical pain and tenderness, ecchymosis, subcutaneous emphysema, and flattening of the thyroid cartilage protuberance (Adam's apple).⁶³ Whether the trauma is blunt or penetrating, attempts at blind tracheal intubation may produce further trauma to the larynx and complete airway obstruction if the endotracheal tube enters a false passage or disrupts the continuity of an already tenuous airway.^{64,65} Thus, whenever possible, intubation of the trachea should be performed using a flexible fiberoptic bronchoscope, or an airway should be established surgically. A CT scan of the neck provides valuable information and should be performed before any airway intervention in all stable patients without respiratory and hemodynamic compromise.

The strategy for tracheal intubation depends on the clinical presentation.⁶⁴ The tracheas of some patients with penetrating airway injuries, especially stab wounds, may be intubated through the airway defect without the need for anesthetics or optical equipment.⁵¹ Patients with a normal airway on endoscopy can be intubated orotracheally under general anesthesia. The presence of cartilaginous fractures or mucosal abnormalities necessitates awake intubation with a fiberoptic bronchoscope or awake tracheostomy. Laryngeal damage precludes cricothyroidotomy. Tracheostomy should be performed with extreme caution because up to 70% of patients with blunt laryngeal injuries may have an associated cervical spine injury.⁶⁴ Uncooperative or confused patients may not tolerate awake airway manipulation. It may be best to transport these patients to the operating room, induce anesthesia with inhalational agents, and intubate the trachea without muscle relaxants.⁶⁴ Episodes of airway obstruction during spontaneous breathing under an inhalational anesthetic can be managed by positioning the patient upright in addition to usual maneuvers. In extreme situations such as near-complete transection of the larynx and trachea, femorofemoral bypass or percutaneous cardiopulmonary support should be considered.⁶⁶

Thoracic Airway Injuries. Whereas penetrating trauma can cause damage to any segment of the intrathoracic airway, blunt injury usually involves the posterior membranous portion of the trachea and the mainstem bronchi, usually within approximately 3 cm from the carina. Pneumothorax, pneumomediastinum, pneumopericardium, subcutaneous emphysema, and a continuous air leak from the chest tube are the usual signs of this injury; they occur frequently, but are not specific for thoracic airway damage. When tracheal intubation is performed without the suspicion of an underlying tracheal injury, difficulty in obtaining a seal around the endotracheal tube, or the presence on a chest radiograph of a large radiolucent area in the trachea corresponding to the cuff, suggests a perforated airway.⁶⁷ Other radiographic findings include a radiolucent line along the prevertebral fascia due to air tracking up from the mediastinum, peribronchial air or sudden obstruction along an air-filled bronchus, and the "dropped lung" sign. The latter occurs when complete intrapleural bronchial transection causes the apex of the collapsed lung to descend to the level of the hilum.⁶⁸

The principles of airway management are similar to those of cervical airway injury. Although in both cervical and thoracic airway injuries, administration of anesthetics and especially muscle relaxants may result in irreversible airway obstruction, presumably because of relaxation of structures that maintain the airway patent in the awake state, airway loss may also occur during attempts at awake intubation.⁶⁹ Certain manipulations may also lead to sudden airway obstruction. For example, cricoid pressure during a rapid-sequence induction in a patient with injury to this cartilage may completely occlude the trachea.⁵⁶ Thus, the cricothyroid membrane should be located before administration of any anesthetic induction agents to permit securing the airway surgically if there are serious problems with direct laryngoscopy.⁶⁹

After intubation of the trachea, the adequacy of the airway intervention is evaluated by clinical examination, capnography, and pulse oximetry. Pulmonary contusion, atelectasis, diaphragmatic rupture with thoracic migration of the abdominal contents, and pneumothorax may complicate the interpretation of chest auscultation. Likewise, CO₂ elimination may be decreased or absent in shock and cardiac arrest.

Management of Breathing Abnormalities

Of the several causes that may alter respiration after trauma, tension pneumothorax, flail chest, and open pneumothorax are immediate threats to the patient's life and therefore require rapid diagnosis and treatment. Hemothorax; closed pneumothorax; pulmonary contusion; diaphragmatic rupture with herniation of abdominal contents; and atelectasis from a mucus plug, aspiration, or chest wall splinting can also interfere with breathing and pulmonary gas exchange and deteriorate into life-threatening complications. Nevertheless, they do not usually carry the same gravity of risk as the first three conditions.

Although cyanosis, tachypnea, hypotension, neck vein distention, tracheal deviation, and diminished breath sounds on the affected side are the classic signs of tension pneumothorax, neck vein distention may be absent in hypovolemic patients and tracheal deviation may be difficult to appreciate. The definitive diagnosis is established by chest radiograph; however, in hypoxemic and hypotensive patients, immediate insertion of a 14-gauge angiocatheter through the fourth intercostal space in the midaxillary line or, at times, through the second intercostal space at the midclavicular line, is essential. There is no time for radiologic confirmation in this setting.

A flail chest results from comminuted fractures of at least three adjacent ribs or rib fractures with associated costochondral separation or sternal fracture.⁷⁰ Respiratory insufficiency or failure in this situation results from coexisting hemopneumothorax, lung contusion, paradoxical chest wall movement, or splinting because of intense pain. Because of splinting, not all trauma victims with flail chest manifest respiratory paradox during initial assessment. The diagnosis, which is primarily based on physical findings, may be delayed in approximately 15% of patients.⁷¹ Repeated evaluation by physical examination, chest radiograph, and arterial blood gas (ABG) determinations is essential for early recognition of flail chest and a possible underlying pulmonary contusion, the clinical manifestations of which may also be delayed.⁷² Patients in whom respiratory insufficiency or failure develop despite analgesic treatment require tracheal intubation and mechanical ventilation^{70,71} and ⁷² (Table 48-1).

Respiratory failure manifested by one or more of the following criteria:
 Clinical signs of progressive fatigue or deterioration.
 Respiratory rate >35 breaths \cdot min⁻¹ or <8 breaths \cdot min⁻¹
 PaCO₂ <60 mm Hg at PaCO₂ ≈ 0.5
 PaCO₂ >55 mm Hg
 PaO₂/PaCO₂ ratio ≤ 200
 Vital capacity <15 ml \cdot kg⁻¹
 Forced expiratory volume in 1 s (FEV₁) ≤ 10 ml \cdot kg⁻¹
 Inspiratory force ≤ -25 cm H₂O
 Alveolar-arterial oxygen gradient (A-a DO₂) in mm Hg at PaO₂ of 100 >450
 Shunt fraction (Q_s/Q_T) >0.2
 Dead space/total volume ratio (V_D/V_T) >0.6
 Clinical evidence of severe shock
 Associated severe head injury with absent airway control or need to hyperventilate
 Severe associated injury requiring surgery
 Airway obstruction
 Significant pre-existing chronic pulmonary disease.

Table 48-1. INDICATIONS FOR MECHANICAL VENTILATION IN PATIENTS WITH FLAIL CHEST

Without significant gas exchange abnormalities, chest wall instability alone is not an indication for respiratory support. There is evidence that liberal use of mechanical ventilation in the presence of a flail chest or pulmonary contusion increases the rate of pulmonary complications and mortality and prolongs the hospital stay.^{71,72} Effective pain relief by itself can improve respiratory function and often avoid the need for mechanical ventilation. For this purpose, continuous epidural analgesia with local anesthetics and opioids, preferably directed to thoracic segments, provides better pain relief and ventilatory function than parenteral opioids, reducing morbidity and mortality in elderly patients with chest wall trauma.^{73,74} Coagulopathy, spine injury, and suspected abdominal injury, however, can be contraindications to epidural analgesia. Other therapeutic measures in patients with chest wall injury include supplemental oxygen, airway humidification, chest physiotherapy, incentive spirometry, bronchodilators, airway suctioning using fiberoptic bronchoscopy if necessary, and nutritional support.⁷⁰ Fluid therapy should also be adjusted carefully. Overzealous infusion of fluids may result in deterioration of oxygenation by worsening underlying pulmonary injury.⁷²

The life-threatening hypoxia and hypercarbia that may complicate an open pneumothorax result from atmospheric air following the path of least resistance and entering the pleural cavity through the chest wall instead of the normal air passages. Immediate management in spontaneously breathing patients involves covering the defect with a dressing taped on three sides, so that a one-way valve is created that prevents air entry into the pleural cavity and allows egress of air during expiration. Another effective maneuver is to apply an occlusive dressing and insert a chest tube at a site distant from the wound. For very large defects, positive-pressure ventilation with pleural decompression is the wisest choice.

Another rare but life-threatening complication that requires special attention during the early phase of trauma is systemic air embolism.⁷⁵ It occurs mainly after penetrating lung trauma and blast injuries, and rarely after blunt thoracic trauma that produces lacerations of both distal air passages and pulmonary veins. The normal response to these injuries is bleeding into the respiratory tree. However, positive-pressure ventilation after tracheal intubation may lead to entrance of air into the systemic circulation through the pulmonary veins. Hemoptysis and circulatory and CNS dysfunction immediately after artificial ventilation and detection of air in the retinal vessels establish the diagnosis. Air bubbles in the coronary arteries may be seen during thoracotomy. Definitive management involves immediate thoracotomy and clamping the hilum of the lacerated lung. Respiratory maneuvers that minimize or eliminate air entry into the systemic circulation have been described:⁷⁶ isolating and collapsing the lacerated lung by means of a double-lumen tube used as a bronchial blocker, and ventilating with low tidal volumes or high frequency. If available, transesophageal echocardiography (TEE) may permit visualization of air bubbles in the left heart and their disappearance with therapeutic maneuvers.

Management of Shock

Hypotension occurring shortly after a traumatic event may have many causes, but hemorrhage is the most common etiology of this complication. Among the other causes of traumatic shock are abnormal pump function (myocardial contusion, pericardial tamponade, pre-existing cardiac disease, or coronary artery or cardiac valve injury), pneumothorax or hemothorax, spinal cord injury, and, rarely, anaphylaxis or sepsis (Table 48-2).

| Shock | Etiology | | | |
|--------------|---|--|---------------------------------|--|
| | Cardiac | Respiratory | Neurologic | Other |
| Hypovolemic | Myocardial contusion, pericardial tamponade, cardiac valve injury, coronary artery injury | Pneumothorax, hemothorax, tension pneumothorax, flail chest, pulmonary contusion | Spinal cord injury, head injury | Other: anaphylaxis, sepsis, drug-induced |
| Cardiogenic | Myocardial contusion, pericardial tamponade, cardiac valve injury, coronary artery injury | | | |
| Obstructive | | Pneumothorax, hemothorax, tension pneumothorax, flail chest, pulmonary contusion | | |
| Distributive | | | Spinal cord injury, head injury | Other: anaphylaxis, sepsis, drug-induced |

Table 48-2. GUIDELINES FOR MANAGEMENT OF TRAUMATIC SHOCK

Evaluation of the severity of hemorrhagic shock in the initial phase is based on a few relatively insensitive and nonspecific clinical signs. For example, the heart rate, which is traditionally used as an index of hypovolemia, may go up or down depending on the amount and rapidity of bleeding, on drugs or alcohol the victim may have taken before the injury, or on the effects of the patient's injuries on different systems. A prolonged decrease in blood volume may cause an increase in vagal activity, thereby restoring the pulse to normal, or even subnormal, levels.⁷⁶ Patients with a history of chronic cocaine use may also exhibit bradycardia with severe hypovolemia, particularly under general anesthesia;^{76,77} acute cocaine intoxication causes tachycardia and hypertension.⁷⁸ The overall incidence of paradoxical or relative bradycardia in severely injured patients is between 2 and 3%; however, up to 30% of hypotensive trauma patients may exhibit paradoxical bradycardia.⁷⁸

In contrast, tissue injury and associated pain may exacerbate the tachycardia induced by hypovolemia without necessarily increasing the cardiac index or tissue oxygen delivery.⁷⁹ In fact, in this setting an increase in intestinal vascular resistance and a decrease in intestinal blood flow may occur, increasing the likelihood of subsequent sepsis and organ failure.⁸⁰ Thus, although tachycardia is one of the earliest signs of hemorrhagic shock, the heart rate does not necessarily correlate with the blood loss. Furthermore, the systemic blood pressure may be sustained by compensatory mechanisms if hypovolemia is not sudden and severe. Equating a normal systemic blood pressure with normovolemia during initial resuscitation may lead to loss of valuable time for treating an underlying occult hypovolemia or hypoperfusion. Nevertheless, heart rate, systemic blood pressure, pulse pressure, respiratory rate, urine output, and mental status remain the best available early indicators of the severity of hemorrhagic shock⁸¹ (Table 48-3).

| | Class I | Class II | Class III | Class IV |
|-------------------------------------|---------------------|----------------|----------------------|---------------------|
| Blood loss (ml) | <75 | 75-150 | 150-300 | >300 |
| Blood loss (% blood volume) | <5 | 5-10 | 10-20 | >20 |
| Pulse rate (per min) | <100 | >100 | >120 | >140 |
| Blood pressure | Normal | Normal | Decreased | Decreased |
| Pulse pressure | Normal or increased | Decreased | Decreased | Decreased |
| Respiratory rate (breaths per min) | 14-20 | 20-30 | 30-40 | >35 |
| Urine output (ml hr ⁻¹) | >30 | 20-30 | 5-25 | Negligible |
| Mental status | Slightly anxious | Mildly anxious | Anxious and confused | Confused, delirious |
| Blood replacement (if any) | Crystalloid | Crystalloid | Crystalloid + blood | Crystalloid + blood |

*The 4-class patient based on initial presentation.
† If this is based on specific observation that most patients require 100 ml balanced electrolyte solution for each 100 ml blood loss. With- out other clinical and monitoring parameters, this guideline may result in excessive or inadequate fluid resuscitation.

Table 48-3. ADVANCED TRAUMA LIFE SUPPORT CLASSIFICATION OF HEMORRHAGIC SHOCK*

The response of the pulse and blood pressure to initial fluid therapy also aids in assessment of the degree of hypovolemia.⁸¹ In hypotensive and tachycardic patients, administration of lactated Ringer's (LR) solution, 2000 ml over 15 minutes in adults, or 20 ml · kg⁻¹ in children, should normalize the vital signs if hemorrhage is mild (10–20%). A transient improvement after fluid infusion suggests a 20–40% decrease in circulating volume or continuing blood loss. More crystalloids and possibly blood transfusion are required in these patients. If the vital signs do not respond to initial fluid resuscitation, there has probably been severe (>40%) hemorrhage, which must be replaced by rapid infusion of crystalloids, colloids, and blood.

If the blood loss has been moderate, the 45 minutes needed for blood typing and cross-matching is acceptable. In more severe hemorrhage, type-specific blood can be available in approximately 15 min. If the situation dictates immediate transfusion, type O, Rh(+) blood is satisfactory in most situations: O, Rh(-) blood should be given to women of childbearing age. However, because of the scarcity of Rh(-) blood, some women require an Rh(+) transfusion. The immunogenicity of the D antigen can be neutralized by administration of Rh immune globulin (anti-Rh antibody).

Invasive hemodynamic monitoring is rarely indicated during initial resuscitation because it slows treatment and thus may be counterproductive. However, if time permits, placement of an arterial catheter during this phase of therapy, and drawing of blood for serial measurements of hemoglobin or hematocrit, can be of great help in determining the need for transfusion. During fluid infusion, a reasonable transfusion threshold is a hematocrit below 25% for young, healthy patients and below 30% for older patients or those with coronary or cerebrovascular disease.⁸² This may not apply to the trauma patient whose underlying medical diseases often are unknown, and the extent of stress-induced by injuries may require a safety buffer. Control of active bleeding has a higher priority than restoration of blood volume in the initial resuscitation of hemorrhage. It has even been suggested that fluid should be withheld until the patient is in the operating room. Fluid administration in the field or in the emergency department after penetrating trauma may accelerate blood loss.⁸³

Parenterally, after normalization of these parameters within the first hour, recognition of occult hypoperfusion with hemodynamic and oxygenation monitoring, and prompt treatment within the first 24 hours of injury decreases the incidence of post-traumatic multisystem organ failure and improves outcome.⁸⁴ Although a variety of methods have been proposed to monitor organ perfusion and oxygenation, currently the serum lactate level, base deficit, or gastric mucosal pH have been accepted as reliable end points for resuscitation in trauma patients.⁸⁵ Preferably, all three of these values should be within normal limits: lactate <2 mmol · l⁻¹, base deficit less than 3, and gastric intramucosal pH >7.33.⁸⁵

Rapid establishment of venous access with large-bore cannulae placed in peripheral veins that drain both above and below the diaphragm is essential for adequate fluid resuscitation in the severely injured patient. When vascular collapse and extremity injury impair access to arm or leg vessels, percutaneous cannulation of the internal jugular, subclavian, or femoral veins, or a cutdown to a saphenous or arm vein can be rapidly performed in older children and adults. In children younger than 5 years of age, intraosseous cannulation has a high success rate and a low incidence of complications. Infusion rates comparable with those obtained with iv lines are possible in small children, although a pressure infusion device may be necessary to achieve adequate flow.⁸⁶ A special screw-type needle or the needle of a 16- or 18-gauge angiocatheter is introduced into the bone marrow of the distal femur or proximal tibia at the level of its tuberosity. Care should be taken not to injure the epiphyseal plate during puncture. Proper placement is indicated by loss of resistance to fluid injection or aspiration of marrow.

A few words of caution are necessary: internal jugular and subclavian vein catheterization carries the danger of infusing large volumes of fluids into the pleural cavity in patients with hemothorax; aspiration of blood or a "central venous pressure" fluctuation does not necessarily indicate that the cannula is in a blood vessel.⁸⁷ The common femoral vein may be accessed 1 cm medial to the artery just below the ilioinguinal ligament. If the femoral artery pulsation is not palpable, the vein may be located at a point one third of the distance from the pubic tubercle to the anterior superior iliac spine, below the ilioinguinal ligament.⁸⁸

Although little, if any, survival benefit has been demonstrated for patients transported within urban areas from the prehospital use of military antishock trousers (MAST), the device is probably useful in rural regions, in combat, and in patients with extensive pelvic fractures.^{89,90} It may help maintain hemodynamic stability during a relatively long prehospital transport, and reduces bleeding from pelvic vessels by stabilizing the fractures.^{89,90} It should not be applied to patients with head and penetrating chest injuries and to those already in respiratory distress. In the emergency department, deflation of this device may be associated with significant hypotension; it should be deflated one segment at a time starting with the abdominal compartment, and a pump should always be available for reinflation of the MAST if the blood pressure falls.

Emergency Room Thoracotomy

Patients who arrive in the emergency department in cardiac arrest require advanced cardiac life support. However, the success rate of external cardiac massage in hypovolemic trauma victims is likely to be low.⁹¹ Emergency department thoracotomy not only permits performance of open cardiac massage but aids resuscitation efforts by allowing drainage of pericardial blood, control of cardiac and great vessel bleeding, application of a cross-clamp to the aorta, and rapid administration of fluids through a small Foley catheter introduced into the right atrium, or in desperate situations, through a large-bore catheter or introducer into the descending aorta. This procedure is not indicated in blunt torso trauma; the mortality rate is similar regardless of whether it is attempted.⁹² In penetrating injuries, success depends on the presence of a blood pressure, spontaneous respiration, and a resuscitatable cardiac rhythm (sinus, ventricular tachycardia, or fibrillation), and on the duration of resuscitation before the thoracotomy is performed. Patients in asystole or idioventricular rhythm, and those who have required cardiopulmonary resuscitation for more than 5 minutes before the performance of the thoracotomy, are unlikely to survive.^{92,93} Tracheal intubation and ventilation with oxygen seem to increase the time limit to 10 minutes and increase the success rate of the procedure.⁹² Unfortunately, there is a major discrepancy between the rates of initial successful resuscitation and of survival without neurologic complications to hospital discharge. Although the initial survival rate of emergency department thoracotomy may be as high as 70%, only 10% of these patients are discharged from the hospital.^{92,93} Serious questions, therefore, have been raised about the indications for and the appropriateness of the procedure.⁹⁴

EARLY MANAGEMENT OF SPECIFIC INJURIES

Head Injury

Approximately 40% of deaths from trauma are caused by head injury, and indeed, even moderate brain injury may increase the mortality rate of patients with other injuries.⁹⁵ In the United States each year, approximately 56,000 head-injured patients die and 90,000 are left with long-term disabilities.⁹⁶ In 65% of nonsurvivors, progression of the damaged area beyond the directly injured region (secondary brain injury) can be demonstrated at autopsy.⁹⁷ The major factor in secondary injury is tissue hypoxia, which results in lactic acidosis, free radical generation, lipid peroxidation, prostaglandin synthesis, release of excitatory amino acids (primarily glutamate), breakdown of cell membranes, and entry of large quantities of sodium and calcium into the cells.⁹⁷ Of all the possible insults to the injured brain, hypotension and hypoxia have the greatest detrimental impact^{98,99} (Table 48-4).

| Secondary Insults | No. of Patients | % of Total Patients | 6-Month Outcome (%) | | |
|-------------------|-----------------|---------------------|---------------------|-------------------|------|
| | | | Good/Moderate | Severe/Vegetative | Dead |
| Total cases | 717 | 100 | 43.0 | 20.2 | 36.8 |
| Neither | 308 | 43.0 | 63.9 | 10.2 | 26.9 |
| Hypoxia | 161 | 22.4 | 50.3 | 21.7 | 28.0 |
| Hypotension | 62 | 11.4 | 32.9 | 17.1 | 50.0 |
| Both | 166 | 23.2 | 20.5 | 22.3 | 57.2 |

Table 48-4. EFFECTS ON OUTCOME OF SECONDARY INSULTS OCCURRING FROM TIME OF INJURY THROUGH RESUSCITATION*

The vulnerability of the brain to decreases in blood pressure and oxygen supply is not surprising. It consumes $3.5 \text{ ml of O}_2 \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ ($\sim 50 \text{ ml of O}_2 \cdot \text{min}^{-1}$), requiring a high blood flow ($700 \text{ ml} \cdot \text{min}^{-1}$) and high O_2 extraction ratio (~ 0.35). Brain injury by itself does not cause hypotension in adults except as a preterminal event. However, more than half of patients with severe head trauma have other injuries that render approximately 15% of them hypotensive; approximately 30% are hypoxic on admission as a result of central respiratory depression or associated chest injuries.¹⁰⁰ Furthermore, exposure to these insults is likely to occur during any phase of the continuum of hospital care: in the radiology unit, the operating room, the recovery room, the ICU, and so forth. The most common early complications of head trauma are intracranial hypertension, brain herniation, seizures, neurogenic pulmonary edema, cardiac dysrhythmias, bradycardia, systemic hypertension, and coagulopathy.

Diagnosis

Because the injured brain is acutely sensitive to hypotension and hypoxia, every effort should be made to support the blood pressure and ensure adequate oxygenation before the unconscious patient is evaluated.¹⁰¹ Indeed, intubating the trachea of the unconscious patient in the field may significantly increase his or her chances of survival.¹⁰² A baseline neurologic examination should be performed after initial resuscitation, but before any sedative or muscle relaxant agents are administered, and should be repeated at frequent intervals because the patient's condition may change rapidly. A brief initial evaluation includes assessment of consciousness, pupillary response, and motor activity of the extremities. Consciousness can be assessed within a few seconds using the AVPU system¹⁰³ (alert; responds to verbal stimuli; responds to painful stimuli; unresponsive; Table 48-5). More precise information is provided by the Glasgow Coma Scale¹⁰³ (GCS; see Table 48-5). In this test, the sum of the scores obtained for eye opening, verbal response, and motor activity correlates with the state of consciousness, the severity of the head injury, and the prognosis.^{104,105} Anesthetic and adjunct drugs render an adequate neurologic examination impossible; thus, long-acting muscle relaxants, opioids, sedatives, or hypnotics should be given selectively.¹⁰¹

| LEVEL 1. AVPU SYSTEM | |
|-----------------------------------|---|
| A | Alert |
| V | Responds to verbal stimuli |
| P | Responds to painful stimuli |
| U | Unresponsive |
| LEVEL 2. GLASGOW COMA SCALE (GCS) | |
| Eye-opening (E) | |
| 4 | Spontaneous, already open and blinking |
| 3 | To speech |
| 2 | To pain |
| 1 | None |
| Verbal response (V) | |
| 5 | Oriented |
| 4 | Answers but confused |
| 3 | Inappropriate but recognizable words |
| 2 | Incomprehensible sounds |
| 1 | None |
| Best motor response (M) | |
| 6 | Obeys verbal commands |
| 5 | Localizes painful stimulus |
| 4 | Withdraws from painful stimulus |
| 3 | Decorticate posturing (upper extremity flexion) |
| 2 | Decerebrate posturing (upper extremity extension) |
| 1 | No movement |

GCS = 8 = deep coma, severe head trauma, poor outcome.
 GCS 9–12 = conscious patient with moderate injury.
 GCS >13 = mild injury.

Table 48-5. TWO-LEVEL INITIAL EVALUATION OF CONSCIOUSNESS

Mental impairment after trauma may have any of several etiologies. However, the possibility of hypoxia and shock must always be considered first. If consciousness remains depressed despite ventilation and fluid replacement, a head injury is assumed to be present and the patient is managed accordingly. Only after all of these causes are excluded should the possibility of toxic or metabolic etiologies be considered. Dilatation and sluggish response of the pupil is a sign of compression of the oculomotor nerve by the medial portion of the temporal lobe (uncus). A maximally dilated and unresponsive “blown” pupil suggests uncal herniation under the falx cerebri. The presence of similar findings in ocular injuries makes interpretation of pupillary findings difficult when eye and head injuries coexist. However, the pupillary reaction to light is usually more sluggish in the head-injured patient. Assessment of motor function should be performed on the extremity that responds best. The limb affected by neurologic injury is examined, but the result is not considered in the GCS.

Computed tomography scanning is used for the diagnosis of most acute head injuries. Magnetic resonance imaging offers additional advantages: it can demonstrate nonhemorrhagic brain contusion (ischemia), indicate the severity of diffuse axonal injury, and may predict the development of a delayed intracerebral hematoma.¹⁰⁶ However, because of its impracticality in the injured patient, it is rarely used. Positive CT findings after acute head injury include midline shift, distortion of the ventricles and cisterns, effacement of the sulci in the uninjured hemisphere, and the presence of a hematoma at any location in the cranial vault. Subdural hematomas usually have a concave border, whereas epidural hematomas present with a convex outline classically termed a *lenticular* configuration. Patients in coma (GCS <8) have a 40% likelihood of an intracranial hematoma.¹⁰⁷ Those with a higher GCS score are less likely to have intracranial bleeding, although it is now evident that the significant incidence of this complication even in these patients necessitates a CT study, preferably with contrast enhancement.¹⁰⁸ Other benefits of CT scanning include detection of intracranial air and depressed skull fractures.

Management

The primary objective in the early management of brain trauma is to prevent or alleviate the secondary injury process that may follow any complication that decreases the oxygen supply to the brain, including systemic hypotension, hypoxemia, anemia, raised ICP, acidosis, and possibly hyperglycemia (serum glucose $>200 \text{ mg} \cdot \text{dl}^{-1}$).¹⁰⁹ These insults cause exacerbation of trauma-induced cerebral ischemia and metabolic derangements, worsening the outcome.^{98,109}

The most important therapeutic maneuvers in these patients are aimed at maintaining CPP and oxygen delivery. Although there are wide variations among the various trauma centers in the specific details of managing the head-injured patient, certain aspects of treatment are virtually universal.^{101,110,111,112} and ¹¹³ They include normalization of systemic blood pressure (mean blood pressure >80) and arterial oxygenation ($\text{SaO}_2 >95$), sedation and paralysis if necessary, mannitol and possibly a loop diuretic to shrink the brain and decrease the ICP, drainage of cerebrospinal fluid through a ventriculostomy catheter, and mechanical hyperventilation if the ICP does not respond to other measures.

Antidysrhythmics and fresh frozen plasma (FFP) are required in those patients with cardiac or hemostatic abnormalities. If the ICP still does not respond, pentobarbital ($3\text{--}10 \text{ mg} \cdot \text{kg}^{-1}$ given over 0.5–2.5 hours, followed by a maintenance infusion of $0.5\text{--}3.0 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$, aimed at a serum concentration between 2.5 and $4.0 \text{ mg} \cdot \text{dl}^{-1}$) may be required.¹¹⁴ High-dose barbiturates, however, are of no value in the routine therapy of head injury, and should be used only for refractory ICP elevation. Of course, immediate surgical decompression, especially of epidural hematomas, is an important factor in reducing morbidity and mortality. Whether active normalization of an elevated serum glucose (a common occurrence in the head-injured patient) has any salutary effect on outcome is not known.

Measurement of the jugular bulb O_2 saturation (SjvO_2) is used in many centers as a guide to therapy of the head-injured patient.¹¹⁵ A catheter is passed retrograde into the jugular bulb. The O_2 saturation may be measured with a co-oximeter or continuously by means of a fiberoptic sensor. An SjvO_2 of $<50\%$ is considered critical desaturation. The value of this technique depends on the fact that the difference between the arterial and jugular venous O_2 content can be used as a measure of the

amount of oxygen used by the brain.

The arteriovenous O₂ difference

$$AVDO_2 = 1.34 \cdot \text{Hgb} \cdot (\text{SaO}_2 - \text{SjvO}_2)$$

is an indicator of the relationship between the demand of the brain for O₂ and its supply by the blood. The normal AVDO₂ is approximately 6. An increase in this value is a sign of insufficient blood flow, whereas a subnormal level indicates hyperemia. Unfortunately, several shortcomings of the technique have hindered its universal acceptance. Because all of the cerebral veins drain into the torcula and from there into the jugular bulbs AVDO₂ measures only global O₂ consumption, which may well be different from regional areas within the brain or the situation in the injured region. Patient or catheter movement may also alter the measured PjvO₂. Thus, there may be a high proportion of inaccurate values—as high as nearly two thirds in one study¹¹⁶—although recent advances in the technique have probably reduced these errors. Cruz¹¹⁷ has suggested that jugular venous monitoring should be used only in sedated, paralyzed patients.

Several therapeutic maneuvers deserve further comment. Hyperventilation to a PaCO₂ level of 25–30 mm Hg was used routinely until the mid-1990s in the initial management of the severely head-injured patient to decrease ICP and correct cerebral acidosis (Table 48-6). Available data suggest that brain ischemia, which is probably the most threatening consequence of head injury, is likely to occur during the first 6 hours after trauma.^{118,119} and ¹²⁰ This decrease in blood flow may be present even when the CPP (the difference between the mean arterial pressure and the ICP) is maintained above the generally recommended 60–70 mm Hg.¹²¹ Thus, the initial hypoperfusion seems to be caused largely by increased cerebral vascular resistance, which may be enhanced by hyperventilation. Ward *et al*¹²² showed that patients ventilated to a PaCO₂ of 24 mm Hg had a significantly worse outcome than did those maintained at a PaCO₂ of 35 mm Hg. In an attempt to correct cerebral acidosis induced by the head injury and hyperventilation, they also administered tris(hydroxymethyl)aminomethane (THAM), an amine buffer, to one of their study groups. There was no difference in outcome between the patients treated with hyperventilation alone and those who also received THAM. However, subsequent studies have demonstrated that THAM may produce an immediate decrease in ICP, limit wide fluctuations of ICP during hyperventilation, and reduce the need for mannitol.^{123,124} Although the role of THAM is not yet clear, some degree of hyperventilation may be necessary in patients who have severe injuries and elevated ICP that does not respond to normal ventilation and diuretics.¹²⁰ Its use after the initial phase should be based on monitoring of the ICP and, if available, the SjvO₂ and AVDO₂. A reduction in ICP with elevation of CPP during treatment is reflected by a rise in SjvO₂ and a narrowing of the AVDO₂, presumably reflecting an improvement in the circulation to the brain.^{120,125}

| Old Treatment | New Treatment |
|--------------------------------|--|
| Hyperventilation | Normal ventilation; hyperventilation only when needed |
| Fluid restriction | Normovolemia |
| Steroids? | No steroids |
| Mannitol | Mannitol or hypertonic saline |
| CPP >70 mm Hg | CPP ≥60 mm Hg (50 mm Hg in Lund protocol) |
| Normotension/mild hypertension | Lund protocol—clonidine, metoprolol, ergotamine SjvO ₂ ? |

CPP = cerebral perfusion pressure.

Table 48-6. CLASSIC AND CONTEMPORARY TREATMENT OF SEVERE HEAD INJURY

Effective reduction in ICP can be provided, or at least aided, by administration of mannitol (0.25–0.5 g · kg⁻¹). In addition to its osmotic diuretic effect, this agent may improve cerebral blood flow (CBF) and O₂ delivery by reducing blood viscosity.¹²⁶ There is a risk of hypovolemia and thus of hypotension when therapeutic doses of mannitol are used. The aim in administration of this agent is a normal volume of mildly hypertonic (~295 mOsm · l⁻¹) plasma. If the ICP elevation persists, additional doses of mannitol should be given with great care. Acute mannitol toxicity, manifested by hyponatremia, high serum osmolality, and a gap between calculated and measured serum osmolality >10 mOsm · l⁻¹, may result when the drug is given in large doses (2–3 g · kg⁻¹) or to patients with renal failure.¹²⁷ Hyponatremia in these patients results from intravascular volume expansion rather than sodium loss; thus, treatment with saline solutions is not appropriate. Because of a synergistic action between mannitol and loop diuretics in improving the ICP, addition of furosemide may be a safer and more effective treatment than increasing the dose of mannitol when intracranial hypertension persists.¹¹⁴

Both intracranial hematomas and hemorrhage in other regions have a high surgical priority. In the multiple trauma victim, prioritization between the two is based on the severity of each injury. Because there is no time to obtain a CT scan of the head in patients with both profuse hemorrhage and brain herniation, the patient is brought directly to the operating room for simultaneous control of the bleeding site and evacuation of the intracranial hematoma. The site of the craniotomy can be determined by a ventriculogram or an ultrasound examination with a pencil-tip probe; both tests may be performed under local anesthesia through a frontal bur hole. If the patient is hemodynamically stable, a CT scan is performed; the strictest attention should be paid to ensuring adequate oxygenation, ventilation, blood pressure, and ICP control during the procedure. If the patient is hemodynamically unstable or requires emergency surgery for associated injuries, and has a history suggesting a head injury even though a significant intracranial hematoma is unlikely on clinical grounds, intraoperative ICP monitoring is indicated to permit rapid detection of ICP elevation.

Excessive fluid resuscitation of the multiple trauma patient with a head injury poses the problem of augmentation of brain edema. Rapid and adequate restoration of the intravascular volume with isotonic crystalloid and, if necessary, with colloid solutions should be aimed at maintaining the CPP while attempting to minimize further brain swelling. LR solution, which is slightly hypotonic (Na⁺ = 130 mEq · l⁻¹ and osmolality ~255 mOsm · l⁻¹), may promote edema in noninjured areas of the brain if it is given in large quantities; edema tends to occur in injured brain regions regardless of the type of solution administered because of increased permeability of the blood–brain barrier. To minimize edema formation, it is wise to monitor serum osmolality and to replace LR solution with truly isotonic normal saline. If serum osmolality cannot be measured, this change can be made empirically after 3 l of LR solution.

There are data suggesting that the addition of relatively small volumes of hypertonic saline in concentrations between 3% (6–8 ml · kg⁻¹) and 7.5% (4 ml · kg⁻¹) followed by infusion of LR may be beneficial in multiple trauma patients with head injury.^{128,129} In head-injured children, administration of 3% saline was associated with an average 4 mm Hg decline in ICP, compared with a 0.7 mm Hg decline after normal saline.¹³⁰ Hypertonic saline draws fluid from the intracellular space and, thus, in addition to restoring the blood volume, it reduces brain edema and prevents elevation of the ICP as effectively as 20% mannitol.^{130,131} and ¹³² The intravascular volume expansion produced by hypertonic saline is transient; it can be prolonged by addition of 6% dextran-70 or hetastarch to the solution.¹³³ The effects of this combination on coagulation are minimal.¹³⁴ However, administration of hypertonic saline cannot be maintained for long periods. It may cause hypernatremia, hyperosmolality, or hyperchloremic acidosis; the latter probably results from renal bicarbonate loss secondary to the increased levels of Cl⁻. Serum concentrations of Na⁺ and Cl⁻ and the patient's acid–base status should be followed, and the administration of hypertonic saline should be discontinued if plasma Na⁺ reaches 160 mEq · l⁻¹. Resuscitation with colloid solutions (hetastarch, pentastarch, pentafraction, human albumin 5% and 25%, or dextran) provides a sustained improvement in vital signs, but the increase in colloid osmotic pressure produced by these solutions may not have an important role in reducing brain edema.¹³⁵

Two recently reviewed therapeutic approaches suggest that it may be possible to improve the long-term survival of severely head-injured patients significantly^{110,136,137,138} and ¹³⁹ (Table 48-7). In 1998, Cruz¹³⁷ described the use of continuous fiberoptic SjvO₂ monitoring in 178 comatose patients (GCS <8) with diffuse brain swelling. The major principles of this approach are not only to maintain an adequate CPP, but to keep ICP below 25 mm Hg and the cerebral extraction of O₂ (CEO₂ = SaO₂ - SjvO₂) within the normal range of 24–42%. All of the patients in the study group were mechanically ventilated, and otherwise treated according to a standard protocol similar to that described previously. In addition, the CEO₂ was monitored. When ICP >20 mm Hg was associated with a normal to low CEO₂, ventilation was increased until both parameters normalized. On the other hand, when elevated ICP was associated with normal to increased CEO₂, mannitol boluses were administered, again aiming at normalization of ICP and CEO₂. Thus, in addition to treating decreased cerebral perfusion, this protocol aims to reverse the effects of hyperperfusion as well.

| Study | No. of Patients | Year | Six-Month Outcome (%) | | | Comments |
|---|-----------------|------|-----------------------|----------------------|------|--|
| | | | Good Outcome | Survived/ Vegetative | Dead | |

Table 48-7. SIX-MONTH OUTCOMES FOR BRAIN-INJURED PATIENTS IN VARIOUS STUDIES

The Lund Treatment is based on an attempt to control increased ICP by reducing the formation of cerebral edema.¹³⁶ There are several components to the protocol. Normovolemia is maintained by colloids and blood products. Sympathetic outflow and catecholamine levels are decreased by the α_2 -agonist clonidine, which helps to maintain CBF because catecholamines produce intracerebral vasoconstriction. An additional antihypertensive effect is produced by the β_1 -adrenergic antagonist, metoprolol, which seems to improve cerebral microcirculation despite a reduction in mean arterial blood pressure.¹⁴⁰ Precapillary vasoconstriction is provided by low-dose thiopental ($0.5\text{--}3\text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) and dihydroergotamine. The latter agent also constricts the large cerebral veins, further reducing the ICP. A CPP of approximately 60 mm Hg is the usual end point, although in some circumstances 50 mm Hg is accepted in adults, and 40 mm Hg in children. More recently, the Lund group has added prostacyclin infusion to the treatment¹⁴¹ to improve the microcirculation, prevent blood cell aggregation, and reduce capillary permeability. The results of this protocol have been very impressive in the 53 patients in their series (see [Table 48-7](#)); however, a larger, controlled study is clearly necessary to prove its value.

The common factor in these newer protocols appears to be reduction in brain swelling. Cruz¹³⁷ seems to accomplish this by hyperventilation—and thus arteriolar constriction—of patients with cerebral hyperperfusion, whereas the Lund group uses a carefully controlled pharmacologic approach. It may be that future improvements in the survival of the head-injured patient will be provided not only by maintaining oxygenation, arterial blood pressure, and CPP, but by limiting the formation of cerebral edema. In any case, the outlook for the head-injured patient has improved significantly since the mid-1990s.¹¹³

Spine and Spinal Cord Injury

Initial Evaluation

The incidence of cervical spine injury in trauma center admissions is 4.3%; 3% of injured patients have bony fractures without spinal cord injury, and 0.7% have a cord injury without a fracture.¹⁴² Delayed diagnosis occurs in 0.01% of trauma admissions.¹⁴²

The objective in the evaluation of spinal trauma is to diagnose instability of the spine and the extent of neurologic involvement. Often the urgency of associated injuries precludes a definitive assessment, necessitating spine protection until a satisfactory diagnosis is established. In the conscious patient, the diagnosis is relatively easy: a history of a motor vehicle, industrial, or athletic accident or a fall; penetrating trauma resulting in a neurologic deficit below a specific spinal level; or pain and tenderness over the involved vertebrae strongly suggests a spine injury. Obviously, these symptoms are difficult to elicit in the comatose patient. In these circumstances, flaccid areflexia, loss of rectal sphincter tone, diaphragmatic breathing, and bradycardia in a hypovolemic patient suggest the diagnosis. In cervical spine trauma, an ability to flex but not to extend the elbow and response to painful stimuli above but not below the clavicle also indicate neurologic injury. Current guidelines consider absence of neck pain or paresthesia and a negative physical examination—lack of tenderness with palpation and during voluntary flexion and extension of the neck—in a neurologically intact, conscious patient as adequate indications for ruling out a cervical spine injury without further radiologic studies.^{143,144} Alcohol intoxication and distracting associated injuries do not seem to alter these guidelines as long as the patient is alert, conscious, and able to concentrate.¹⁴⁵

Depending on the degree of deficit, spinal cord injuries are categorized as *complete* or *incomplete*. Intact sensory perception over the sacral distribution and voluntary contraction of the anus (sacral sparing) are present in incomplete, but not in complete, injuries. There is practically no possibility of neurologic recovery in complete injury, whereas functional restoration may occur in up to 50% of patients after incomplete injuries.¹⁴⁶ In some patients the development of *spinal shock*, which is manifested by absolute flaccidity and loss of reflexes, precludes distinguishing between complete and incomplete injuries during the initial phase of injury. Therefore, even in the absence of sacral sparing, the possibility of neurologic recovery dictates that all possible efforts be made in the early stages of the injury to prevent further damage and to preserve cord function. A similar principle applies to the evaluation of the level of injury. After the first few days, spinal cord edema subsides and the final level is commonly a few segments lower than on initial presentation. Thus, early therapeutic efforts should not be abandoned even in the patient with a high-level injury, which carries a grim functional prognosis.

Spinal shock is probably caused by direct trauma to the spinal cord, and usually subsides within days to weeks.¹⁴⁷ The term is frequently used as a misnomer for *neurogenic shock*, which is defined as hypotension and bradycardia caused by the loss of vasomotor tone and sympathetic innervation of the heart as a result of functional depression of the descending sympathetic pathways of the spinal cord. It is usually present after high thoracic and cervical spine injuries and improves within 3–5 days.

Radiologic Evaluation

In patients with neck pain and those who are unable to describe their symptoms, the diagnosis of spine injury is made radiologically. Some clinicians believe that radiologic evaluation is necessary to eliminate cervical spine injury in all blunt trauma victims, even those with normal clinical findings, and request lateral cervical spine films. However, the cross-table lateral view is capable of detecting only 35–65% of fracture–dislocations in this region.¹⁴⁵ The sixth and seventh cervical and the first thoracic vertebrae must be visualized clearly because 30–35% of all cervical spine injuries occur at these levels.¹⁴⁶ Higher injuries may also be missed if the radiologic examination is limited to a single lateral view. Other views (anteroposterior, open-mouth, and oblique) may be necessary for definitive diagnosis. The CT scan is the most reliable diagnostic technique for cervical spine fracture detection, but not for ligamentous injuries. Woodring and Lee¹⁴⁸ found that CT scans detected 90% of the fractures, but only 54% of the subluxation–dislocations, whereas plain films identified only 58% of the fractures but 93% of the subluxation–dislocations. Thus, plain films and CT scans are complementary and together increase the likelihood of accurate diagnosis. A recent strategy is to obtain a three- or five-view series of radiographs and to examine suspect or suboptimally visualized areas with limited, focused CT scans. Examination of the entire cervical spine with CT scanning necessitates obtaining narrowly spaced images, which may require as much as 1 hour with a conventional scanner. Berne *et al*¹⁴⁹ suggested that a complete examination of the cervical spine with the new spiral CT scanner had a sensitivity of 90%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 95%. The expense of this technique, however, is higher than that of plain radiographic or focused CT evaluation.¹⁴⁹ Of course, when associated injuries dictate immediate management, radiographic diagnosis may have to be postponed for several hours or days as long as proper immobilization of the spine is maintained. On the other hand, patients, especially when they are paralyzed, should not be left on a rigid spine board for longer than 1 hour because of the risk of decubitus ulcers. Radiologic evaluation of the thoracolumbar vertebrae requires a minimum of two views: lateral and anteroposterior.

It is important that any radiologic examination be performed with the patient in supine position until a spine injury is ruled out, so that the risk of displacement of the fracture is minimized. A systematic evaluation of spine radiographs involves examination of the vertebrae, the vertebral alignment, and the adjacent soft tissue.¹⁵⁰ Bony parts are assessed by examining the height of the vertebral bodies and the integrity of the spinous and transverse processes, laminae, facets, and pedicles. Vertebral alignment is determined on the lateral cervical radiograph by evaluating four longitudinal curves: the anterior and posterior borders of the vertebral bodies (the latter representing the anterior border of the spinal canal), the posterior border of the spinal canal, and the tips of the spinous processes¹⁵⁰ ([Fig. 48-3](#)). Vertebral dislocation should be suspected if there is >3 mm of malalignment in any of these curves. The prevertebral space measures 10 mm at the level of the anterior arch of the atlas, 4 mm between C2 and C4, and 15 mm below C4¹⁵⁰ (see [Fig. 48-3](#)). An increase in these measurements by >5 mm suggests a hematoma, presumably caused by a body fracture. Irregularity of the prevertebral fat also suggests a fracture at that level. Enlargement of the prevertebral space in the neck may incidentally also be due to a retropharyngeal hematoma, which may cause tracheal deviation and tenderness and complicate airway management. Radiologic interpretation of thoracolumbar fractures is based on principles similar to those applied to cervical injuries.

Figure 48-3. Normal cervical spine alignment and soft tissue measurement. Measurements denote normal width of soft tissues. (A) Anterior vertebral line; (B) posterior vertebral line; (C) spinolaminar line; (D) spinous process line. (Reprinted with permission from Bernstein RL, Rosenberg AD: Trauma. In Bernstein RL, Rosenberg AD [eds]: Manual of Orthopedic Anesthesia and Related Pain Syndromes, p 66. New York, Churchill Livingstone, 1993.)

Despite cervical pain and tenderness, cervical spine radiographs may at times be normal. A high index of suspicion of an unstable injury should appropriately lead to obtaining a flexion–extension series, which may demonstrate a fracture or dislocation that has been missed by the standard views.

Initial Management

The spinal cord is a microcosm of the brain. Thus, it is also vulnerable to a secondary injury process that may be a product of hypotension, hypoxia, and probably other physiologic complications.¹⁵¹ Therefore, prompt recognition and treatment of these insults, which usually result from associated injuries, may minimize exacerbation of spinal cord lesions and significantly improve the long-term outlook of patients with spinal cord injuries.^{105,152}

Steroids

For several years, high-dose methylprednisolone has been used in many centers in an attempt to improve the outcome from spinal cord injuries. The drug is usually given as a bolus of $30 \text{ mg} \cdot \text{kg}^{-1}$ within 8 hours of injury followed in 1 hour by an infusion of $5.4 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$ for the next 23–47 hours. The National Acute Spinal Cord Injury Studies (NASCIS-2 and NASCIS-3)^{153,154} and ¹⁵⁵ demonstrated some improvement in motor function in treated patients who had partial sensory and motor loss. The results were best in patients who received 24 hours of therapy starting within 3 hours of injury, and those receiving 48 hours of treatment starting within 3–8 hours of injury. There was no improvement in sensory scores in any of the groups. There was little or no difference from untreated patients in groups with more severe injuries or in those who were treated after 8 hours. Furthermore, although some improvement could be demonstrated by neurologic examination, the change in the functional status of most of the patients was at best minimal.

Unfortunately, there are many problems with the design and analysis of the NASCIS trials.¹⁵⁶ Serious questions have been raised about the randomization of the patients, the analysis of the results, the clinical end points used, the definitions of motor levels, and the reliability of data collection. Furthermore, the results of these studies have not been duplicated in any other prospective or retrospective trials.^{157,158} and ¹⁵⁹

The most definite finding of NASCIS-2 was that such large doses of methylprednisolone over a 24-hour period were not associated with an increased rate of complications. Unfortunately, NASCIS-3 patients who were treated for 48 hours had a higher incidence of both severe sepsis and severe pneumonia. In another study,¹⁶⁰ even patients who had been treated for only 24 hours had a 2.6-fold increase in the incidence of pneumonia and an increase in ventilated and intensive care days, although there was some decrease in the period of rehabilitation. Given these results, the best that can be said about the use of methylprednisolone in the spinal cord–injured patient is that there is a small chance that it may help some patients, but certainly its usefulness in the treatment of spinal cord injury remains to be clarified.

Immobilization

Maintenance of immobilization of the injured spine is of paramount importance. All changes in the patient's position must be performed carefully. If a cervical spine fracture is suspected, immobilization or MIS of the neck is necessary before the patient is moved. If the patient has a thoracic or lumbar injury, a careful log-rolling maneuver should be used.

Respiratory Complications

Respiratory complications are common in all phases of the care of spinal cord–injured patients. During the initial period, respiratory dysfunction caused by paralysis of the accessory muscles may be augmented by associated brain, neck, chest, or abdominal injury, alcohol intoxication, or the effects of self-administered or iatrogenic drugs. Accessory respiratory muscle paresis may cause a significant loss of expiratory reserve even when the injury involves the lower spinal segments.¹⁶¹ The need for ventilatory assistance depends on the level of the spinal cord involved. Injuries at C5 or lower are usually associated with normal tidal volumes because the function of the diaphragm is intact, whereas patients with levels at C4 or above require ventilatory assistance.

Pulmonary edema is another significant cause of respiratory dysfunction. A severe catecholamine surge follows acute trauma to the spinal cord.¹⁶² Although the resultant hypertension lasts for only a few minutes, its effects persist; it may produce both pulmonary capillary damage, as a result of shifting of a large portion of the blood volume into the pulmonary circulation, and left ventricular dysfunction. Overzealous fluid therapy to treat the patient's initial hypotension may lead to acute pulmonary edema when the sympathetic activity returns approximately 3–5 days after the injury.

Paradoxical respiration in the quadriplegic patient results from partial chest wall collapse during inspiration; it may produce limitation of the tidal volume and an increased risk of hypoventilation. The situation is aggravated when the patient is in an upright position. The diaphragm cannot maintain its normal domed shape, the only way it can contract efficiently, because the weight of the thoracic contents is not opposed by the normal tone of the abdominal muscles. Thus, in contrast to other diseases that produce respiratory insufficiency, the supine position improves respiration in persons with quadriplegia.

Other causes of inadequate respiration in the early phase of spinal cord injury are aspiration of gastric contents, atelectasis, and bronchoconstriction. Management includes careful observation of the patient's breathing and preparation to intubate the trachea and ventilate the lungs at the first sign of respiratory depression.

Severe bradycardia or dysrhythmias may result from unopposed vagal activity during tracheal intubation or suctioning: the patient must be preoxygenated and atropine (0.4–0.6 mg) should be given before any instrumentation. If bradycardia develops during airway management, treatment includes additional atropine, glycopyrrolate, isoproterenol, or, if necessary, cardiac pacing.

Hemodynamic Management

Hemodynamic management of patients with quadriplegia includes a complete assessment, if necessary, with a pulmonary artery catheter, as early as possible after injury. In as many as 25% of patients with cervical spinal cord injuries, left ventricular dysfunction may contribute to the hypotension.¹⁶³ Decreased preload can be treated with fluid infusion using cardiac function curves as a guide. In general, volume may be safely replaced to a pulmonary capillary wedge pressure (PCWP) of 18 mm Hg.¹⁶³ This avoids, or at least limits, the severity of the pulmonary edema described previously. Hypotension despite adequate fluid infusion, acidosis, or low mixed venous PO_2 requires treatment with inotropes such as dopamine.

Anesthetic Considerations

Any anesthetic technique compatible with the patient's general condition is satisfactory for the spinal cord–injured patient. Hypotension is very common during anesthesia in quadriplegic patients. Placement of a central venous or pulmonary artery catheter may facilitate management of the patient's volume and blood pressure status.

The danger of administering succinylcholine to spine-injured patients is well known.¹⁶⁴ Succinylcholine produces massive and simultaneous depolarization of all the involved muscles; within 3 minutes a sudden, severe increase in serum K^+ occurs. Levels as high as $14 \text{ mEq} \cdot \text{l}^{-1}$ may be reached: the result may be irreversible ventricular dysrhythmias and cardiac arrest. Although succinylcholine is probably safe during the first week after injury, it is probably best to avoid it altogether in the paraplegic patient and use rapid-onset nondepolarizing agents such as rocuronium or rapacuronium when a rapid-sequence induction is required.

Neck Injury

In addition to the cervical spine, penetrating and blunt trauma may injure the other major structures in the neck: vessels, respiratory and digestive tracts, and nervous system. Devastating complications, including hemorrhage, asphyxia, mediastinitis, paralysis, stroke, or death, may result from these injuries if they are not promptly recognized and treated. Successful anesthetic and airway management also depends on timely diagnosis of these injuries. A chart designed by Demetriades *et al*¹⁶⁵ provides a systematic tool for assessing penetrating neck trauma and minimizing the rate of missed injuries (Fig. 48-4). With minor modifications it may also be used for evaluation of blunt cervical trauma.

| Secondary Insults | No. of Patients | % of Total Patients | 6-Month Outcome (%) | | |
|-------------------|-----------------|---------------------|---------------------|-------------------|------|
| | | | Good/Moderate | Severe/Vegetative | Dead |
| Total cases | 717 | 100 | 43.0 | 20.2 | 36.8 |
| Neither | 308 | 43.0 | 63.9 | 10.2 | 26.9 |
| Hypoxia | 161 | 22.4 | 50.3 | 21.7 | 28.0 |
| Hypotension | 62 | 11.4 | 32.9 | 17.1 | 50.0 |
| Both | 166 | 23.2 | 20.5 | 22.3 | 57.2 |

Figure 48-4. Comprehensive evaluation chart used for penetrating neck trauma in Los Angeles County/University of Southern California Medical Center. (Reprinted with permission from Demetriades D, Asensio JA, Velmahos G, Thal E: Complex problems in penetrating neck trauma. Surg Clin North Am 76:661, 1996.)

Physical signs and symptoms are often sufficient for evaluating penetrating neck injuries; they usually present with obvious clinical manifestations. Blunt cervical trauma may be more subtle. Airway compromise or obstruction, brisk bleeding from the wound site, an expanding pulsatile hematoma, and shock with or without external bleeding are obvious signs of cervical vascular injuries and dictate immediate airway management and vascular control. Decreased or absent upper extremity or distal carotid pulses, and carotid bruit or thrill are pathognomonic for cervical arterial injury; however, these often do not require immediate surgery. Hemothorax, pneumothorax, and signs of air embolism are also suggestive. Respiratory distress, cyanosis, or stridor are obvious signs of airway injury and require immediate tracheal intubation. Other signs that strongly suggest airway injury are dysphonia, hoarseness, cough, hemoptysis, air bubbling from the wound, subcutaneous crepitus, laryngeal tenderness, pneumothorax, and hemothorax. Because of their dynamic nature, cervical airway injuries may rapidly progress to obstruction; the patient therefore should be observed carefully and the trachea intubated at the first sign of problems.

Esophageal injuries, whether in the neck or the chest, are insidious and difficult to diagnose. Dysphagia, odynophagia, hematemesis, subcutaneous crepitus, prevertebral air on a lateral cervical radiograph, and major concomitant injuries to other cervical structures suggest an esophageal injury and call for confirmation with an esophagram.

The neurologic manifestations of a penetrating neck injury vary depending on the injured structure. Partial spinal cord transection produces the Brown-Sequard syndrome with ipsilateral motor and contralateral sensory deficit below the injury. Complete spinal cord transection, depending on the level of injury, produces paraplegia or quadriplegia, usually with neurogenic shock. Occasionally luminal occlusion of the carotid and vertebral arteries may lead to hemispheric cerebrovascular accident; associated hypotension increases the likelihood of this event.

Patients with severe active bleeding, persistent hypotension, and air bubbling through the wound require immediate surgery without further diagnostic studies.¹⁶⁵ Controversy exists over the indications for surgical management of stable penetrating neck injuries. Mandatory exploration is associated with negative findings in approximately 70% of patients.¹⁶⁵ Thus, in many centers patients are evaluated with an angiogram, an esophagram, or a color flow Doppler, and undergo surgery only when there are positive findings.¹⁶⁵

Blunt cervical vascular injuries usually present with a hematoma that may displace the airway and produce pharyngeal and laryngeal congestion. Injury to an artery may produce an intimal tear, pseudoaneurysm, fistula, or thrombosis.¹⁶⁶ If a carotid or vertebral artery is involved, cerebral ischemia may occur. Often thrombosis develops gradually over minutes to a few hours; therefore, the appearance of neurologic symptoms may be delayed in approximately 40% of patients.¹⁶⁶

Blunt carotid injury, a rare entity before 1980, is now being diagnosed more frequently, probably because of increasing awareness and the increased use of shoulder belts that may compress the neck during automobile collisions. Although there are no reliable means to suspect this injury before neurologic abnormalities develop, knowledge of associated injuries should arouse suspicion in asymptomatic patients.¹⁶⁷ Carotid injury can occur with a history of severe hyperextension or flexion and rotation of the neck during an accident; concomitant cervical spine and displaced facial fractures; a basilar skull fracture involving the sphenoid, mastoid, or petrous bones, or the foramen lacerum; and significant soft tissue injury of the anterior part of the neck. Symptomatic patients may present with a cervical bruit, altered mental status, or lateralizing neurologic deficits including hemiparesis, transient ischemic attacks, amaurosis fugax, or Horner's syndrome. The mortality rate associated with blunt carotid injury varies between 15 and 28%, and 15–50% of survivors have neurologic deficits.^{166,167} Identification of a blunt carotid injury in an asymptomatic patient using CT, magnetic resonance angiography, or four-vessel arteriography not only allows early institution of antiplatelet therapy, systemic anticoagulation, endovascular intervention, or surgical repair,^{166,167} but occasionally it may prevent the neurologic deficits that may follow surgery for associated injuries in an unprotected patient.

Airway injuries after blunt trauma are rare, occurring in approximately 1/137,000 patients, with an overall mortality rate of 2%.¹⁶⁸ Their severity varies from a simple mucosal tear or hematoma to a comminuted laryngeal cartilage fracture or complete cricotracheal separation. They frequently require primary laryngeal repair or tracheostomy. Anesthetic management is not only complicated by relatively complex airway management problems^{64,65} and ⁶⁶ (discussed in the section on Airway Evaluation and Intervention), but with associated skull base, intracranial, open neck, cervical spine, esophageal, or pharyngeal injuries.¹⁶⁸

Chest Injury

Trauma to almost any structure in the chest may produce serious and often life-threatening complications that require prompt diagnosis and intervention. Although a high percentage of these injuries can be treated conservatively, patients who need surgery may have major intraoperative physiologic disturbances.

Chest Wall Injury

The type and severity of trauma to the chest wall (ribs, sternum, and scapula) can, to a certain extent, predict the likelihood and severity of internal injuries. As is well known, rib fractures may produce pneumothorax or hemothorax, but both the frequency and severity of visceral injuries also increase as the number of fractured ribs increases. Patients with three or more fractured ribs have a greater likelihood of hepatic and splenic injury, a higher mortality rate, a higher injury severity score, and longer ICU and hospital stays than those with fewer rib fractures.¹⁶⁹ Patients with lower rib fractures may have underlying spleen or liver injury. Because of the large amount of energy required to fracture the first rib in its protected location, injury to this bone indicates severe underlying trauma, commonly to the aorta, the subclavian vessels, the heart, or the abdominal viscera, but also to the maxillofacial complex, the brain, or the spinal cord.^{170,171} Of the remaining components of the chest wall, scapular fractures suggest severe injuries in other locations, especially the heart and lungs.¹⁷² Sternal fractures are mainly encountered in elderly female motor vehicle occupants wearing seat belts; they are usually not associated with serious trauma to the thoracic or abdominal viscera.^{173,174}

The management principles for chest wall injuries are similar to those previously described for flail chest. Of course, the need for mechanical ventilation is less likely in

single rib fractures than in a flail chest. Effective pain relief, preferably with continuous thoracic epidural anesthetics or opioids, is central to management.^{73,74}

Pleural Injury

Two life-threatening chest injuries, tension and open pneumothorax, have already been discussed. Uncomplicated closed pneumothorax most commonly develops as a result of lung puncture by a displaced rib fracture after blunt trauma, or by missile injuries or stab wounds. The presence of subcutaneous emphysema suggests coexisting pneumothorax, although this finding alone is not an indication for chest tube placement; a tracheobronchial or esophageal perforation, interstitial lung injury, chronic pleural adhesions from pre-existing disease, facial injury with tracking of air through the fascial planes of the neck, and retroperitoneal air escape through the esophageal hiatus may also produce this finding. Tension pneumothorax involving >50% of a hemithorax presents with dyspnea, tachycardia, cyanosis, agitation, diaphoresis, neck vein distention, tracheal deviation, and displacement of the maximal cardiac impulse to the contralateral side.

The definitive diagnosis of this and other chest injuries is made by plain chest radiograph, a routine film obtained during initial evaluation of all trauma victims. Although an upright film provides the best opportunity for detection of pleural air, this position may be impossible or contraindicated in patients who are experiencing major hemorrhage or those with suspected spine or severe head injury. The supine chest radiograph can detect most pneumothoraces large enough to require immediate thoracostomy. Intrapleural free air in supine patients tends to move to the highest portion of the chest, which corresponds to the cardiophrenic or anteromedial and subpulmonic spaces.¹⁷⁵ Air in these regions is most likely to be detected with a lateral radiograph. Nevertheless, a small pneumothorax can easily be missed under these conditions. CT of the chest is more reliable than plain radiography for diagnosis of these so-called “occult pneumothoraces,” which occur in approximately 6% of patients with blunt abdominal trauma.¹⁷⁶ There is a recent suggestion that a small closed pneumothorax can be safely managed by observation alone, without a chest tube, even in those patients who require positive-pressure ventilation, as long as continuing vigilance is maintained.¹⁷⁶ However, based on an earlier study¹⁷⁷ and our own experience, we strongly believe that once diagnosed, a traumatic pneumothorax, no matter how small, should be treated with thoracostomy drainage before tracheal intubation and positive-pressure ventilation.

Bleeding intercostal vessels are responsible for most hemothoraces. Severe airway deviation may be produced by a hemothorax, although it is not as common as it is after a pneumothorax. Treatment consists of drainage with a 30–40 French chest tube (26–32 French is used for pneumothorax). Initial drainage of 1000 ml of blood, or collection of >200 ml · hr⁻¹ is an indication for thoracotomy. Additional indications for thoracotomy are a “white lung” appearance on the anteroposterior chest radiograph, a continuous major air leak from the chest tube, which may result from a direct airway injury or major lung laceration, and evidence of pericardial tamponade. Hemodynamically stable patients with persistent bleeding of <150 ml · hr⁻¹ are managed with video-assisted thoracoscopic surgery (VATS) to control bleeding.¹⁷⁸ This procedure requires placement of a double-lumen tube to collapse the lung on the involved side; it can also be useful in diagnosis of suspected diaphragmatic, cardiac, or mediastinal injuries; evaluation of some bronchopleural fistulas; and evacuation of clotted blood or an empyema that does not drain with a chest tube.¹⁷⁸ Use of VATS decreases the need for open thoracotomy and the number of negative explorations in trauma patients.¹⁷⁹ Parenthetically, blood drained from the pleural space does not coagulate. This defibrinated blood can be collected into citrate-phosphate-dextrose-containing bags and returned to the patient.

Pulmonary Contusion

Pathologically, pulmonary contusion can be described as intra-alveolar hemorrhage and edema, with atelectasis, parenchymal disruption, and lung consolidation resulting from a sudden increase in intra-alveolar pressure and rupture of the alveolar–capillary interface. There is evidence to suggest that prostanoids are also involved in the development and progression of pulmonary abnormalities on the injured side as well as in the contralateral lung.¹⁸⁰ The presence of a pulmonary contusion cannot be predicted from rib fractures; severe chest wall injuries may be associated with no lung damage and vice versa. Pulmonary contusion may not be apparent on admission, although physiologic, clinical, and radiologic manifestations usually begin to appear within 4 hours after injury. In all patients with suspected blunt chest trauma, ABGs and a chest radiograph should be obtained on admission and several times during the first day. Even a small contusion may enlarge to involve most of a lung volume within a few hours.¹⁸¹ Patients with involvement of >60% of a lung at any time within the first 24 hours after admission, or a PaO₂/FIO₂ ratio of <300 are very likely to need positive-pressure ventilation and are at increased risk of death.¹⁸¹

Initial management of pulmonary contusion is supportive, and includes tracheal intubation; mechanical ventilation, preferably with positive end-expiratory pressure (PEEP), judicious fluid resuscitation, and frequent tracheobronchial suctioning. Clearing of airway secretions is important; many trauma patients smoke and have copious secretions that may cause bronchial plugging and atelectasis in the acute stage and pneumonia later if they are not cleared; the presence of rib fractures probably increases the likelihood of these complications.

Experimental studies suggest that, probably because of pulmonary vascular changes, a pulmonary contusion may interfere with the accuracy of the PCWP as an estimate of left ventricular end-diastolic pressure. The central venous pressure (CVP) may be a better measure of cardiac preload than the PCWP in this situation.¹⁸² Furthermore, significant myocardial depression, probably due to circulating arachidonic acid metabolites, has been seen after isolated pulmonary contusion. Thus even without direct cardiac injury, pulmonary contusion may contribute to the development of congestive heart failure.¹⁸²

Penetrating Cardiac Injury

Pericardial tamponade, cardiac chamber perforation, and fistula formation between the cardiac chambers and the great vessels are the consequences of this type of trauma. Any penetrating wound of the chest, especially one within the “cardiac window” (midclavicular lines laterally, clavicles superiorly, and costal margins inferiorly), can cause this injury. Pneumopericardium visible on a plain chest radiograph after penetrating chest trauma should increase the suspicion, although it is not seen in all patients. Unstable patients require immediate sternotomy or left thoracotomy; transthoracic two-dimensional echocardiography (TTE) can be used for screening stable patients.¹⁸³ Transthoracic two-dimensional echocardiography may be inconclusive in obese patients and in those with pneumothorax; TEE may provide an accurate diagnosis in these patients.¹⁸⁴ Alternative diagnostic measures are more problematic. The CVP is not always accurate, and a subxiphoid pericardial window is invasive, must be performed in the operating room under general anesthesia, takes longer, and cannot detect an intracardiac shunt.

Pericardial Tamponade

The classic findings of pericardial tamponade—tachycardia, hypotension, distant heart sounds, distended neck veins, pulsus paradoxus, or pulsus alternans—are difficult to appreciate or may be absent in a hypovolemic trauma patient. Transthoracic echocardiography or TEE can demonstrate blood in the pericardial sac and the presence of ventricular “diastolic collapse,” which indicates at least a 20% reduction in cardiac output. Initial management consists of intravenous fluids and, if necessary, careful selection and titration of anesthetic agents. Ketamine and etomidate, which produce little myocardial depression, are the agents of choice. Evacuation of the pericardial blood by pericardiocentesis or surgery should be performed as soon as possible.

Myocardial Contusion

This injury is probably present in a large proportion of blunt chest trauma victims, but it usually is not recognized because its symptoms are absent, vague, or nonspecific. The prominent clinical findings are angina-like pain, which may or may not respond to nitrates, dysrhythmias of any type, and right- or left-sided congestive heart failure. Initial management includes identification of those patients in whom dysrhythmias or pump dysfunction may develop. Echocardiography, creatine phosphokinase MB (CPK-MB) isoenzyme determination, and electrocardiography (ECG) seem to be most helpful for this purpose. Of these, two-dimensional echocardiography appears to be the most reliable test,^{185,186} especially when it is combined with a color Doppler study. Findings that suggest the presence of this injury are segmental wall motion abnormalities, increased end-diastolic wall thickness, right ventricular (RV) dilatation, septal shift, myocardial hematoma, and an intracavitary filling defect produced by the hematoma in the myocardium. Valvular dysfunction and pericardial fluid may also be seen. CPK-MB isoenzyme elevation usually occurs within the first day after the injury. The usual ECG abnormalities are ST segment and T-wave changes, axis shift, bundle-branch block, and dysrhythmias; they may be detectable for a few days.¹⁸⁷ Diagnosis can be made on the basis of clinical data and positive results of all three of the screening tests,¹⁸⁵ which indicate a clinically significant myocardial contusion; cardiac failure is unlikely if only one or two tests are positive.¹⁸⁸ Patients with a normal admission ECG are unlikely to have a significant cardiac abnormality, and further diagnostic studies are not indicated.¹⁴³

Thoracic Aortic Injury

A history of high-impact trauma, especially to the chest, should raise the suspicion of thoracic aortic injury. It occurs most frequently in the proximal portion of the descending aorta; injury to the ascending aorta and the arch is much less likely. Clinical findings are not always detectable in the emergency department (Table 48-8). A widened mediastinum on the chest radiograph should prompt a search for this injury. This sign is a reflection of mediastinal hemorrhage due to aortic injury in only 20% of cases; at other times, it is a result of bleeding from other thoracic or cervical vessels.¹⁸⁹ Although biplanar aortography is the definitive diagnostic test, it has major drawbacks: a prolonged procedure time and the risks of vascular catheterization, dye injection, and transport of a potentially unstable patient to the radiology suite. Less invasive diagnostic tests have, therefore, been attempted. A thoracic CT scan may be problematic. The procedure time may be prolonged; in some cases, the scan is incapable of adequately visualizing parts of the aorta and its branches; and it may be difficult to demonstrate an intimal flap or aortic wall irregularities. Diagnosis is made by identifying the mediastinal hemorrhage and demonstrating its proximity to the aorta or other great vessels. With the spiral CT, power-injected

contrast studies have a high degree of accuracy. Although this technique is reliable for the diagnosis of aortic injuries, there has been little experience with trauma around the aortic arch.¹⁸⁹ TEE is a relatively simple, minimally invasive diagnostic test.¹⁹⁰ An intimal flap and turbulent flow (detected by the Doppler technique) are the characteristic signs of aortic injury on TEE. It can be used during surgery for patients with unstable injuries that preclude preoperative examination of the aorta. Nevertheless, neither the CT scan nor the TEE are absolutely reliable diagnostic tests¹⁹⁰; aortography is still indicated whenever there is uncertainty about the results of these studies, or when there are contraindications to their use.

| Clinical | Radiographic | Spinal Computed Tomography | Ultrasound |
|---|---|----------------------------|----------------|
| Increased arterial pressure and pulse amplitude in upper extremities | Mediastinal widening | Mediastinal hematoma | Intimal flap |
| Decreased arterial pressure and pulse amplitude in lower extremities | Disruption of the aortic contour | Aortic wall irregularity | Turbulent flow |
| Hoarse or weak left radial artery pulse | Mediastinal paraspinal interface | Intimal flap | |
| Chest x-ray discrepancy between left and right arm blood pressure | Cyphoid pulmonary window | | |
| Retrosternal or interscapular pain | Reinforced paratracheal stripe | | |
| Hemoptysis | Displacement of the left mainstem bronchus | | |
| Isolated low diaphragm over the pedicle or medial to the left scapula | Regional deviation of the esophagus and trachea | | |
| Neurologic deficits in the lower extremities | Left hemothorax | | |
| | Sternal or upper rib fractures | | |

Table 48-8. COMMON CLINICAL, RADIOGRAPHIC, AND ULTRASOUND FEATURES OF THORACIC AORTIC INJURIES

Thoracic aortic rupture rarely presents without an associated injury. Surgical prioritization depends on the hemodynamic and neurologic status of the patient. Although the aorta should be repaired as early as possible, control of active hemorrhage from other sites and surgery for intracranial hematomas have a higher surgical priority, unless the aorta is leaking.¹⁹¹ In most instances, a blood clot between the aorta and the mediastinal pleura occludes the vessel. Any disturbance of the vessel in the tamponaded region may reinitiate bleeding. A rapid flow of blood in a large artery tends to pull its endothelium with it and thus may rupture an injured vessel that is sealed with a clot or a hematoma. Such an increase in the aortic blood flow is usually caused by increased myocardial contractility. Thus, during management of patients with aortic injury, every effort should be made to prevent hypertension.

Diaphragmatic Injury

In addition to interfering with the competence of the esophagogastric junction, a diaphragmatic injury may permit migration of abdominal contents into the chest where they may compress the lung, producing abnormalities of gas exchange, or the heart, resulting in dysrhythmias. Even when the abdominal contents do not migrate, there may be breathing abnormalities because of diaphragmatic dysfunction. Patients usually present with shortness of breath and, less frequently, with symptoms of gastrointestinal obstruction. Other injuries often accompany diaphragmatic trauma. Because the defect produced by blunt trauma is larger than that resulting from a penetrating injury, migration of abdominal contents, which requires a defect of at least 6 cm in diameter, is also more common after blunt trauma.¹⁹² The liver protects the right side of the diaphragm, thus traumatic herniation is more common on the left side.¹⁹² The abdominal contents may rarely herniate into the mediastinum and cause persistent tachycardia, which may be attributed to other factors.

With the exception of laparoscopy, all of the available methods of abdominal diagnosis have their limitations. Nevertheless, noting that the end of a nasogastric tube is above the diaphragm on the chest radiograph is a certain sign that the stomach is displaced into the chest. Failure to retrieve the instilled fluid during diagnostic peritoneal lavage (DPL) also suggests this injury.¹⁹³ If a thoracostomy tube is in place, drainage of DPL fluid from the chest is another indication of a ruptured diaphragm.¹⁹³ A chest radiograph with or without a contrast study of the gastrointestinal tract that shows intestinal markings and lung compression is diagnostic in patients with intestinal contents in the chest.¹⁹³ A contrast-enhanced abdominal CT scan that includes the lower third of the thorax can also provide important information.¹⁹³ As mentioned previously, laparoscopic examination or VATS provides a definitive intraoperative diagnosis.

Abdominal and Pelvic Injuries

The management of acute abdominal injuries has changed significantly in the 1990s, and the current trend suggests that there will be additional modifications in the future. Thus, preferences in management of abdominal trauma vary widely among centers. [Table 48-9](#) summarizes the strengths and weaknesses of the currently available diagnostic tools used for abdominal injuries.¹⁹⁴ Because of the unpredictable course of bullets in the body, exploratory laparotomy or, in selected cases, laparoscopy is required after any gunshot wound of the abdomen. Stab wounds may be managed with tractotomy to determine whether the peritoneum is involved, and then a DPL may be performed if necessary. A positive DPL is an indication for laparotomy. In some hemodynamically stable patients, abdominal and flank gunshot wounds may be managed safely with an initial CT scan.¹⁹⁵ Patients with a negative study are observed, whereas those with positive findings undergo exploratory surgery. Equivocal CT results are followed by a laparoscopy and, if this is positive, by laparotomy.

| Diagnostic Tool | Strength | Weakness |
|-----------------------------------|---|---|
| Physical examination | Expeditious, safe, and inexpensive potential for serial examination | Diagnosis of specific injury (eg, diaphragm) |
| Diagnostically peritoneal lavage | Expeditious, safe, and inexpensive | Diagnosis of diaphragmatic injury, hollow viscus injury, retroperitoneal injury can be insensitive and nonspecific |
| Computed tomography | Evaluation of peritoneum and retroperitoneum; staging of solid organ injury | Diagnosis of diaphragmatic injury, hollow viscus injury |
| Ultrasonography | Expeditious, safe, and inexpensive accurate for free peritoneal fluid; feasible for serial examinations | Requires conventional need for contrast; diagnosis of diaphragmatic injury, hollow viscus injury |
| Laparoscopy | Diagnosis of peritoneal penetration, diaphragm injury, hollow viscus injury; evaluation of bleeding or solid organ injury; feasible for therapy | Diagnosis of hollow viscus injury, retroperitoneal injury; expensive (especially in OIC); difficult to perform in busy emergency department |
| Unconventional diagnostic surgery | Evaluation of lung, diaphragm, mediastinum, chest wall and pericardium; potential for treatment | Requires OIC experience |

OIC = operating room.

Table 48-9. DIAGNOSTIC TOOLS IN ABDOMINAL TRAUMA: STRENGTHS AND WEAKNESSES

Blunt abdominal trauma requires a diagnostic workup before a laparotomy is performed, unless the patient is hemodynamically unstable and there are overt abdominal signs such as tenderness, guarding, and gross distention. Absence of abdominal distention, however, does not rule out intra-abdominal bleeding; at least 1 liter of blood can accumulate before the smallest change in girth is apparent, and the diaphragm can also move cephalad, allowing further significant blood loss without any change in abdominal circumference.

In hemodynamically stable patients, there are two major diagnostic algorithms: focused approach with sonography for trauma (FAST; [Fig. 48-5](#)) and the conventional approach, without ultrasonography ([Fig. 48-6](#)). The diagnostic accuracy of these algorithms is similar, but FAST requires one-third of the time and is 3.5 times less expensive than the conventional approach.¹⁹⁶ Screening with abdominal ultrasonography is performed by placing the probe (3.0–5.0 MHz) on four distinct areas of the abdomen: subxiphoid, to detect pericardial blood; right upper quadrant, for blood in the hepatorenal pouch; left upper quadrant, to detect perisplenic blood; and just above the pubic symphysis, for blood in the rectovesical pouch. FAST provides rapid, cost-effective results, and may be implemented by the physician responsible for initial evaluation in the emergency department. It is accurate for detection of hemoperitoneum,^{196,197} and can also identify solid organ injuries, although experience with these is limited. It cannot reliably detect trauma to the intestines unless they are associated with bleeding.¹⁹⁷ Fortunately, isolated intestinal injuries are uncommon after blunt trauma. Depending on the results of FAST, patients are managed with observation, repeat FAST, DPL, abdominal CT, laparoscopy, or laparotomy¹⁹⁶ (see [Fig. 48-5](#)). Patients managed with the conventional algorithm are evaluated by CT if they are stable, and DPL if they are hemodynamically or neurologically unstable; depending on the results of these studies, they are observed or undergo surgery¹⁹⁶ (see [Fig. 48-6](#)).

Diagnostic peritoneal lavage is considered positive if (1) >10 ml of gross blood is obtained, or (2) the erythrocyte count is >100,000 per mm³, the leukocyte count is >500 per mm³, the amylase level is above 200 U · l⁻¹, and there are bacteria in the drainage fluid. Using these criteria, the overall sensitivity of DPL is 91%, specificity 94%, accuracy 93%, positive predictive value 80%, and negative predictive value 98%.¹⁹⁸ Nevertheless, intestinal injuries may be missed with these criteria.¹⁹⁹

Problems with DPL include its lack of organ specificity, inability to evaluate the retroperitoneal region, and potential to perforate an organ in patients with abdominal adhesions. Abdominal CT scanning presents none of these difficulties. It is an excellent diagnostic technique in flank injuries, which usually involve retroperitoneal structures. More important, it permits the use of an organ injury scaling system, which has decreased the rate of diagnostic laparotomy. In this system, the injury to each organ is classified according to its severity; patients with lower scores are treated conservatively. The overall sensitivity of the CT scan is approximately 74%, the specificity 99.5%, and the accuracy 92%.²⁰⁰ If there is leukocytosis combined with free fluid on abdominal CT, this should raise the suspicion of a hollow viscus injury.²⁰¹

Laparoscopy is an excellent screening tool in trauma patients. An analysis showed that it avoided laparotomy in 63% of patients and missed only 1% of the injuries.¹⁹⁴ However, it is not an accurate tool for identifying injuries to specific organs; the missed injury rate per patient was 44–77%.¹⁹⁴ Although the therapeutic advantages of laparoscopy have not been demonstrated in trauma patients, it is possible that diaphragm, bladder, and solid organ injuries may be repaired with this technique. The complication rate of laparoscopy in trauma is approximately 1%, including pneumothorax, small bowel injury, intra-abdominal vascular injury, and extraperitoneal CO₂ insufflation.¹⁹⁴

Fractures of the Pelvis

Pelvic fractures result in major hemorrhage in 25% and exsanguination in 1% of patients.²⁰² Although there is no reliable way to predict the extent of bleeding in a given patient, as a simple guide, all patients with “open book” fractures (disruption of the pubic symphysis) and those with >0.5 cm displacement on an anteroposterior pelvic film can be considered candidates for administration of between 4 and 10 units of blood within 48 hours after the injury.²⁰³ In most trauma victims with pelvic fractures, bleeding results from disruption of veins by the bone fragments. Pelvic retroperitoneal bleeding is self-limited in most patients with venous injuries, except those with open fractures, in whom the tamponading effect does not occur. Approximately 18–20% of patients have arterial bleeding, which does not stop. The retroperitoneal space in these patients may serve as a distensible container, expanding superiorly and anteriorly toward the abdominal wall and totally obliterating the lower part of the abdominal cavity. Thus, DPL, as in pregnant trauma patients, should be performed above the umbilicus. Large retroperitoneal hematomas may also cause respiratory difficulty because of pressure on the diaphragm. Application of MAST to prevent friction of fracture fragments and thus bleeding can worsen the respiratory difficulty in these patients.

Angiography after external pelvic fixation provides information about the type and location of bleeding. Arterial bleeding is treated with embolization; the angiography suite should be prepared in advance not only for anesthesia but for invasive monitoring and resuscitation. Pelvic fractures may also injure the bladder and the urethra. Thus, a urethrogram should be performed before insertion of a urinary catheter.

Extremity Injuries

Surgical repair of extremity fractures, whether they are open or closed, should be performed as soon as possible. Delayed fracture repair is associated with increased risk of deep vein thrombosis (DVT), pneumonia, sepsis, and the pulmonary and cerebral complications of fat embolism.²⁰⁴ Thus, contrary to the old understanding that considered skeletal injuries a low surgical priority, the current belief is that long bone fractures must be reduced and pelvic fractures immobilized with external fixators during the initial surgery, simultaneously with or shortly after the repair of thoracoabdominal and brain injuries. In open fractures, an additional important concern is infection. Wounds left unrepaired for more than 6 hours are likely to become septic. Other factors that influence the incidence of extremity infection include the extent of soft tissue damage, the location of the injury (upper extremities are less likely to become infected than lower extremities), the mechanism of trauma, the use of prophylactic antibiotics, the type of fixation, and the amount of blood transfused.²⁰⁵

Associated vascular trauma must be recognized early. Most vascular injuries exhibit at least some part of the classic syndrome of pain, pulselessness, pallor, paresthesias, and paresis. The definitive diagnosis is made with arteriography; in selected patients a duplex ultrasound study may be used as a screening test. *Compartment syndrome*, which is characterized by severe pain in the affected extremity or calf pain on dorsiflexion of the foot, should be recognized early so that emergency fasciotomy can be effective in preventing irreversible muscle and nerve damage. In unconscious patients, swelling and tenseness of the extremity indicate the presence of this complication. The definitive diagnosis is made by measuring compartment pressures, using a transducer attached to a fluid-filled extension tube and a needle inserted into the various compartments of the extremity. A pressure exceeding 40 cm H₂O is an indication for immediate surgery. Caution must be exercised when using epidural or nerve block analgesia for perioperative pain relief in the presence of extremity fractures. Absence of pain could delay diagnosis of a compartment syndrome.

Burns

Determination of the size and depth of the burn sets the guidelines for resuscitation as well as the indications for surgical intervention.²⁰⁶ A partial-thickness burn is red, blanches to touch, and is sensitive to painful stimuli and heat. Superficial partial-thickness (first-degree) burns involve the epidermis and upper dermis and heal spontaneously. Deep partial-thickness (second-degree) burns involve the deep dermis and require excision and grafting to ensure rapid return of function. A full-thickness (third-degree) burn does not blanch even with deep pressure and is insensate. Complete destruction of the dermis requires wound excision and grafting.

Some limitation of function due to scar formation results. Fourth-degree burns involve muscle, fascia, and bone, necessitating complete excision and leaving the patient with limited function. The size of the burned area as a fraction of the total body surface area (TBSA) is estimated by the “rule of nines.” In an adult, the head contributes to 9%, the upper extremities, 18%, the trunk, 36%, and the lower extremities, 36% of the TBSA. These proportions are somewhat different in children.

Information about the mechanism of injury facilitates the diagnosis of associated clinical abnormalities. For example, thermal trauma caused by flames in a closed space is likely to be associated with airway damage. Burns resulting from motor vehicle, airplane, or industrial accidents may be complicated by other traumatic injuries. Finally, burns caused by electrocution may show little external evidence but may be associated with severe fractures, hematomas, visceral injury, and skeletal and cardiac muscle injury resulting in pain, myoglobinuria, and dysrhythmias or other ECG abnormalities.

Full-thickness burns involving >10% of the TBSA; partial-thickness burns covering >25% of TBSA in adults and over 20% at the extremes of age; burns involving the face, hands, feet, or perineum; inhalation, chemical, and electrical burns; and burns in patients with severe pre-existing medical disorders are considered to be *major burns*.²⁰⁶ A severe burn is a systemic disease that stimulates the release of mediators locally—producing wound edema—and into the circulation, that cause immune suppression, hypermetabolism, protein catabolism, sepsis, and multisystem organ failure.²⁰⁶

Airway Complications

Respiratory distress in the initial phase of a burn is usually caused by airway injury involving the pharynx or the trachea. Singed facial hair, facial burns, dysphonia or hoarseness, cough, soot in the mouth or nose, and swallowing difficulties in patients without respiratory distress should increase the suspicion of upper (frequent) and lower (occasional) airway injury. In the upper airway, particles with high heat capacity, such as plastics and absorbed chemicals, cause glottic and periglottic edema and copious, thick secretions, resulting in obstruction and possibly interfering with laryngeal protection of the lower airway. Fluid resuscitation probably contributes greatly to upper airway obstruction even in the absence of significant inhalation injury.²⁰⁷ The trachea and bronchi may be damaged by toxic gases. Decreased surfactant and mucociliary function, mucosal necrosis and ulceration, edema, tissue sloughing, and secretions produce bronchial obstruction, air trapping, and bronchopneumonia. The development of parenchymal lung injury takes approximately 1–5 days and presents with the clinical picture of adult respiratory distress syndrome. Pneumonia and PE are late complications that occur 5 or more days after burns. The presence of respiratory difficulty markedly increases the mortality rate from thermal injuries.²⁰⁸

Administration of the highest possible concentration of O₂ by face mask is the first priority in moderately to severely burned patients with a patent airway. In patients with massive burns, stridor, respiratory distress, hypoxemia, hypercarbia, loss of consciousness, or altered mentation, immediate tracheal intubation is indicated.²⁰⁹ The intubation technique selected depends on the operator’s experience, the age of the patient, and the extent of airway compromise. In adults, awake fiberoptic intubation under adequate topical anesthesia is probably the safest approach. In most pediatric patients, awake intubation is not possible. An inhalation induction with O₂ and halothane or sevoflurane, followed by intubation using a fiberoptic bronchoscope or conventional laryngoscope is appropriate.²⁰⁶ Personnel and equipment should be available for a possible needle or formal cricothyroidotomy or tracheostomy. It is generally believed that a surgical airway entails a significant risk of pulmonary sepsis, late upper airway sequelae, and death in burned patients; it should be reserved for those whose airway management cannot be handled in any other way.^{206,210} Immediately after securing the airway, ventilation with low levels of PEEP may prevent the pulmonary edema that may develop secondary to loss of laryngeal auto-PEEP in patients with significant airway obstruction before intubation.²¹¹ Airway humidification, bronchial toilet, and bronchodilators if needed for bronchospasm, are also indicated.

Decisions about airway management can be difficult. Some patients may not have overt signs and symptoms initially, but may later develop airway compromise with progressive supraglottic edema or pulmonary abnormalities. The pediatric airway is particularly challenging because it may be occluded by minimal amounts of swelling owing to its small diameter. Prophylactic intubation may therefore be required in children who are suspected of having an inhalation injury even though they are not yet in respiratory distress. Prophylactic tracheal intubation may also be indicated in adults when the resources for careful follow-up are insufficient.²¹¹ However, this approach may subject some patients to unnecessary risks of laryngeal sequelae such as granuloma formation, bleeding, or vocal cord paralysis. Information obtained from radiologic, ABG, and endoscopic examinations and pulmonary function testing may be useful to predict which patient will need tracheal intubation.²⁰⁹

Fiberoptic laryngoscopy is easy to perform and can provide direct information about the glottic and periglottic structures. It may avoid tracheal intubation in patients who would otherwise be considered candidates for this procedure.²⁰⁹ Fiberoptic bronchoscopy has the additional advantage of providing information about the lower airway, although it is more uncomfortable for the patient and requires topical anesthesia of the tracheobronchial tree.²¹² These studies should be performed every 3–4 hours for the first 12 hours after injury. In cooperative patients, pulmonary function testing may aid in the evaluation of airway obstruction. A sawtoothed or flattened inspiratory flow and an extrathoracic obstruction pattern on the flow/volume loop suggest upper airway obstruction. Decreased peak expiratory flow, forced vital capacity, and pulmonary compliance, and increased airway resistance suggest lower airway injury.

The initial chest radiograph is usually negative even in patients with pulmonary complications. However, a baseline film should be obtained for later comparison. Perivascular fuzziness and peribronchial cuffing within the first 24 hours of a burn suggest inhalation injury. Grading the severity of chest radiograph findings within the first 5 days after a thermal injury has been shown to correlate with the increase in lung water and pulmonary shunting, and the decrease in lung compliance.²¹³ As expected, the more extensive the pulmonary edema, the more severe are the functional abnormalities of the lung. The treatment of smoke inhalation in burns involves ventilatory management, intensive care, and treatment of carbon monoxide (CO) and cyanide (CN⁻) toxicity.

Carbon Monoxide Toxicity

The patient’s inspired oxygen should be maintained at the highest possible concentration, even when there is no evidence of significant smoke-induced lung injury, until CO toxicity is ruled out by measurement of blood carboxyhemoglobin (COHb). A high FIO₂ not only improves oxygenation but promotes elimination of CO; an FIO₂ of 1.0 decreases the blood half-life of COHb from the 4 hours seen in room air to <1 hour.²⁰⁶ A normal oxygen saturation on a pulse oximeter does not exclude the possibility of CO toxicity, although low arterial O₂ saturation measured by a co-oximeter should raise the suspicion.²¹⁴ Similarly, the mixed venous oximeter catheters that are used for continuous *in vivo* measurement of $\bar{S}\bar{V}O_2$ overestimate oxyhemoglobin concentration in the presence of CO.²¹⁵ If CO toxicity is not accompanied by a lung injury and thus by decreased PaO₂, tachypnea is absent; the carotid bodies are sensitive to the arterial O₂ tension and not to the O₂ content. The classic cherry-red color of the blood is also absent in most patients because it occurs only at COHb concentrations above 40%, and it may also be obscured by coexistent hypoxia and cyanosis.

Although CO may interfere with mitochondrial cytochrome function, it produces tissue hypoxia primarily by its 200-fold greater affinity for hemoglobin than oxygen and by its ability to shift the hemoglobin dissociation curve to the left. Thus, it reduces the oxyhemoglobin concentration and blood oxygen content and oxygen-carrying capacity, and impairs the release of oxygen to tissues.^{216,217} The greater the blood concentration of COHb, the more severe are the presenting symptoms (Table 48-10). Delayed neuropsychiatric disorders have been described in patients exposed to toxic levels of CO, and there is evidence to suggest that early hyperbaric O₂ treatment may prevent these symptoms.²⁰⁶ The decision to institute this treatment should be based on comparing the risks of transport, decreased patient access, and delay in emergency treatment against the possible neurologic sequelae. MacLennan *et al*²⁰⁶ recommend hyperbaric O₂ for patients with COHB >30% at admission if the treatment of life-threatening problems will not be compromised.

| Blood COHb Level (%) | Symptoms |
|----------------------|---|
| <15–20 | Headache, dizziness, and occasional confusion |
| 20–40 | Nausea, vomiting, disorientation, and visual impairment |
| 40–60 | Agitation, combativeness, hallucinations, coma, and shock |
| >60 | Death |

Table 48-10. SYMPTOMS OF CO TOXICITY AS A FUNCTION OF THE BLOOD CARBOXYHEMOGLOBIN (COHb) LEVEL

Cyanide Toxicity

Another cause of tissue hypoxia in burned patients is CN^- toxicity. Cyanide or hydrocyanic acid is produced by incomplete combustion of synthetic materials, and may be inhaled or absorbed through mucous membranes. As in CO toxicity, the usual clinical presentation is unexplained metabolic acidosis. Nonspecific neurologic symptoms such as agitation, confusion, or coma are also common findings. Elevated plasma lactate levels in severe burns may result from hypovolemia, CO toxicity, or CN^- toxicity. However, lactic acidosis after smoke inhalation in a patient without a major burn suggests CN^- toxicity.²¹⁸ The definitive diagnosis can be made only by determination of the blood cyanide level, which is toxic above $0.2 \text{ mg} \cdot \text{l}^{-1}$ and lethal at levels beyond $1 \text{ mg} \cdot \text{l}^{-1}$.²¹⁹ A spectrophotometric assay using methemoglobin as a colorimetric indicator provides a timely and reliable determination of blood CN^- .²²⁰ Increased CN^- in the blood can cause generalized cardiovascular depression and cardiac rhythm disturbances, especially in patients with lactic acidosis. Fortunately, the half-life of CN^- is short (approximately 1 hour),²¹⁸ and rapid improvement of hemodynamics should be expected after rescue of the victim from the toxic environment. Immediate administration of O_2 , which is required for all burn victims, may be life saving for this complication. Although there are specific therapies for CN^- toxicity (e.g., amyl nitrate, sodium nitrite, thiosulfate), given the short half-life of the ion, it is not clear whether these measures offer significant help to the patient whose blood CN^- usually decreases to low levels during transport from the field to the hospital.²²¹ Of course, hyperbaric O_2 treatment can be used for all of the complications of thermal injury: CO and CN^- poisoning, smoke-induced lung damage, and cutaneous burns.²²² However, as mentioned, placement of a critically ill patient who may have other injuries in a hyperbaric chamber is technically difficult and fraught with complications.

Fluid Replacement

Immediately after a burn, microvascular permeability increases for 3–5 days in the injured tissues, and for less than a day in normal tissues, causing a loss of a substantial amount of protein-rich fluid.²⁰⁶ This fluid flux is enhanced by increased intravascular hydrostatic and interstitial osmotic pressures and a decrease in interstitial hydrostatic pressure. In addition, cardiac contractility decreases because of circulating mediators, a diminished response to catecholamines, decreased coronary blood flow, and increased systemic vascular resistance.²⁰⁶ This may result in shock, whose origin is primarily hypovolemic and to a small extent cardiogenic. If the hypotension is treated appropriately with fluids, the hemodynamic picture is replaced within 24 to 48 hours by one resembling sepsis or septic shock, with increased cardiac output and diminished systemic vascular resistance caused by the release of inflammatory mediators.²⁰⁶

Fluid resuscitation is essential in the early care of the burned patient, but restoration of intravascular volume should be done with utmost care to prevent excessive edema formation in both damaged and intact tissues resulting from the generalized increase in capillary permeability caused by the injury. Edema from overaggressive resuscitation has many deleterious and potentially life-threatening effects. Mention has already been made of the facilitation of upper airway edema after rapid fluid infusion in large cutaneous burns with or without smoke inhalation.²⁰⁷ Likewise, chest wall edema may develop after administration of large quantities of fluid, causing respiratory difficulties and necessitating excision of burned tissue from the anterior axillary line to improve breathing. Abdominal edema may also occur and occasionally increase intra-abdominal pressure and impede venous return. Edema formation may also increase the tissue pressure in the burned area, resulting in reduction of blood flow to distal sites. This, together with decreased tissue oxygen tension, may produce necrosis of damaged but viable cells, increasing the extent of injury and the risk of infection.

Both crystalloid and colloid solutions are effective in restoring tissue perfusion. However, colloids do not seem to offer any advantage over crystalloids in most instances, and are more expensive. The ACS Committee on Trauma recommends the use of crystalloids for this reason.²⁰⁶ Nevertheless, crystalloid resuscitation, especially in children, may cause a rapid decline in plasma protein concentration and necessitate colloid administration.²²³ Normal saline is isotonic and inexpensive, and can be used in most burn patients during initial resuscitation. Because of its slight hypotonicity, large quantities of LR solution may cause edema in intact tissues. However, it is used frequently in thermal injuries because it contains electrolytes in addition to Na^+ and Cl^- . Patients with inhalation injury require a larger volume of fluids than those without it, and thus are prone to edema formation with isotonic solutions.²²⁴ Hypertonic salt solutions draw intracellular water into the bloodstream and thus decrease the fluid volume needed to maintain perfusion. Patients with burns occupying >50% of the TBSA, circumferential extremity burns, or inhalational injury may benefit from these solutions, which both maintain extracellular volume and limit the severity of edema.²⁰⁶ Unfortunately, hypertonic solutions cause hypernatremia and intracellular water depletion; patients receiving these fluids for burn therapy had an unacceptably high incidence of renal failure and death compared with those receiving LR.²²⁵

Various burn centers have developed guidelines for fluid resuscitation²¹⁶ (Table 48-11). Of these, the Evans and Brooke formulas suggest the combined use of colloid, crystalloid, and 5% dextrose solutions. However, the early glucose intolerance seen in burn patients, especially in children, should probably preclude sugar-containing fluids in the first 24 hours after injury. These formulas are guidelines only, and none can be expected to provide adequate restoration of intravascular volume in all burn victims, especially small children and patients with inhalation injuries.²¹⁶ Therefore, administration of fluids during the initial phase should be titrated to specific goals such as a urine output of approximately $0.5 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$; a heart rate of 110–120 $\text{beats} \cdot \text{min}^{-1}$; a minimal base deficit; a normal blood lactate level; and, if a pulmonary artery catheter is placed, acceptable filling pressures and a mixed venous oxygen tension ($\text{P}\bar{\text{V}}\text{O}_2$) of 35–40 mm Hg. Careful monitoring of the hematocrit may also guide fluid management. An increase in hematocrit during the first day suggests inadequate fluid resuscitation because hemolysis and sequestration are actually expected to cause a decrease in this parameter. Acute anemia, as may occur during excision and grafting of burns, is usually well tolerated. Blood replacement is usually not initiated until the hematocrit is below 15–20% in healthy patients requiring limited operations, approximately 25% in those who are healthy but need extensive procedures, and 30% or more when there is a history of pre-existing cardiovascular disease.²²⁶

| Blood COHb Level (%) | Symptoms |
|----------------------|---|
| <15–20 | Headache, dizziness, and occasional confusion |
| 20–40 | Nausea, vomiting, disorientation, and visual impairment |
| 40–60 | Agitation, combativeness, hallucinations, coma, and shock |
| >60 | Death |

Table 48-11. INITIAL FLUID RESUSCITATION AFTER THERMAL INJURY

Pulmonary artery catheters should not be used indiscriminately because they are associated with a high rate of complications, including septic emboli, in these patients.²¹⁶ On the other hand, in severe burns urine output and vital signs alone may not provide reliable information about the hemodynamic status of the patient.^{227,228} In major burns, invasive central monitoring and inotropic agents are often indicated. Rarely, initial fluid resuscitation may fail in patients with large, deep burns, inhalational injury, or pre-existing disease, and those at the extremes of age. Plasma exchange may be useful in these patients.²⁰⁶

OPERATIVE MANAGEMENT

Pre-existing Diseases

Pre-existing medical conditions have an overall prevalence of at least 19% in the population of trauma patients, increasing to >30% in those older than 55 years of age.²²⁹ Coexisting cirrhosis, cardiovascular, pulmonary, and renal diseases, coagulation disorders, and diabetes increase trauma-related morbidity and mortality.²²⁹ Alcohol intoxication or substance abuse is very common in injured patients, especially in those sustaining intentional injury. Surveys have shown that nearly 50% of trauma patients test positive for alcohol or drugs.^{230,231} Table 48-12 summarizes the clinical implications and management of some of these conditions in trauma patients.²³²

| Blood COHb Level (%) | Symptoms |
|----------------------|---|
| <15-20 | Headache, dizziness, and occasional confusion |
| 20-40 | Nausea, vomiting, disorientation, and visual impairment |
| 40-60 | Agitation, combativeness, hallucinations, coma, and shock |
| >60 | Death |

Table 48-12. IMPLICATIONS OF PRE-EXISTING CONDITIONS FOR INTRAOPERATIVE MANAGEMENT OF THE TRAUMA PATIENT

Premedication

Premedication is not indicated in most trauma patients, particularly those who are hypovolemic, head injured, or intoxicated. If deemed necessary, it can be given intravenously to patients with adequate circulating volume and unimpaired mental status. Small doses of opioid (morphine, 1–2 mg; fentanyl, 25–50 µg) or sedative (diazepam, 2.5 mg; midazolam, 0.5–1 mg) are administered with close monitoring of vital signs, and repeated as required to obtain the desired degree of analgesia and sedation. Regional techniques may also provide analgesia for some patients with skeletal injuries awaiting surgery. Femoral nerve block, for example, provides excellent analgesia for fractures of the femur.

Preinduction Phase

The operating room must be ready to receive critically injured patients on a moment's notice. This requires not only advance preparation of anesthetic equipment, supplies, and drugs but rapid coordination of adequate help from other departments such as nursing, blood bank, radiology, and the laboratory. All equipment necessary for anesthetic management of the trauma patient must be prepared in advance; consideration should be given to timely provision of those items that are essential but not routinely used (Table 48-13). Stocking and periodic checking of a dedicated “trauma anesthesia cart” are essential. In addition, availability of sophisticated equipment such as TEE, a rapid infusion system, and an autotransfusion (cell saver) device is highly desirable.

| EQUIPMENT |
|--|
| Fiberoptic bronchoscope with light source |
| Critical care ventilator* |
| FiO2 monitor system† |
| Positive end-expiratory pressure valve |
| Blood and fluid bag warming device |
| Level 2 concentration fluid infusion and warming system |
| Rapid infusion system (FlowSonic) |
| Autotransfusion device |
| Preced (low air) warming device (Bair Hugger) |
| Heated humidifier to warm inspired gases |
| Calibrated infusion device |
| Transcranial Doppler ultrasonography |
| Transcranial sonography |
| Cardiopulmonary bypass pump‡ |
| Defibrillator |
| SUPPLIES |
| Equipment for special airway management (jet ventilation, retrograde intubation, videoendoscopy, tracheostomy, lung isolation) |
| Equipment for placement of arterial and pulmonary artery lines |
| DRUGS |
| Vasopressors and inotropes (epinephrine, phenylephrine, dopamine, dobutamine, amrinone, milrinone, nifedipine) |
| Calcium chloride or gluconate |
| TEEA§ (specially modified bicarbonate) |
| Topical anesthetic |
| TECHNIQUES |
| TEEA§ - Endotracheal intubation/ventilation |
| * For treatment of patients with severely decreased lung compliance (e.g., pulmonary contusion, aspiration) |
| † For management of patients with penetrating cardiac injury involving a major coronary artery. |

Table 48-13. EQUIPMENT, SUPPLIES, AND DRUGS THAT MAY BE NEEDED IN ADDITION TO THOSE USED FOR ROUTINE ANESTHETIC CARE DURING INTRAOPERATIVE MANAGEMENT OF TRAUMA

Transport of the trauma victim to the operating room should take place with close monitoring of blood pressure, heart rate, O₂ saturation, and, in intubated patients, end-expired CO₂. In intubated patients, correct position and patency of the endotracheal tube must be confirmed, and oxygen must be administered to all patients immediately on arrival in the operating room. Severe hypoxemia is likely to develop in the operating room after chest trauma despite acceptable blood gases in the emergency department. This may be secondary to progressive inflammatory response to injury with pulmonary contusion and aspiration pneumonia, development of heart failure and pulmonary edema, respiratory insufficiency or failure in those with rib fractures, or lung collapse in patients with diaphragmatic rupture and hernia, hemothorax, or pneumothorax. Auscultation of breath sounds, examination of the chest film, and measurement of ABGs provide a baseline with which subsequent intraoperative changes can be compared. Rapid clinical determination of the patient's fluid volume status is difficult. Gross estimation of intravascular volume can be made by observing blood pressure, pulse rate, external bleeding, chest tube drainage, and the rate and amount of fluid infusion. Performance of a “tilt test” for orthostatic hypotension²³² is unreliable and delays necessary management of the patient.²³³

Continued assessment of the patient for missed injuries is important before and during surgery. Information is obtained from the surgeon, evaluation of the patient, and review of radiographs and laboratory results. Injuries that if missed in initial evaluation can lead to major perioperative complications include those of the head and cervical spine, eye, airway, diaphragm, liver, and spleen, and conditions such as hemothorax, pneumothorax, pulmonary and cardiac contusion, hemopericardium, and injury to major thoracic and abdominal vessels. In addition, if time permits, appropriate resuscitative measures should be ensured before induction. The anesthesiologist should check venous lines for proper and unimpeded flow, monitor arterial pressure and CVP and waveforms on the oscilloscope, observe the amount and color of the urine, and monitor the ECG for heart rate, dysrhythmias, and ST segment and T-wave abnormalities. In patients presenting with impalement injuries, the impaling object, which may have injured a large internal vessel, should not be manipulated until the patient is anesthetized, and then only by the surgeon.

Monitoring

Table 48-14 lists monitoring techniques currently used in the operating room and indicates their relative importance in the intraoperative care of the trauma patient.²³⁴ Clearly, valuable time can be lost if the placement of invasive monitors takes precedence over resuscitation.

| Monitoring Parameter | Technique | Monitoring Parameter | Relative Importance |
|-------------------------------|-------------------|-------------------------------|---------------------|
| End-tidal CO ₂ | Capnography | End-tidal CO ₂ | High |
| Arterial blood pressure | Invasive | Arterial blood pressure | High |
| Central venous pressure | Invasive | Central venous pressure | High |
| Heart rate | ECG | Heart rate | High |
| SpO ₂ | Pulse oximetry | SpO ₂ | High |
| Temperature | Rectal/Esophageal | Temperature | Low |
| Urine output | Catheter | Urine output | Low |
| Respiratory rate | Respiratory | Respiratory rate | Low |
| Respiratory volume | Respiratory | Respiratory volume | Low |
| Respiratory pressure | Respiratory | Respiratory pressure | Low |
| Respiratory compliance | Respiratory | Respiratory compliance | Low |
| Respiratory resistance | Respiratory | Respiratory resistance | Low |
| Respiratory work of breathing | Respiratory | Respiratory work of breathing | Low |
| Respiratory effort | Respiratory | Respiratory effort | Low |
| Respiratory volume | Respiratory | Respiratory volume | Low |
| Respiratory pressure | Respiratory | Respiratory pressure | Low |
| Respiratory compliance | Respiratory | Respiratory compliance | Low |
| Respiratory resistance | Respiratory | Respiratory resistance | Low |
| Respiratory work of breathing | Respiratory | Respiratory work of breathing | Low |
| Respiratory effort | Respiratory | Respiratory effort | Low |

Table 48-14. TECHNIQUES TO MONITOR PHYSIOLOGIC PARAMETERS AND THEIR IMPORTANCE IN INTRAOPERATIVE MANAGEMENT OF THE TRAUMA PATIENT

Hemodynamic Monitoring

There is no effective substitute for direct intra-arterial pressure monitoring, which permits beat-to-beat data acquisition and sampling for measurement of blood gases. Every effort must be made to place this line before surgery, even if it requires surgical cut-down. A relatively stable patient may rapidly become unstable when the abdomen or chest is opened. The radial artery is most commonly used because it is accessible, easy to cannulate, and relatively free from serious complications. It is the artery of choice in abdominal or chest trauma in which the aorta may be cross-clamped, making a femoral or dorsalis pedis cannula nonfunctional. The right radial artery is preferred in cases of chest trauma in which cross-clamping of the descending aorta might result in occlusion of the left subclavian artery. In mechanically ventilated patients, the magnitude of systolic pressure variation (the difference between the maximum and minimum systolic pressure over the respiratory cycle) and its Ddown component (the difference between systolic pressure at end- expiration and the lowest value during the respiratory cycle) can provide reliable information about the intravascular volume status (Fig. 48-7). A systolic pressure variation >5 mm Hg and a Ddown >2 mm Hg suggest hypovolemia.²³⁵ Most trauma patients are young, with a healthy heart. Consequently, delaying emergent surgery to place a central venous line is rarely indicated unless a large-bore catheter is needed for volume resuscitation. Reasonable assessment of the patient's volume status can be made by repeated observation of blood pressure, urine output, hematocrit, and ABG. However, if the patient is elderly, there is a likelihood of myocardial damage, or there is multiple organ damage with requirement for prolonged surgery and massive fluid replacement, early placement of a CVP or pulmonary artery catheter is indicated before the development of coagulopathy renders it hazardous.

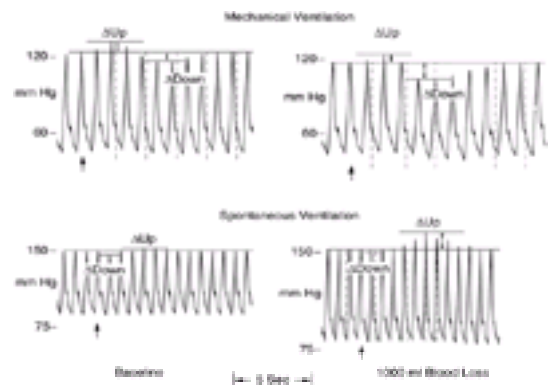

Figure 48-7. Arterial pressure records of a mechanically ventilated patient before (*left*) and after (*right*) 1000 ml blood loss. Note the increase in systolic pressure variation and Ddown component following blood loss. Decrease in blood pressure occurs during exhalation with mechanical ventilation, and inspiration in spontaneously breathing subjects (*upgoing arrow* defines inhalation). DU_p is the difference between the end-expiratory systolic pressure and the maximum systolic pressure over a respiratory cycle. See text for definition of systolic pressure variation and Ddown component. (Reprinted with permission from Rooke GA, Schwid HA, Shapira Y: The effect of graded hemorrhage and intravascular volume replacement on systolic pressure variation in humans during mechanical and spontaneous ventilation. *Anesth Analg* 80:925, 1995.)

Both CVP and PCWP assess preload indirectly from pressure measurements that are subject to error in the presence of altered ventricular compliance or, in the case of PCWP, significant pulmonary abnormality such as contusion. Volumetric assessment of preload appears to correlate better with cardiac index than the CVP or PCWP.^{236,237} A pulmonary artery catheter equipped with a rapid-response thermistor and intracardiac electrodes is capable of measuring RV cardiac output and ejection fraction, and calculating RV end-diastolic volume index. The latter appears to correlate with cardiac output better than CVP and PCWP in trauma patients. An RV end-diastolic volume index >130 ml · m⁻² is considered optimal for organ perfusion.^{236,237}

Transesophageal echocardiography provides valuable diagnostic information in myocardial contusion, cardiac septal or valvular damage, coronary artery injury, pericardial tamponade, and aortic rupture.¹⁸⁴ Intraoperative TEE can permit assessment of cardiac function, including right and left ventricular volume, ejection fraction, wall motion abnormalities, pulmonary hypertension, and cardiac output, and detects acute ischemia more accurately than either ECG or pulmonary artery pressure monitoring.²³⁸ Monitoring left ventricular volume alone can provide information about the adequacy of the intravascular volume. This technique also allows visualization of fat and air entry into the right heart, or the left heart through a patent foramen ovale, during internal fixation of lower extremity fractures.²³⁹ The complication rate from insertion of TEE probe is small (0.18%); esophageal perforation and bleeding from esophageal varices are the most frequent problems.²⁴⁰ In the trauma setting, it is possible that the TEE probe may be introduced into an unrecognized esophageal tear because the insidious nature of esophageal injury makes diagnosis difficult during the first 24 hours after trauma.

In most hypovolemic trauma patients, almost all available methods of determining cardiac preload correlate poorly with circulating blood volume.²⁴¹ Preload remains stable up to a critical level of volume reduction because of a compensatory increase in sympathetic tone. Therefore, a direct measurement of circulating blood volume may be advantageous in this setting. Japanese investigators using a pulsed dye densitometer, a technique that relies on indocyanine green distribution and elimination, were able to measure blood volume at 20-minute intervals.²⁴²

Urine Output

Urine output is routinely monitored as an indicator of organ perfusion, hemolysis, skeletal muscle destruction, and urinary tract integrity after trauma. As a rough guideline, urine output should be maintained at >0.5 ml · kg⁻¹ · hr⁻¹. Caution should be exercised in interpretation of urine output as an indicator of intravascular volume and kidney perfusion. After prolonged shock, renal failure (low or high output) may already be present at the time of the patient's arrival in the operating room. Osmotic diuresis produced by preoperative radiopaque dye or mannitol also reduces the reliability of urine output as an index of renal perfusion. Dark, cola-colored urine in the trauma patient suggests either hemoglobinuria resulting from incompatible blood transfusion, or myoglobinuria caused by massive skeletal muscle destruction after blunt or electrical trauma. Rapid differential diagnosis can be made by centrifugation of a blood specimen. Pink-stained serum suggests hemoglobinuria, whereas unstained serum indicates myoglobinuria. Both of these conditions may result in acute renal failure. Prevention involves mannitol diuresis and, in myoglobinuria, alkalinization of the urine with sodium bicarbonate to pH levels above 5.6. Red-colored urine usually is caused by hematuria, which, in the traumatized patient, suggests urinary tract injury. It should be investigated with iv pyelography, if possible. Intravenous injection of methylene blue (5–10 ml) or indigo carmine may be useful in helping the surgeon to locate the site of urinary tract injury during laparotomy.

Organ Perfusion and Oxygen Utilization

Mention has already been made about the importance of occult hypoperfusion that may not be detected by traditional hemodynamic monitoring such as blood pressure, heart rate, and urine output.^{84,85} Unrecognized or untreated, this condition may lead to organ failure and death. The intestinal mucosa lacks autoregulatory control in splanchnic ischemia and is particularly vulnerable to occult hypoperfusion. Ischemia and resulting acidosis in the intestinal wall then permits the passage of luminal microorganisms into the circulation and release of inflammatory mediators, causing sepsis and multiorgan failure.⁸⁴ Thus, efforts have been made to find a monitoring technique that can promptly and reliably detect organ hypoperfusion in the *apparently* resuscitated patient and set the optimal end points of resuscitation.

Oxygen transport variables, blood lactate level, base deficit, and gastric intramucosal pH (pHi) are considered as acceptable markers of organ perfusion and O₂ utilization.⁸⁵ Currently, only the blood lactate level and base deficit and, in some instances, O₂ transport variables are used during surgery. However, with improved technology, alimentary tract pHi or PCO₂ may also be used in this setting.

Oxygen delivery (DO₂), O₂ consumption (VO₂), and O₂ extraction ratio are the three monitored O₂ transport variables:

$$\begin{aligned} \dot{D}O_2 &= \text{Cardiac output (Qt)} \cdot CaO_2 \\ \dot{V}O_2 &= Qt \cdot (CaO_2 - Cvo_2) \\ O_2 \text{ extraction ratio} &= \dot{V}O_2 / \dot{D}O_2 \end{aligned}$$

Shock induces an oxygen debt, which is defined as the amount of O₂ that cells are deprived of as a result of the imbalance between DO₂ and VO₂. Correction of this debt is one of the endpoints of resuscitation. Achieving supernormal values of cardiac index (4.5 l · min⁻¹ · m⁻²), DO₂ index (600 ml · min⁻¹ · m⁻²), and VO₂ index (170 ml · min⁻¹ · m⁻²) by fluid infusion and inotropes is a possible way to repay this debt and salvage tissues.⁸⁵ Although some clinicians believe in this concept, others have found that this approach actually may increase mortality.⁸⁵ Resuscitation with fluids and inotropes in patients who cannot increase their VO₂ because of the damage

sustained from shock may be deleterious. Nevertheless, monitoring these parameters with a pulmonary artery catheter may provide useful information.

Determination of plasma lactate is a more direct way to evaluate hypoperfusion-induced metabolic dysfunction. Normal plasma lactate concentration is $0.5\text{--}1.5\text{ mmol} \cdot \text{l}^{-1}$; higher levels, especially above $5\text{ mmol} \cdot \text{l}^{-1}$, suggest lactic acidosis.²⁴³ Because the half-life of lactic acid is approximately 3 hours, improvement in blood lactate levels occurs rather gradually after the cause of the problem is corrected.²⁴³ Failure to clear lactate within 24 to 48 hours after hypovolemic shock is a predictor of increased mortality.²⁴⁴

The base deficit, which is the amount of base required to titrate 1 liter of whole blood to a normal pH at normal PaO₂, PaCO₂, and temperature, has been shown to be a good indicator of metabolic dysfunction during hypovolemic shock.²⁴⁵ Base deficit reliably reflects the severity of shock, oxygen debt, changes in oxygen delivery, the adequacy of fluid resuscitation, and the likelihood of survival.^{246,247} A base deficit between 2 and 5 mmol · l⁻¹ suggests mild hypovolemia, 6–14 mmol · l⁻¹ indicates moderate hypovolemia, and >14 mmol · l⁻¹ is a sign of severe hypovolemia. Normalization of the base deficit is usually considered the end point of resuscitation.

Carbon dioxide accumulates in gastric mucosal cells as a result of ischemia. pHi is calculated from intracellular CO₂, which diffuses freely across the gastric mucosa and equilibrates with saline contained in a silicone balloon attached to the distal end of a nasogastric tube.²⁴⁸ It takes 30–60 minutes for gastric luminal CO₂ to equilibrate, after which the saline is recovered and its PCO₂ measured. After applying a correction factor for gastric luminal PCO₂, pHi is calculated using the Hasselbach-Henderson equation. Patients are given histamine (H₂) blockers to prevent errors caused by gastric acid. The normal PCO₂ value is approximately 50 mm Hg and the lower limit for pHi is 7.33, approximately 0.06 lower than the blood pH.²⁴⁸ An intramucosal pH of <7.32 is considered a sign of splanchnic ischemia. A pHi of <7.25 and a gradient between mucosal and arterial PCO₂ >18 mm Hg is predictive of multiple organ failure and death,²⁴⁸ as is a delay in normalization of pHi of >24 hours.⁸⁵ Resuscitation is therefore aimed at obtaining a pHi >7.32. Obviously, this technique is cumbersome and cannot be used in the operating room. A recently designed fiberoptic PCO₂ probe obviates this problem and measures luminal PCO₂ directly.²⁴⁹ It can easily be introduced into the stomach through a standard nasogastric tube. It has significant advantages over tonometry: it is continuous, easy to use, and noninvasive, and provides real-time data. A more promising variant of this technology, sublingual capnometry, has been introduced by Weil *et al.*²⁵⁰ A CO₂ sensor is applied sublingually and mucosal PCO₂ is measured directly. The normal value for sublingual PCO₂ is approximately 45–50 mm Hg. They noted a significant elevation ($81 \pm 24\text{ mm Hg}$) in patients with circulatory shock and a blood lactate level >2.5. Patients who were not in circulatory shock had values of $53 \pm 8\text{ mm Hg}$. Values over 70 mm Hg correlated with shock, and those under 70 mm Hg were predictive of survival. Combined measurement of O₂ transport variables, base deficit, lactate, and pHi or intramucosal PCO₂ is likely to be a more accurate indicator of the patient's condition than any of these values alone.

Coagulation

Conventional blood coagulation monitoring includes a baseline and subsequent serial measurements of prothrombin time (PT), activated partial thromboplastin time (aPTT), platelet count, blood fibrinogen level, and fibrin degradation products (FDP). Although not always possible, a trauma center laboratory should provide results of the standard coagulation tests in <1 hour. A blood sample should be sent to the laboratory to determine, at least retrospectively, the etiology of any coagulation abnormality. The “tube test,” which involves obtaining a tube of blood with no anticoagulant and observing coagulation, clot retraction, and clot lysis, is a practical intraoperative method of coagulation monitoring. If a good-quality clot does not form, or does so only after 10–20 minutes, clotting factor deficiency is the most likely cause. Failure of clot retraction within 1 hour after blood sampling suggests platelet depletion or dysfunction. Clot lysis earlier than 6 hours indicates fibrinolysis, which is infrequent in trauma patients.²⁵¹ However, disseminated intravascular coagulation (DIC) occurs frequently after trauma and is associated with absence of spontaneous clotting in the tube test. In addition to causing bleeding, it may prevent typing and cross-matching of blood.²⁵²

Thromboelastography (TEG) is similar in principle to the tube test but provides a quantitative, graphic evaluation of clotting function.²⁵³ TEG determines the time necessary for initial fibrin formation, the rapidity of fibrin deposition, clot consistency, the rate of clot formation, and the times required for clot retraction and lysis²⁵³ (Fig. 48-8). Basically, the R and K values are indices of formation, buildup, and cross-linking of fibrin and depend on the function of coagulation factors. The maximum amplitude (MA) corresponds to the widest portion of the curve and indicates the absolute strength of the fibrin clot. It represents the function of platelets. The α angle is the slope of the external divergence of the tracing from the R value point, indicating the speed of clot formation and fibrin cross-linking. The value of this index is determined by both coagulation factors and platelets. Hypothermia causes coagulopathy by interfering with both platelet and coagulation factor functions.^{254,255} and ²⁵⁶ When the blood of a cold and coagulopathic patient is placed in the TEG cuvette, which is normally heated to 37°C, a near-normal trace may be obtained.²⁵⁶ Newer TEG devices are temperature adjustable; thus, the temperature in the cuvette can be adjusted to that of the patient.

Figure 48-8. Thromboelastogram. R = time interval from blood deposition in the cuvette to an amplitude of 1 mm on the thromboelastogram; K = time interval between the end of R and a point with an amplitude of 20 mm on the thromboelastogram; MA = maximum amplitude of thromboelastogram; α angle = slope of the external divergence of the tracing from the R value point; A₆₀ = amplitude of thromboelastogram 60 minutes after maximum amplitude; F = time from MA to return to 0 amplitude (normal >300 minutes). (Reprinted with permission from Capan LM, Gottlieb G, Rosenberg A: General principles of anesthesia for major acute trauma. In Capan LM, Miller SM, Turndorf H [eds]: Trauma: Anesthesia and Intensive Care, p 259. Philadelphia, JB Lippincott, 1991.)

Coagulation test (PT, aPTT) results are often abnormal in major trauma patients. However, these findings do not necessarily indicate that factor and platelet therapy should be initiated, unless there is a clinical indication to do so.²⁵⁷ The administration of FFP is generally recommended when PT and aPTT exceed 1.5 times control,²⁵⁸ but treatment is based primarily on clinical bleeding (oozing from puncture sites and wound), the amount of blood lost, and the quantity transfused. The likelihood of bleeding, for example, after one blood volume is replaced, increases to 60%, so that platelet and factor replacement becomes almost unavoidable once replacement exceeds this volume.^{259,260} The results of coagulation tests have little primary impact on treatment. Nevertheless, they should be performed to determine the direction and extent of coagulation dysfunction over time.

Anesthetic and Adjunct Drugs

Apart from regional anesthesia techniques, which are used in patients with minor extremity injuries and stable hemodynamics, anesthetic and adjunct drugs for general anesthesia need to be tailored to five major clinical conditions. The varying contribution of these conditions to the clinical picture of a given patient necessitates priority-oriented planning.

Airway Compromise

The primary issue in these patients is whether to manage the airway with or without the use of anesthetics and muscle relaxants. The principles are discussed in the section on initial management. In general, these agents should be avoided if there is significant airway obstruction or if there is doubt as to whether the patient's trachea can be intubated because of anatomic limitations. If time permits, lateral neck radiographs, CT scanning, and endoscopy can be used to define the problem better. Topical anesthesia with mild sedation can be used with or without a flexible fiberoptic scope, Bullard blade, WuScope, or other aids, and with surgical standby for cricothyroidotomy should intubation attempts be unsuccessful.⁵⁷

Hypovolemia

Hypovolemic patients are sensitive to the cardiovascular depressant action of iv and inhalational anesthetics. These not only have direct effects, but they inhibit hemodynamic compensatory mechanisms such as central catecholamine output and baroreflex (neuroregulatory) mechanisms, which maintain systemic pressure in hypovolemia. Among iv agents, etomidate has the least²⁶¹ and thiopental, propofol, and midazolam the greatest direct cardiovascular depressant activity;^{262,263} ketamine has stimulatory effects when the autonomic nervous system is intact.²⁶⁴ Among the inhalational agents, isoflurane depresses the myocardium least but it produces a decrease in mean arterial pressure comparable with that of halothane and enflurane, and offers no distinct advantage over the other agents.²⁶⁵ Nitrous oxide has a direct depressant action on the myocardium, but *in vivo* it increases sympathetic activity, resulting in a negligible overall change in systemic blood pressure.²⁶⁶

There are also differences among anesthetics in the direction and extent of their effects on compensatory mechanisms. For example, the baroreceptor depression produced by iv agents is usually milder than that of inhalational agents. Data from animal and human studies have demonstrated that thiopental, propofol, and ketamine depress the baroreflex mechanism most and for approximately 10 minutes, whereas etomidate has little effect; the effects of midazolam, diazepam, and droperidol are intermediate.^{267,268} and ²⁶⁹ Among inhalational agents, isoflurane has less of an inhibitory effect on the baroreflex mechanism than halothane or enflurane.²⁷⁰ Opioid agents have little direct cardiovascular or baroreflex depressant effect. However, these agents can cause hypotension by inhibiting central sympathetic activity, especially in the hypovolemic trauma patient whose apparent hemodynamic stability is maintained by hyperactive sympathetic tone.²⁷¹ In addition, experimental data suggest a significant alteration in fentanyl pharmacokinetics, resulting in elevated plasma concentrations due to decreased volume of distribution and clearance.²⁷²

Two important principles in the use of anesthetic agents are accurate estimation of the degree of hypovolemia and reduction of the dose accordingly. The presence of hypotension suggests uncompensated hypovolemia, in which case anesthetics almost invariably produce further deterioration of systemic blood pressure and sometimes cardiac standstill. Intravascular volume, to the extent possible, must be restored before their use. When time constraints or continuing hemorrhage prevent restoration of blood volume, the airway must be secured without the benefit of anesthesia (perhaps using only rapidly acting muscle relaxants and very small doses of opioids, etomidate, or ketamine), even though this approach may result in recall of induction and intraoperative events. In a study by Bogetz and Katz,²⁷³ only 11% of patients to whom ketamine and low-dose inhalational anesthetics were administered had recall. When hypovolemia precluded the use of anesthesia for 20 minutes, the incidence of recall increased to 43%. Studies of memory performance during general anesthesia in acute trauma patients with varying injury severity indicated that hypnotic depth plays an important role in reducing the occurrence of memory.²⁷⁴ The memory detected in these patients is implicit rather than explicit, and is not associated with postoperative recall. Use of the Bispectral Index (BIS) monitor in these patients showed that significant implicit memory persisted even at BIS values between 40 and 60, which correspond to an acceptable level of surgical anesthesia.²⁷⁴ Nevertheless, these patients did not recall auditory events after surgery. It is possible they would have had recall if anesthetics were titrated to higher BIS values. Although as yet unproved, intraoperative use of the BIS monitor and, whenever possible, titrating anesthetics to levels <60 may prevent recall in trauma patients. Hypothermia, alcohol intoxication, drug use before anesthesia, and metabolic disturbances in the acute trauma patient cannot reliably prevent recall. Scopolamine, 0.6 mg, given before airway management may decrease the likelihood of this complication, however.

Hypotension is also likely after administration of anesthesia in normotensive but hypovolemic patients. In these patients, restoration of volume as well as selection of an agent with the least cardiovascular depressant effect appears logical. Ketamine, because of its stimulatory action on the circulation,²⁶⁴ and etomidate, because of its lack of histamine release and relatively mild cardiovascular depressant effect, are the preferred induction agents.^{262,267,269,275} At low doses, however, other iv anesthetics are also unlikely to produce hypotension. Therefore, although ketamine and etomidate confer some hemodynamic advantages over other iv agents in acutely hypovolemic trauma patients, the use of any of these drugs in reduced doses is probably more important than the particular agent chosen.^{276,277} Usually, reducing the dose of the anesthetic does not result in inadequate anesthesia because the dose needed for induction is also decreased in the hypovolemic patient secondary to a variety of effects, such as decreased volume of distribution, preferential distribution of the cardiac output to the brain and the heart, brain hypoxia, dilutional hypoproteinemia, acidosis, and increased sensitivity of the brain to anesthetics.³⁴ If there is concern that inadequate anesthesia will result from reducing the dose of anesthetic, patients may be pretreated with small doses of opioids. These principles may become especially important for the anesthesiologist if the concept of delayed fluid resuscitation, with hypovolemia prolonged until hemorrhage is controlled surgically, becomes widely accepted.⁸³

The maintenance of anesthesia in the hypovolemic trauma patient raises concerns similar to those pertaining to induction of anesthesia. Although normally nitrous oxide's myocardial depressant effect is somewhat counterbalanced by its ability to increase sympathetic outflow, in acute hemorrhage there is already a dramatic increase in sympathetic activity and stimulation of baroreceptors. Under these circumstances, patients are unlikely to respond to the sympathetic effect of N₂O, and the cardiovascular depressant properties of the gas are unmasked. Weiskopf and Bogetz²⁷⁸ have demonstrated that in swine with 30% blood volume loss, hemodynamic and oxygenation indices produced by N₂O were the same as those caused by equipotent doses of halothane. In addition, N₂O, by reducing FIO₂, incurs a risk of hypoxemia in patients with reduced cardiac output or pulmonary compromise. Isoflurane, despite causing little impairment of reflex tachycardia and having a vasodilatory action that preserves organ blood flow in normovolemic patients, can impair cardiac output and organ blood flow in hypovolemia—that is, it can cause cardiovascular depression. Desflurane and sevoflurane are not significantly better than isoflurane in this regard. Because of their low solubility in blood, severe hemodynamic depression produced by these agents can be rapidly reversed, preventing suboptimal perfusion for a significant time.²⁷⁹ In summary, in the hypovolemic patient, all inhalational agents may reduce both global and regional blood flows, and therefore should be used only in small concentrations (<1 minimum alveolar concentration [MAC]). Opioid supplementation is usually well tolerated and often indicated.

Head and Open Eye Injuries

The importance of deep anesthesia and adequate muscle relaxation during airway management of patients with head or open eye injuries has already been discussed. Anesthetic agents selected for management of brain injury should produce the least increase in ICP, the least decrease in mean arterial pressure, and the greatest reduction in cerebral metabolic rate (CMRO₂). As demonstrated by intraoperative S_{ijv}O₂ measurements in acutely head-injured patients, the most important factor in causing cerebral ischemia is increased ICP from intracranial hematoma.²⁸⁰ Prompt decompression is the most crucial means of ensuring cerebral well-being. Hypotension caused by anesthetics or other factors contributes to the development or progression of cerebral ischemia. Utmost attention should be paid during anesthesia to avoidance of hypotension (mean arterial pressure <80 mm Hg) and, more important, if reliable S_{ijv}O₂ monitoring is in place, to avoid values <55–60%. Perhaps with the exception of ketamine,⁴⁴ all iv anesthetics cause comparable degrees of cerebrovascular constriction.^{281,282,283} and ²⁸⁴ Thiopental, midazolam, propofol, and etomidate therefore also produce a dose-dependent reduction in cerebrospinal fluid formation.²⁸⁵ Again with the exception of ketamine, CMRO₂ is also reduced by all of the available iv anesthetics.^{44,281,282,283} and ²⁸⁴ An important drawback to these agents is that their cardiovascular depressant effects may reduce CPP.^{281,282,284} This problem can be ameliorated by administering pretreatment doses of opioids (fentanyl, 2–3 mg · kg⁻¹), which permit reduction of the anesthetic dose. This may also prevent the myoclonic movements associated with etomidate and occasionally with propofol, and thus reduce the risks of ICP and IOP increase. Nevertheless, myoclonus is best prevented by careful timing of the dose of muscle relaxants.²⁸⁶ Another measure to preserve CPP during anesthesia is to administer vasopressors, while taking care not to mask hypovolemia by their use.

Ordinarily, administration of succinylcholine should follow pretreatment doses of nondepolarizing agents to prevent fasciculation-induced elevation of ICP and IOP.^{46,287} The results of clinical trials in search of an induction technique to avoid IOP rise without precurarization are inconsistent. However, the combination of propofol, 2 mg · kg⁻¹ and alfentanil, 40 µg · kg⁻¹ prevented IOP elevation caused by succinylcholine, laryngoscopy, and intubation in all but one patient, without producing hemodynamic depression.²⁸⁸ Avoiding succinylcholine usually does not alleviate the problem because laryngoscopy and tracheal intubation themselves produce a greater and longer-lasting increase in IOP and ICP.²⁸⁸ However, rocuronium, at a dose of 0.9–1.2 mg · kg⁻¹ has an onset time comparable with that of succinylcholine.²⁸⁹ Mivacurium has a longer onset time than rocuronium and, unlike rocuronium, can cause vasodilatation and hypotension.²⁹⁰ Finally, rapacurium 1.5–2.5 mg · kg⁻¹ most closely resembles succinylcholine in onset of action and duration and may be an appropriate agent for head- or eye-injured patients.³⁸ None of the nondepolarizing muscle relaxants causes elevation of ICP or IOP in the absence of associated endotracheal intubation.

All inhalation anesthetics may increase cerebral blood flow (CBF), cerebral blood volume (CBV), and thus the ICP.²⁸¹ Cerebral autoregulation, CO₂ responsiveness, and CMRO₂ are reduced. Unlike most iv anesthetics, which decrease both CBF and CMRO₂ in parallel, inhalational anesthetics decrease CMRO₂ while increasing the CBF. The extent of this uncoupling varies with the agent and the dose. Halothane has the greatest vasodilatory effect, whereas isoflurane has the least; enflurane is intermediate. CMRO₂ is reduced least by halothane and most by isoflurane.²⁹¹ Because it produces the most pronounced CBF–CMRO₂ uncoupling, halothane is not a desirable agent in brain injury. Enflurane produces a better CBF–CMRO₂ relationship, but its convulsive potential, which is increased by the hyperventilation frequently used in brain injury, makes it an undesirable agent as well. Isoflurane is the most widely used inhalation anesthetic, although desflurane and sevoflurane have similar effects on the cerebral circulation.²⁹² In hyperventilated patients with cerebral tumors or mild edema, isoflurane does not raise the ICP if it is administered at an inspired concentration of <1 MAC.²⁹³ In the presence of severe head injury, when cerebral autoregulation and CO₂ responsiveness are impaired, isoflurane has the potential to increase CBF and ICP even if it is given at levels below 1 MAC and with hyperventilation.²⁹³ Therefore, it may be prudent not to use this agent at high concentrations in the presence of elevated ICP, at least until the skull is opened and the ICP is controlled. In these patients, anesthesia can be maintained initially with opioids plus thiopental, propofol, midazolam, or etomidate. There is also some evidence to suggest that increasing PaO₂ to levels above 250–300 mm Hg by elevation of FIO₂ can partly compensate for the possible increase in cerebral ischemia caused by hyperventilation.²⁹⁴ Thus, if hyperventilation is used to compensate for isoflurane-induced

cerebral vasodilation, it should be accompanied by high levels of FIO_2 .

Nitrous oxide may increase CBF, CBV, and ICP when administered with inhalation anesthetics if the PaCO_2 is normal or increased.²⁹⁵ This effect may be eliminated when this agent is administered with adequate doses of barbiturates or hyperventilation. The effect on CMRO_2 is variable: both an increase and decrease have been observed. Thus, N_2O probably is not deleterious in head-injured patients with minimal ICP elevation, in hypocapnic patients, and if it is used after a bolus dose or during infusion of iv anesthetics.

Opioids are frequently used during induction and maintenance of anesthesia in neurotrauma. In a spontaneously breathing patient, they may produce hypoventilation with an associated increase in CBF and ICP; they should, therefore, be used only in mechanically ventilated head trauma patients. Some reports suggest that opioids and, to a smaller extent, opiates may interfere with CPP by increasing ICP, decreasing mean arterial pressure, or both.^{42,296} Fentanyl and sufentanil are most implicated, and it appears that this phenomenon occurs when the head injury is severe.^{297,298} As mentioned before, ICP increased in patients with both preserved and altered cerebral autoregulation.⁴² It also appears that mechanisms other than cerebral vasodilation are responsible for these changes. The clinical significance of these findings is not yet clear. However, it is prudent to administer fentanyl or its analogues slowly, when the arterial pressure is normal or slightly elevated, possibly after establishing mild hypocarbia, and ensuring preservation of systemic blood pressure with vasoactive agents, if necessary.

Cardiac Injury

If there is pericardial tamponade, preload and myocardial contractility should be maintained. Any decrease in these parameters may exacerbate an already existing RV inflow occlusion. A decrease in heart rate should also be treated promptly to maintain adequate cardiac output. Because all of the available anesthetics can depress myocardial contractility and cause vasodilation, it is preferable to administer these agents after evacuation of pericardial blood under local anesthesia. If this is not possible, an agent that best preserves sympathetic tone should be selected. In chronic pericardial effusion, ketamine supports the cardiac index better than diazepam.²⁹⁹ In acute pericardial tamponade, even minor insults can bring cardiac activity to a halt. Ketamine thus remains the agent of choice. It should be given in small doses after adequate fluid infusion. Similar principles apply to the use of maintenance agents, which should be given in the smallest possible doses until the heart is decompressed. If general anesthesia is required to relieve the tamponade, induction should be delayed until the patient is prepared and draped. Both anesthetics and controlled ventilation impair cardiac output. Deep anesthesia and high airway pressures should be avoided before evacuation of the hemopericardium.

In patients with myocardial contusion, the objective is not only to maintain cardiac contractility but to lower the elevated pulmonary vascular resistance that may result from concomitant pulmonary contusion or aspiration. All anesthetics should preferably be administered after restoration of intravascular volume and titrated to maintain adequate systemic blood pressure and cardiac output. If necessary, inotropes, preferably amrinone or milrinone, which produce some pulmonary vasodilation, may be used. Anesthetic maintenance by infusion of iv anesthetics and opioids to avoid the myocardial depression produced by inhalational agents should also be considered.

Burns

Anesthesia may be required during all three phases of burn injury: during the resuscitation phase (first 24–48 hours), during convalescence (a few weeks) for escharotomies, and during reconstruction (6 months). Extensive and repeated escharotomies may be required during the initial phase of convalescence, usually between the second day and the second week after injury, often necessitating massive transfusion, temperature control, and management of fluid, electrolyte, and coagulation abnormalities. A hypermetabolic state characterized by tachycardia, tachypnea, catecholamine surge, increased O_2 consumption, and augmented catabolism follows the initial few hours of a burn injury and continues into the convalescent phase, necessitating increased oxygen, ventilation, and nutrition.²⁰⁶

Anesthetic management of escharotomies presents several difficulties. Burned tissue may prevent access for ECG, pulse oximeter, neuromuscular function, and noninvasive blood pressure monitoring; needle electrodes or surgical staples, a reflectance pulse oximeter, and an arterial catheter may be necessary. Large-bore iv catheters are essential. Hyperthermia occurs, but hypothermia is more likely in the operating room and is to be avoided. Exposure and evaporative fluid loss necessitate maintenance of the operating room temperature between 28° and 32°C , use of countercurrent fluid and blood warming devices, surface heating with forced dry, warm air, and humidified inspired gases. Blood loss can be controlled by restricting the escharotomy to 15–20% of TBSA, use of extremity tourniquets, applying dilute epinephrine solution topically (1:10,000) or by injection (0.5 mg per 1000 ml), and using compression bandages. Epinephrine doses of up to 6.7 mg topically or 0.8 mg by injection into the surgical area are well tolerated³⁰⁰; the affinity of β -adrenergic receptors to ligands is decreased after burns. The administration of a large amount of blood and blood products subjects the patient to complications of transfusion such as coagulopathy. Although citrate-induced hypocalcemia is a relatively rare complication of transfusion,³⁰¹ monitoring of Ca^{2+} and administration of calcium chloride ($2.5\text{--}5.0\text{ mg} \cdot \text{kg}^{-1}$) or gluconate ($7.5\text{--}10.0\text{ mg} \cdot \text{kg}^{-1}$) should be considered when blood products are administered rapidly. A preliminary report demonstrated that reconstituted whole blood minimizes coagulation abnormalities and septic and pulmonary complications in pediatric burn patients.³⁰² Transfusion-related coagulopathy is less common now than formerly because of the measures we have described to reduce blood loss and because lower hematocrit levels are now accepted.²⁰⁶

The multiple pathophysiologic changes that occur with burns, such as shock, hyperdynamic circulation, decreased serum albumin concentration, increased α_1 -acid glycoprotein concentration, and altered receptor sensitivity, alter the response to various drugs during the resuscitative and convalescent phases.^{206,216} As in hypovolemic trauma patients, the doses of iv anesthetics should be reduced during the resuscitation phase to prevent excessive hemodynamic depression. Anesthesia should be maintained with opioid or inhalational agents as the hemodynamic status of the patient permits. However, burn patients have excruciating pain and exceedingly high opioid requirements. A proven anesthetic regimen for excision and grafting of burns is isoflurane plus large doses of opioid. The response to depolarizing and nondepolarizing muscle relaxants remains unaltered during the first 24 hours after burn injury. However, after the first day, succinylcholine should be avoided for at least 1 year because it can result in a potentially lethal increase of serum K^+ when the burn size exceeds 10% of TBSA. Resistance develops to all nondepolarizing muscle relaxants in patients with burns of >30% TBSA starting approximately 1 week and peaking 5–6 weeks after injury. Pharmacodynamic causes, such as an increased number of acetylcholine receptors in the neuromuscular junction, may be responsible, but the exact mechanism is not known.^{206,216}

Ketamine is a commonly used anesthetic for serial wound débridements during the convalescent phase. It allows adequate spontaneous ventilation at a surgical plane of anesthesia, does not depress hemodynamics, and produces excellent analgesia. However, patients often experience dysphoric reactions with ketamine. Participation of an anesthesiologist using more common drugs and techniques is a safe and effective alternative.²⁰⁶

Management of Intraoperative Complications

Persistent Hypotension

Persistent hypotension is usually the result of one of four mechanisms in the trauma setting: bleeding, tension pneumothorax, neurogenic shock, and cardiac injury. Although many other causes, such as citrate intoxication (hypocalcemia), hypothermia, coronary artery disease, allergic reactions, or incompatible transfusion, can be responsible for this complication, they occur less frequently.

Hypotension due to bleeding is most likely. The source may be obvious, such as external bleeding from the skull or an open vessel in the extremities, or occult. The thoracic and abdominal cavities and the pelvic retroperitoneal space are the most common sites of occult hemorrhage that results in hypotension. Management includes early diagnosis and control of the bleeding site plus effective fluid resuscitation. The latter can best be accomplished using an infusion system with large-diameter tubing (5 mm) and a countercurrent heat exchanger, such as the Level 1 system (Level 1 Technologies, Inc., Marshfield, MA). Up to $1000\text{ ml} \cdot \text{min}^{-1}$ of crystalloid solution or $600\text{ ml} \cdot \text{min}^{-1}$ of packed cells can be given if a box-type pressure pump and a large-bore iv cannula are used.³⁰³ The system should be connected to 14-gauge or larger cannulae, preferably inserted into veins both above and below the diaphragm. If a pulmonary artery catheter introducer is used, the tubing should be connected directly to the hub because the flow rate from its side port is equal to that of a 16-gauge catheter. The rapid infuser system (Haemonetics, Braintree, MA), which consists of a reservoir, countercurrent heating system, and roller pump, is capable of delivering up to $1600\text{ ml} \cdot \text{min}^{-1}$ of warm fluids once the rate of infusion is programmed. Although a more powerful system than the Level 1, it is more costly, difficult to assemble, and infrequently necessary in the trauma patient.

Lactated Ringer's solution is the crystalloid of choice in most centers. However, it is slightly hypotonic ($273\text{ mOsm} \cdot \text{l}^{-1}$), acidic ($\text{pH} 5.1$), and contains a small amount of Ca^{2+} , which may counteract the citrate anticoagulant in packed red blood cells (PRBC). Normal saline does not cause this problem, but, as mentioned, its infusion in large quantities may result in hyperchloremic acidosis. Both Plasma-lyte A and Normosol-R have the advantages of a pH of 7.4, no Ca^{2+} , and a normal osmolarity (295 mOsm). Because of their prolonged intravascular retention and decreased tendency to produce edema, colloid solutions may be used in selected trauma patients such as those with head injury and those in whom edema develops due to inflammatory reactions or prior administration of large amounts of crystalloids. However, consistent evidence for the benefit of colloids over crystalloids is lacking.³⁰⁴ Human serum albumin (5 and 25%) and hydroxyethyl starch are the most commonly used solutions. Hydroxyethyl starch may produce coagulation abnormalities primarily by reducing the levels of fibrinogen, factor VIII, and von Willebrand's factor, and by reducing platelet function. This is especially important in head-injured patients in whom fatal intracranial hemorrhage may develop.³⁰⁵ The recommended safe dose of

this agent as a component of therapy for surgical blood loss is $20 \text{ ml} \cdot \text{kg}^{-1}$, although a review suggests that there is little support for this recommendation.³⁰⁵

Ideally, transfusion of hemorrhaging trauma patients should be done with whole blood so that depletion of the patient's coagulation factors can be prevented. Even labile factors (V and VIII) rarely decrease below a critical 20–30% level as long as whole blood is administered.²⁵⁸ However, of the 8 million units of blood administered annually in the United States, only 3% are provided as whole blood. Practically speaking, therefore, PRBC is the only preparation that is available for trauma resuscitation in this country (see also [Chapter 10](#)).

Inconvenience, safety, and cost factors associated with transfusion therapy prompted the development of artificial oxygen-carrying solutions. Various hemoglobin solutions and new-generation perfluorochemicals are in the advanced stage of human research. In a preliminary study, modified human polymerized hemoglobin was administered to 44 trauma patients and judged safe and effective as an oxygen-carrying solution.³⁰⁶ Despite a reduction in red cell mass, tissue oxygenation was maintained by the plasma hemoglobin. Nevertheless, systemic hypertension, as a result of endothelial nitric oxide binding, and pancreatitis may occur after administration of hemoglobin solutions.

Hypotension due to tension pneumothorax continues and frequently leads to fatality unless this complication is diagnosed and treated rapidly.
