

Clinical Anesthesia 4th edition (January 2001): by MD Paul G. Barash (Editor), MD Bruce F. Cullen (Editor), MD Robert K. Stoelting (Editor) By Lippincott Williams & Wilkins Publishers

By OkDoKeY

Clinical Anesthesia

CONTENTS

[Editors](#)

[Preface](#)

[Contributing Authors](#)

[Dedication](#)

I INTRODUCTION TO ANESTHESIA PRACTICE

[Chapter 1. The History of Anesthesiology](#)
Judith A. Toski, Douglas R. Bacon, and Rod K. Calverley

[Chapter 2. Practice Management](#)
George Mychaskiw II and John H. Eichhorn

[Chapter 3. Experimental Design and Statistics](#)
Nathan Leon Pace

[Chapter 4. Hazards of Working in the Operating Room](#)
Arnold J. Berry and Jonathan D. Katz

[Chapter 5. Professional Liability, Risk Management, and Quality Improvement](#)
Karen L. Posner, Frederick W. Cheney, and Donald A. Kroll

[Chapter 6. Value-Based Anesthesia Practice, Resource Utilization, and Operating Room Management](#)
Kenneth J. Tuman and Anthony D. Ivankovich

II BASIC PRINCIPLES OF ANESTHESIA PRACTICE

[Chapter 7. Cellular and Molecular Mechanics of Anesthesia](#)
Alex S. Evers

[Chapter 8. Electrical Safety](#)
Jan Ehrenwerth

[Chapter 9. Acid-Base, Fluids, and Electrolytes](#)
Donald S. Prough and Mali Mathru

[Chapter 10. Hemotherapy and Hemostasis](#)
Charise T. Petrovitch and John C. Drummond

III BASIC PRINCIPLES OF PHARMACOLOGY IN ANESTHESIA PRACTICE

[Chapter 11. Basic Principles of Clinical Pharmacology](#)
Robert J. Hudson

[Chapter 12. Autonomic Nervous System: Physiology and Pharmacology](#)
Noel W. Lawson and Joel O. Johnson

[Chapter 13. Nonopioid Intravenous Anesthesia](#)
Jen W. Chiu and Paul F. White

[Chapter 14. Opioids](#)
Barbara A. Coda

[Chapter 15. Inhalation Anesthesia](#)
Thomas J. Ebert and Phillip G. Schmid III

[Chapter 16. Muscle Relaxants](#)
David R. Bevan and François Donati

[Chapter 17. Local Anesthetics](#)
Spencer S. Liu and Peter S. Hodgson

IV PREPARING FOR ANESTHESIA

[Chapter 18. Preoperative Evaluation](#)
Lee A. Fleisher

[Chapter 19. Anesthesia for Patients with Rare and Coexisting Diseases](#)
Stephen F. Dierdorf

[Chapter 20. Malignant Hyperthermia and Other Pharmacogenetic Disorders](#)
Henry Rosenberg, Jeffrey E. Fletcher, and Barbara W. Brandom

[Chapter 21. Preoperative Medication](#)
John R. Moyers and Carla M. Vincent

[Chapter 22. Delivery Systems for Inhaled Anesthetics](#)
J. Jeffrey Andrews and Russell C. Brockwell

[Chapter 23. Airway Management](#)
William H. Rosenblatt

[Chapter 24. Patient Positioning](#)
Mark A. Warner and John T. Martin

[Chapter 25. Monitoring the Anesthetized Patient](#)
Glenn S. Murphy and Jeffrey S. Vender

V MANAGEMENT OF ANESTHESIA

[Chapter 26. Epidural and Spinal Anesthesia](#)
Christopher M. Bernards

[Chapter 27. Peripheral Nerve Blockade](#)
Michael F. Mulroy

[Chapter 28. Anesthesia for Neurosurgery](#)

Audrée A. Bendo, Ira S. Kass, John Hartung, and James E. Cottrell

[Chapter 29. Respiratory Function in Anesthesia](#)

M. Christine Stock

[Chapter 30. Anesthesia for Thoracic Surgery](#)

James B. Eisenkraft, Edmond Cohen, and Steven M. Neustein

[Chapter 31. Cardiovascular Anatomy and Physiology](#)

Carol L. Lake

[Chapter 32. Anesthesia for Cardiac Surgery](#)

Serle K. Levin, W. Chase Boyd, Peter T. Rothstein, and Stephen J. Thomas

[Chapter 33. Anesthesia for Vascular Surgery](#)

John E. Ellis, Michael F. Roizen, Srinivas Mantha, Gary Tzeng, and Tina Desai

[Chapter 34. Anesthesia and the Eye](#)

Kathryn E. McGoldrick

[Chapter 35. Anesthesia for Otolaryngologic Surgery](#)

Alexander W. Gotta, Lynne R. Ferrari, and Colleen A. Sullivan

[Chapter 36. The Renal System and Anesthesia for Urologic Surgery](#)

Terri G. Monk and B. Craig Weldon

[Chapter 37. Anesthesia and Obesity and Gastrointestinal Disorders](#)

F. Peter Buckley and Kenneth Martay

[Chapter 38. Anesthesia for Minimally Invasive Procedures](#)

Anthony J. Cunningham and Noreen Dowd

[Chapter 39. Anesthesia and the Liver](#)

Phillip S. Mushlin and Simon Gelman

[Chapter 40. Anesthesia for Orthopaedic Surgery](#)

Terese T. Horlocker and Denise J. Wedel

[Chapter 41. Anesthesia and the Endocrine System](#)

Jeffrey J. Schwartz, Stanley H. Rosenbaum, and George J. Graf

[Chapter 42. Obstetric Anesthesia](#)

Alan C. Santos, David A. O'Gorman, and Mieczyslaw Finster

[Chapter 43. Neonatal Anesthesia](#)

Frederic A. Berry and Barbara A. Castro

[Chapter 44. Pediatric Anesthesia](#)

Joseph P. Cravero and Linda Jo Rice

[Chapter 45. Anesthesia for the Geriatric Patient](#)

Stanley Muravchick

[Chapter 46. Anesthesia for Ambulatory Surgery](#)

J. Lance Lichtor

[Chapter 47. Monitored Anesthesia Care](#)

Simon C. Hillier

[Chapter 48. Trauma and Burns](#)

Levon M. Capan and Sanford M. Miller

[Chapter 49. The Allergic Response](#)

Jerrold H. Levy

[Chapter 50. Drug Interactions](#)

Carl Rosow

[Chapter 51. Anesthesia Provided at Alternative Sites](#)

Charles E. Laurito

[Chapter 52. Anesthesia for Organ Transplantation](#)

Leonard L. Firestone and Susan Firestone

VI POST ANESTHESIA AND CONSULTANT PRACTICE

[Chapter 53. Postoperative Recovery](#)

Roger S. Mecca

[Chapter 54. Management of Acute Postoperative Pain](#)

Timothy R. Lubenow, Anthony D. Ivankovich, and Robert J. McCarthy

[Chapter 55. Chronic Pain Management](#)

Stephen E. Abram and Christian R. Schlicht

[Chapter 56. ICU: Critical Care](#)

Morris Brown

[Chapter 57. Cardiopulmonary Resuscitation](#)

Charles W. Otto

[APPENDIX: Electrocardiography](#)

James R. Zaidan and Paul G. Barash

PREFACE

The twelve years since the publication of the first edition of *Clinical Anesthesia* have witnessed some of the most significant advances our specialty has ever seen. In 1989, the term “managed care” was a new phrase in the health-care lexicon. In contrast, both the medical *and* economic considerations now play an important role in the care of all patients. The mortality rate from all anesthetic causes has plummeted, and operating rooms are now considered among the safest sites in the hospital. Anesthesiologists are pioneers in maintaining a safe environment for our patients, and the techniques we have used are now being emulated and adopted by initiatives from the federal government and other medical specialties. In addition, anesthesiologists are now “perioperative physicians” supervising care in a variety of locations from preoperative evaluation clinics, to intensive care units and pain clinics, and to operating room sites as varied as the cardiac OR and a physician’s office. Finally, both critical care and pain are now recognized subspecialties of anesthesiology, pediatric anesthesia is now recognized for fellowship status, and certification can be achieved for transesophageal echocardiography.

It is with this background of vast change that we have undertaken the editorial process for the fourth edition of *Clinical Anesthesia*. New paradigms for OR management and cost containment are highlighted. Our safety and that of our patients is extensively reviewed with particular emphasis on latex allergy. Recent developments are enhancing our understanding of the mechanism of action of anesthetics, and this research has important implications for the creation of new anesthetic agents. The preanesthetic clinic is becoming a major focus of activity, since it serves as an important gateway to the OR. Efficient, medically appropriate, and cost-effective care is covered extensively. With the rapid proliferation of new drugs, publicity about medical errors related to drug administration, and public concern about herbal preparations, the addition of an entirely new chapter on drug interactions and anesthesia is timely. Newer monitoring techniques, including transesophageal echocardiography and transcranial Doppler, are discussed in several chapters including those on neuroanesthesia, cardiac anesthesia, and monitoring. Minimally invasive surgery presents challenges to the anesthesiologist and enhances our ability to contribute significantly to the care of the patient. Here again, in addition to a chapter specifically focused on minimally invasive surgical procedures, a number of contributors have emphasized the critical issues for patient management in their individual chapters. With an increasing number of patients in the geriatric age group, even relatively noncomplex surgical procedures pose a significant anesthetic challenge. The geriatrics chapter has been considerably revised to reflect this concern. As trauma continues to be a leading cause of mortality and morbidity in the United States, the updated chapter on anesthesia for trauma provides an excellent review of the many new methods for treatment of trauma patients. The extensive use of conscious sedation protocols not only in the OR but throughout the hospital has placed the anesthesiologist in a leadership role for our peers. The relevant chapter serves to prepare us to enter these discussions with a broad base of information. Recently, no area in anesthesiology has garnered more attention and controversy than office-based anesthesia. The complexities of administering an anesthetic in this environment are reviewed by national leaders in this field. In addition to these subjects, each of the other chapters has been extensively revised for the current edition, with emphasis on up-to-date information and relevance to contemporary anesthetic clinical care.

The hallmark of *Clinical Anesthesia* is the presentation of concepts in a crisp and clinically useful manner. Clinical options are prioritized by the contributors, each of whom is a recognized expert within the scope of his/her chapter. As editors, we have eliminated duplication among chapters and have presented an integrated approach to the specialty of anesthesiology. On occasion, however, redundancy and even disagreement in approaches to patient management have been kept because they also reflect the realities of the practice of anesthesiology.

We hope that you, the reader, will benefit from this new edition, and we trust that it will improve your understanding of the field and your clinical care of patients. We welcome your comments and suggestions as to how we may continue to make *Clinical Anesthesia*—and its companion handbook, review book, and CD-ROM—as useful as possible to clinicians, residents, and students.

Finally, we wish to express our gratitude to the individual contributors whose hard work and dedication expedited the development and production of this edition. We also acknowledge the support of our administrative assistants, Gail Norup, Karen Rutherford, and Deanna Walker, each of whom gave unselfishly of her time to facilitate the editorial process. Thanks to our colleagues at Lippincott Williams & Wilkins who continually demonstrate their commitment to excellence in medical publishing: Craig Percy, Executive Editor; Tanya Lazar, Developmental Editor; Andrea Allison-Williams, Administrative Assistant; and Mary McDonald and Peggy Gordon at P.M. Gordon Associates for making the final stages of production a joy.

The sixteenth of October 1846 marked the start of a silent revolution in medicine. William T. G. Morton provided anesthesia to a patient named Edward Gilbert Abbott, administering diethyl ether prior to the surgical removal of a vascular lesion from the side of Mr. Abbott's neck. The pain that this patient would otherwise have suffered was thus laid mute. October 16, 1846, has obvious importance to historians of medicine, but it is also pertinent to anesthesia providers. It is the inauguration of a specialty that is driven to relieve pain. In the operating room, battlefield, delivery suite, and pain clinic, countless patients have benefited from the attentions of the anesthesia care team whose members trace their origins to this momentous event. A firm understanding of the historical aspects of the development of anesthetic technique and technology—and an appreciation for the diverse personalities involved in the evolution of anesthesiology as a specialty—reveals that the practice of relieving pain is more than a technical skill. It is an art.

THE EARLY HISTORY OF ANESTHESIOLOGY

“Prehistory”

Pain control during surgery was not always as centrally important as it is today. The Roman writer Celsus encouraged “pitilessness” as an essential characteristic of the surgeon, an attitude that prevailed for centuries. Although some surgeons confessed that they found elements of their work intensely disturbing, most became inured to their patients' agony. Medical students emulated their teachers, usually omitting any appraisal of the patient's distress while taking notes of the operations that they witnessed. Even the authors of leading surgical texts often ignored surgical pain as a topic of discussion. Just before the advent of anesthesia, Robert Liston's 1842 edition of *Elements of Surgery* contained detailed descriptions of elective and emergency procedures on the extremities, head and neck, breast, and genitals, but neglected a significant discussion of any form of analgesia. In Liston's time, as in the countless ages before, pain was considered primarily a symptom of importance.¹

Prior to the introduction of anesthesia with diethyl ether, many surgeons like Liston held that pain was, and would always be, an inevitable consequence of surgery. Despite this sentiment, many different agents were used to achieve anesthesia. Dioscorides, a physician from the first century A.D., commented upon mandragora, a drug prepared from the bark and leaves of the mandrake plant. He stated that the plant substance could be boiled in wine and strained, and used “in the case of persons . . . about to be cut or cauterized, when they wish to produce anesthesia.”² Mandragora was still being used to anesthetize patients as late as the 17th century.

From the 9th to the 13th centuries, the soporific sponge was a dominant mode of providing pain relief during surgery. Mandrake leaves, along with black nightshade, poppies, and other herbs, were boiled together and cooked onto a sponge. The sponge was then reconstituted in hot water, and placed under the patient's nose prior to surgery. Prepared as indicated by published reports of the time, the sponge generally contained morphine and scopolamine in varying amounts—drugs used in modern anesthesia.³ In addition to using the “sleeping sponge,” Europeans attempted to relieve pain by hypnosis, by the ingestion of alcohol, herbs, and extracts of botanical preparations, and by the topical application of pressure or ice.

In the 11th century, the anesthetic effects of cold water and ice were being discovered. In the middle of the 17th century, Marco Aurelio Severino described “refrigeration anesthesia”; placing snow in parallel lines across the incisional plane, he was able to render a surgical site insensate within minutes. The technique never became popular, probably because of the challenge of maintaining stores of snow year-round.⁴

Diethyl ether had been known for centuries prior to its first public use in surgical anesthesia. It may have been compounded first by an 8th-century Arabian philosopher Jabir ibn Hayyam, or possibly by Raymond Lully, a 13th-century European alchemist. But diethyl ether was certainly known in the 16th century, both to Valerius Cordus and Paracelsus, who prepared it by distilling sulfuric acid (oil of vitriol) with fortified wine to produce an *oleum vitrioli dulce* (sweet oil of vitriol). Paracelsus (1493–1541) observed that it caused chickens to fall asleep and awaken unharmed. He must have been aware of its analgesic qualities, because he reported that it could be recommended for use in painful illnesses. There is, however, no record that his suggestion was followed.

For three centuries thereafter, this simple compound remained a therapeutic agent with only occasional use. Some of its properties were examined by distinguished British scientists, including Robert Boyle, Isaac Newton, and Michael Faraday, but without sustained interest. Its only routine application came as an inexpensive recreational drug among the poor of Britain and Ireland, who sometimes drank an ounce or two of ether when taxes made gin prohibitively expensive. An American variation of this practice was conducted by groups of students who held ether-soaked towels to their faces at nocturnal “ether frolics.”

Like ether, nitrous oxide was known for its ability to induce lightheadedness and was often inhaled by those seeking a thrill. It was not used as frequently as was ether because it was more complex to prepare and awkward to store. It was produced by heating ammonium nitrate in the presence of iron filings. The evolved gas was passed through water to eliminate toxic oxides of nitrogen before being stored. Nitrous oxide was first prepared in 1773 by Joseph Priestley, an English clergyman and scientist, who ranks among the great pioneers of chemistry. During his years of study, Priestley prepared and examined several gases, including nitrous oxide, ammonia, sulfur dioxide, oxygen, carbon monoxide, and carbon dioxide.

At the end of the 18th century in England, there was a strong interest in the supposed salubrious effects of mineral waters and healthful gases. This led to the development of spas, which were sought out by people of society. Particular waters and gases were believed to prevent and treat disease. A dedicated interest in the potential use of gases as remedies for scurvy, tuberculosis, and other diseases led Thomas Beddoes to open his Pneumatic Institute close to the small spa of Hotwells,

in the city of Bristol, where he hired Humphry Davy in 1798 to conduct research projects.

Humphry Davy (1778–1829) was a young man of ability and drive. He performed a brilliant series of investigations of several gases but focused much of his attention on nitrous oxide, which he and his associates inhaled through face masks designed for the Institute by James Watt, the distinguished inventor of the steam engine. Davy used this equipment to measure the rate of uptake of nitrous oxide and its effect on respiration and other central nervous system actions. These results were combined with research on the physical properties of the gas in *Nitrous Oxide*, a 580-page book published in 1800. This impressive treatise is now best remembered for a few incidental observations: Davy's comments that nitrous oxide transiently relieved a severe headache, obliterated a minor headache, and briefly quenched an aggravating toothache. The most frequently quoted passage was a casual entry: "As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place."⁵ Although Davy did not pursue this prophecy, perhaps because he was set on a career in basic research, he did coin the persisting sobriquet for nitrous oxide, "laughing gas."

Another lost opportunity to discover anesthesia occurred two decades before the demonstration of ether in Boston. An English physician searched intentionally in 1823 and 1824 for an inhaled anesthetic to relieve the pain of surgery. Henry Hill Hickman might have succeeded if he had used nitrous oxide or ether, but the mice and dogs he studied inhaled high concentrations of carbon dioxide. Carbon dioxide has some anesthetic properties, as shown by the absence of response to an incision in the animals of Hickman's study, but it is not an appropriate clinical anesthetic. Hickman's concept was magnificent; his choice of agent, regrettable. This seminal work was ignored both by surgeons and by the scientists of the Royal Society.

Almost Discovery: Clarke, Long, and Wells

William E. Clarke may have given the first ether anesthetic in Rochester, New York, in January 1842. From techniques learned as a chemistry student in 1839, Clarke entertained his companions with nitrous oxide and ether. Lyman reported that "Clarke diligently propagated this convivial method among his fellow students. Emboldened by these experiences, in January 1842, having returned to Rochester, he administered ether, from a towel, to a young woman named Hobbie, and one of her teeth was then extracted without pain by a dentist named Elijah Pope."⁶ A second indirect reference to Clarke's anesthetic suggested that it was believed that her unconsciousness was due to hysteria. Clarke was advised to conduct no further anesthetic experiments.⁷

There is no doubt that two months later, on March 30, 1842, Crawford Williamson Long (1815–1878) administered ether with a towel for surgical anesthesia in Jefferson, Georgia. His patient, James M. Venable, was a young man who was already familiar with ether's exhilarating effects, for he reported in a certificate that he had previously inhaled it frequently and was fond of its use. Venable had two small tumors on his neck but refused to have them excised because he dreaded the cut of the knife. Knowing that Venable was familiar with ether's action, Dr. Long proposed that ether might alleviate pain and gained his patient's consent to proceed. After inhaling ether from the towel, Venable reported that he was unaware of the removal of the tumor.⁸ In determining the first fee for anesthesia and surgery, Long settled on a charge of \$2.00.

As a rural physician with a very limited surgical practice, Crawford Long had few opportunities to give ether anesthesia, but he did conduct the first comparative trial of an anesthetic. He wished to prove that insensibility to pain was caused by ether and was not simply a reflection of the individual's pain threshold or the result of self-hypnosis. When ether was withheld during amputation of the second of two toes, his patient reported great pain and strenuously proclaimed a preference for ether.

For Long to gain an unrivaled position as the discoverer of anesthesia, all that remained was for him to present his historic work in the medical literature. Long, however, remained silent until 1849, when ether anesthesia was already well known. He explained that he practiced in an isolated environment and had few opportunities for surgical or dental procedures. From our perspective it is difficult to understand why he was so reluctant to publish. This remarkable man might have changed the course of the history of medicine, but, because of his failure to publish, the public introduction of anesthesia was achieved by more assured and bolder persons.

In contrast to the limited opportunities for surgery presented to rural practitioners in the mid-19th century, urban dentists regularly met patients who refused restorative treatment for fear of the pain inflicted by the procedure. From a dentist's perspective, pain was not so much life-threatening as it was livelihood-threatening. A few dentists searched for new techniques of effective pain relief. Pasteur's yet-to-be-delivered aphorism, that chance only favors the prepared mind, would have provided an apt description of one of these men, Horace Wells (1815–1848), of Hartford, Connecticut. Wells recognized what others had ignored, the analgesic potential of nitrous oxide.

Horace Wells' great moment of discovery came on December 10, 1844, when he attended a lecture-exhibition by an itinerant "scientist," Gardner Quincy Colton, who prepared nitrous oxide and encouraged members of the audience to inhale the gas. Wells observed that a young man, Samuel Cooley (later, Colonel Cooley of the Connecticut militia), was unaware that he had injured his leg while under the influence of nitrous oxide. Sensing that nitrous oxide might also relieve the pain of dental procedures, Wells contacted Colton and boldly proposed an experiment in which Wells was to be the subject. The following day, Colton gave Wells nitrous oxide before a fellow dentist, William Riggs, extracted a tooth.⁹ When Wells awoke, he declared that he had not felt any pain and termed the experiment a success. Colton taught Wells to prepare nitrous oxide, which the dentist administered with success in his practice. His apparatus probably resembled that used by Colton. The patient placed a wooden tube in his mouth through which he rebreathed nitrous oxide from a small bag filled with the gas.

A few weeks later, in January 1845, Wells attempted a public demonstration in Boston at the Harvard Medical School. He had planned to anesthetize a patient for an amputation, but, when the patient refused surgery, a dental anesthetic for a medical student was substituted. Wells, perhaps influenced by a large and openly critical audience, began the extraction without an adequate level of anesthesia, and the trial was judged a failure.

The exact circumstances of Wells' lack of success are not known. His less than enthusiastic patient may have refused to breathe the anesthetic. Alternatively, Wells might have lost part of his small supply of nitrous oxide, which might have happened if the patient involuntarily removed his lips from the mouthpiece or if his nostrils were not held shut. It might have been that Wells did not know that nitrous oxide lacks sufficient potency to serve predictably as an anesthetic without supplementation. In any event, the student cried out, and Wells was jeered by his audience. No one offered Wells even conditional encouragement or recognized that, even though Wells' presentation had been flawed, nitrous oxide might become a valuable therapeutic advance.

The disappointment disturbed Wells deeply, and, although he continued to use nitrous oxide in his dental practice for some time, his life became unsettled. While profoundly distressed, Wells committed suicide in 1848. Wells was an important pioneer of anesthesia, for he was the first person to recognize the anesthetic qualities of nitrous oxide, the only 19th-century drug still in routine use.

W. T. G. Morton and October 16, 1846

A second New Englander, William Thomas Green Morton (1819–1868), briefly shared a dental practice with Horace Wells in Hartford. Wells' daybook shows that he gave Morton a course of instruction in anesthesia, but Morton apparently moved to Boston without paying for his lessons. In Boston, Morton continued his interest in anesthesia and, after learning from Charles Jackson that ether dropped on the skin provided analgesia, began experiments with inhaled ether. The diethyl ether that Morton used would prove to be much more versatile than nitrous oxide.

Before the invention of the hollow needle and an awareness of aseptic technique, the only class of potential anesthetics that could offer a prompt, profound, and temporary action were the inhaled drugs. Of the available drugs, ether was a superb first choice. Bottles of liquid ether were easily transported, and the volatility of the drug permitted effective inhalation. The concentrations required for surgical anesthesia were so low that patients did not become hypoxic when breathing air. It also possessed what would later be recognized as a unique property among all inhaled anesthetics: the quality of providing surgical anesthesia without causing respiratory or cardiovascular depression. These properties, combined with a slow rate of induction, gave the patient a great margin of safety when physicians were attempting to master the new art of administering an inhaled anesthetic.¹⁰

After anesthetizing a pet dog, Morton became confident of his skills and anesthetized patients in his dental office. Encouraged by that success, Morton gained an invitation to give a public demonstration in the Bullfinch amphitheater of the Massachusetts General Hospital. William Morton's demonstration of ether caught the world's attention in part because it took place in a public arena, the surgical amphitheater of a public institution, the Massachusetts General Hospital. Surgical amphitheatres, and the charitable hospitals of which they were a part, were then a relatively recent addition to American medical teaching.

On Friday, October 16, 1846, William T. Morton secured permission to provide an anesthetic to Edward Gilbert Abbott before the surgeon, John Collins Warren, excised a vascular lesion from the left side of Abbott's neck. Morton was late in arriving, so Warren was at the point of proceeding when Morton entered. The dentist had been obliged to wait for an instrument-maker to complete his inhaler (Fig. 1-1). It consisted of a large glass bulb containing a sponge soaked with colored ether and a spout, which was to be placed in the patient's mouth. An opening on the opposite side of the bulb allowed air to enter and to be drawn over the ether-soaked sponge with each breath.

Figure 1-1. Morton's ether inhaler (1846)

The conversations of that morning were not accurately recorded; however, popular accounts state that the surgeon responded testily to Morton's apology for his tardy arrival by remarking, "Sir, your patient is ready." Morton directed his attention to his patient and first conducted a very abbreviated preoperative evaluation. He inquired, "Are you afraid?" Abbott responded that he was not and took the inhaler in his mouth. After a few minutes, Morton is said to have turned to the surgeon to respond, "Sir, your patient is ready." Gilbert Abbott later reported that he was aware of the surgery but had experienced no pain. At the moment that the procedure ended, Warren turned to his audience and announced, "Gentlemen, this is no humbug."¹¹ Oliver Wendell Holmes soon suggested the term *anaesthesia* to describe this state of temporary insensibility.

What would be recognized as America's greatest contribution to 19th-century medicine had been realized, but the immediate prospect was clouded by subterfuge and argument. Some weeks passed before Morton admitted that the active component of the colored fluid, which he had called "Letheon," was the familiar drug, diethyl ether. Morton, Wells, Jackson, and their supporters soon became caught up in a contentious, protracted, and fruitless debate over priority for the discovery, popularly termed "the ether controversy." In short, Morton had applied for a patent for Letheon, and when it was granted, tried to receive royalties for the use of ether as an anesthetic. Eventually, the matter came before the U.S. Congress where the House of Representatives voted to grant Morton a large sum of money for the discovery; however, the Senate quashed the deal.

When the details of Morton's anesthetic technique became public knowledge, the information was transmitted by train, stagecoach, and coastal vessels to other North American cities, and by ship to the world. Anesthetics were performed in Britain, France, Russia, South Africa, Australia, and other countries almost as soon as surgeons heard the welcome news of the extraordinary discovery. Even though surgery could now be performed with "pain put to sleep," the frequency of operations did not rise rapidly. Several years would pass before anesthesia was even universally recommended.

A "Blessing" to Obstetrics

James Young Simpson, a successful obstetrician of Edinburgh, Scotland, had been among the first to use ether for the relief of the pain of labor. He became dissatisfied with ether and sought a more pleasant, rapid-acting anesthetic. He and his junior associates conducted a bold search for a new inhaled anesthetic by inhaling samples of several volatile chemicals collected for Simpson by British apothecaries. David Waldie suggested chloroform, which had first been prepared in 1831. Simpson and his friends inhaled it at a dinner party in Simpson's home on the evening of November 4, 1847. They promptly fell unconscious. They awoke delighted at their success. Simpson quickly set about encouraging the use of chloroform. Within 2 weeks, he had dispatched his first account of its use to *The Lancet*. Although Simpson introduced chloroform with celerity, boldness, and enthusiasm and was later to become a vocal defender of the use of anesthesia for women in labor, he gave few anesthetics himself. His goal was simply to improve a patient's comfort during his operative or obstetric activities.

The relief of obstetrical pain had significant social ramifications, particularly in the 19th century, and made anesthesia during delivery a controversial subject. Simpson himself argued against the prevailing view that relieving the pain of childbirth was contrary to God's will. The pain of the parturient was perceived as both a component of punishment, and a means of atonement for Original Sin. Less than a year after administering the first anesthesia during childbirth, Simpson addressed these concerns in a pamphlet entitled "Answers to the Religious Objections Advanced Against the Employment of Anaesthetic Agents in Midwifery and Surgery and Obstetrics." In this work, Simpson recognized the Book of Genesis as being the root of this sentiment, and noted that God promised to relieve the descendants of Adam and Eve of the curse. Additionally, Simpson asserted that labor pain is a result of scientific and anatomic causes, and not the result of religious condemnation. He stated that the upright position humans assumed necessitated strong pelvic muscles to support the abdominal contents. As a result, he argued, the uterus necessarily developed strong musculature—with such great contractile power that it caused pain—to overcome the resistance of the pelvic floor.¹²

The response to Simpson's assertions was variable. While he was criticized for these ideas by fellow physician Samuel Ashwell in an editorial published in *The Lancet*, many other physicians commented favorably, including some who had opposed obstetric anesthesia for medical reasons. All in all, Simpson's pamphlet probably did not have much impact in terms of changing the prevailing viewpoints about pain control during labor, but he did articulate many concepts that his contemporaries were debating at the time.¹³ But it was John Snow (1813–1858), an English contemporary of the Scottish Simpson, who achieved fame as an obstetric anesthetist by treating Queen Victoria.

Queen Victoria's consort, Prince Albert, interviewed John Snow before he was called to Buckingham Palace, at the request of the Queen's obstetrician, to give chloroform for the Queen's last two deliveries. During the monarch's labor, Snow gave analgesic doses of chloroform on a folded handkerchief, a technique that was soon termed *chloroform à la reine*. Victoria abhorred the pain of labor and enjoyed the relief that chloroform provided. She wrote in her journal, "Dr. Snow gave that blessed chloroform and the effect was soothing, quieting, and delightful beyond measure."¹⁴ After the Queen, as head of the Church of England, endorsed obstetric anesthesia, the religious debate over the appropriateness of the use of anesthesia in labor terminated abruptly. Four years later, Snow was to give a second anesthetic to the Queen, who was again determined to have chloroform. Snow's daybook states that by the time he arrived, Prince Albert had begun the anesthetic and had given his wife "a little chloroform." This may be the only time in history that a Queen had a Prince as her anesthetist. Both monarch and consort were fortunate that there was no complication of their anesthetic adventure.

John Snow: The First Anesthesiologist

John Snow ([Fig. 1-2](#)) was already a respected physician who had presented papers on physiologic subjects when the news of ether anesthesia reached England in December 1846. He took an interest in anesthetic practice and was soon invited to work with many of the leading surgeons of the day. He was not only facile at providing anesthesia but was also a remarkably keen observer. His innovative description of the stages or degrees of ether anesthesia based on the patient's responsiveness was not improved upon for 70 years.

Figure 1-2. John Snow, the first anesthesiologist.

In addition to developing a stronger understanding of aspects of anesthetic physiology, Snow also promoted the development of the anesthesia apparatus. He soon realized the inadequacies of ether inhalers into which the patient rebreathed through a mouthpiece. After practicing anesthesia for only 2 weeks, Snow designed the

first of his series of ingenious ether inhalers.¹⁵ His best-known apparatus featured unidirectional valves within a malleable, well-fitting mask of his own design, which closely resembles the form of a modern face mask (Fig. 1-3). The face piece was connected to the vaporizer (Fig. 1-4) by a breathing tube, which Snow deliberately designed to be wider than the human trachea so that even rapid respirations would not be impeded. A metal coil within the vaporizer ensured that the patient's inspired breath was drawn over a large surface area to promote the uptake of ether. The device also incorporated a warm water bath to maintain the volatility of the agent. Snow did not attempt to capitalize on his creativity; he closed his account of its preparation with the generous observation, "There is no restriction respecting the making of it."¹⁶

Figure 1-3. John Snow's face mask (1847). The expiratory valve can be tilted to the side to allow the patient to breathe air.

Figure 1-4. John Snow's ether inhaler (1847). The ether chamber (B) contained a spiral coil so that the air entering through the brass tube (D) was saturated by ether before ascending the flexible tube (F) to the face mask (G). The ether chamber rested in a bath of warm water (A).

The following year, John Snow introduced a chloroform inhaler; he had recognized the versatility of the new agent and came to prefer it in his practice. At the same time, he initiated what was to become an extraordinary series of experiments that were remarkable in both their scope and in the manner in which they anticipated sophisticated research performed a century later. Snow realized that successful anesthetics must not only abolish pain but also prevent movement. He anesthetized several species of animals with varying concentrations of ether and chloroform to determine the concentration required to prevent movement in response to a sharp stimulus. Despite the limitations of the technology of 1848, this element of his work anticipated the modern concept of minimum alveolar concentration (MAC).¹⁷ Snow assessed the anesthetic action of a large number of potential anesthetics, and, although he did not find any to rival chloroform or ether, he determined a relationship between solubility, vapor pressure, and anesthetic potency that was not fully appreciated until after World War II when Charles Suckling employed Snow's principles in creating halothane. He also fabricated an experimental closed-circuit device in which the subject (Snow himself) breathed oxygen while the exhaled carbon dioxide was absorbed by potassium hydroxide. Snow published two remarkable books, *On the Inhalation of the Vapour of Ether* (1847) and *On Chloroform and Other Anaesthetics* (1858), which was almost completed when he died of a stroke at the age of 45.

Snow's investigations were not confined to anesthesia. His memory is also respected by specialists in infectious and tropical diseases for his proof, through an epidemiologic study in 1854, that cholera was transmitted by water. At that time, before the development of microbiology by Louis Pasteur and Robert Koch, most physicians in North America and Europe attributed the mysterious recurring epidemics of cholera to the contagion of "fecalized air." For many years, however, Snow had believed that because the disease affected the gastrointestinal tract, the causative agent must be ingested rather than inhaled. In 1854, he found an opportunity to prove his thesis when cholera visited his section of London and caused the deaths of more than 500 people near his residence. Snow determined that the water supply for these persons had been the Broad Street pump. He prepared what would come to be appreciated as the first epidemiologic survey to prove his contention. With that information, he was able to encourage the parish authorities to remove the pump handle so that residents were obliged to find other sources of water. The prompt end of this already-resolving epidemic was attributed to his action.

Nineteenth-Century British Anesthesia—After John Snow

Throughout the second half of the 19th century, other compounds were examined for their anesthetic potential, but these random searches uniformly ended in failure. The pattern of fortuitous discovery that brought nitrous oxide, diethyl ether, and chloroform forward between 1844 and 1847 continued for decades. The next inhaled anesthetics to be used routinely, ethyl chloride and ethylene, were also discovered as a result of unexpected observations. Ethyl chloride and ethylene were first formulated in the 18th century, and had been examined as anesthetics in Germany soon after the discovery of ether's action; but they were ignored for decades. Ethyl chloride retained some use as a topical anesthetic and counterirritant. It was so volatile that the skin transiently "froze" after ethyl chloride was sprayed upon it. Its rediscovery as an anesthetic came in 1894, when a Swedish dentist sprayed ethyl chloride into a patient's mouth to "freeze" a dental abscess. Carlson was surprised to discover that his patient suddenly lost consciousness. Ethyl chloride became a commonly employed inhaled anesthetic in several countries.

Joseph Clover (1825–1882) became the leading anaesthetist* of London after the death of John Snow in 1858. Clover was a talented clinician and facile inventor, but he never performed research or wrote to the extent achieved by Snow. If he had written a text, he might be better remembered, but most physicians have little knowledge of Clover beyond identifying the familiar photograph in which he is seen anesthetizing a seated man while palpating his patient's pulse (Fig. 1-5).

Figure 1-5. Joseph Clover anesthetizing a patient with chloroform and air passing through a flexible tube from a Clover bag.

This photograph deserves our attention because it introduces important qualities of the man who maintained the advancement of anesthesia from 1860 until 1880. Clinicians now accept Clover's monitoring of the pulse as a simple routine of prudent practice, but in Clover's time this was a contentious issue. Prominent Scottish

surgeons scorned Clover's emphasis on the action of chloroform on the heart. Baron Lister and others preferred that senior medical students give anesthetics and urged them to "strictly carry out certain simple instructions, among which is that of never touching the pulse, in order that their attention may not be distracted from the respiration."¹⁸ Lister also counseled, "it appears that preliminary examination of the chest, often considered indispensable, is quite unnecessary, and more likely to induce the dreaded syncope, by alarming the patients, than to avert it."¹⁹ Little progress in anesthesia could come from such reactionary statements. In contrast, Clover had observed the effect of chloroform on animals and urged other anesthetists to monitor the pulse at all times and to discontinue the anesthetic temporarily if any irregularity or weakness was observed in the strength of the pulse. He earned a loyal following among London surgeons, who accepted him as a dedicated specialist.

Clover was the first anaesthetist to administer chloroform in known concentrations through the Clover bag. This unique device rests over his shoulder in [Figure 1-5](#). He obtained a 4.5% concentration of chloroform in air by pumping a measured volume of air with a bellows through a warmed evaporating vessel containing a known volume of liquid chloroform. The apparatus featured inspiratory and expiratory valves of ivory supported by springs. A flap valve in the face mask permitted the dilution of the anesthetic with air. In 1868, Clover reported no deaths among 1802 anesthetics using his device, but he later reviewed a later fatality in searching detail. He attributed the death to an unrecognized error in calculating the volume of air diluting the chloroform.²⁰ After 1870, Clover favored a nitrous oxide–ether sequence. The portable anesthesia machines that he designed were in popular use for decades after his death.

In addition to his work with anesthetic agents, Clover was very facile in managing the airway. He was the first Englishman to urge the now universal practice of thrusting the patient's jaw forward to overcome obstruction of the upper airway by the tongue. Despite the limitation of working before the first tracheal tube was used in anesthesia, Clover published a landmark case report in 1877. His patient had a tumor of the mouth that obstructed the airway completely, despite the jaw thrust maneuver, once the anesthetic was begun. Clover averted disaster by inserting a small curved cannula of his design through the cricothyroid membrane. He continued anesthesia *via* the cannula until the tumor was excised. Clover, the model of the prepared anesthesiologist, remarked, "I have never used the cannula before although it has been my companion at some thousands of anaesthetic cases."²¹

Every element of Clover's records and his published accounts reflect a consistent dedication to patient safety coupled with a prudent ability to anticipate potential difficulties and to prepare an effective response beforehand. In that way, his manner was very much like that of his successor, the first English anaesthetist to be knighted, Sir Frederick Hewitt.

Frederick Hewitt (1857–1916) gained the first of his London hospital anesthesia appointments in 1884. He earned a reputation as a superb and inventive clinician and came to be considered the leading British practitioner of the next 30 years. Hewitt engineered modifications of portable ether and nitrous oxide inhalers and, recognizing that nitrous oxide and air formed a hypoxic mixture, designed the first anesthetic apparatus to deliver oxygen and nitrous oxide in variable proportions. He also was influential in ensuring that anesthesia was taught in all British medical schools. His book, *Anaesthetics and Their Administration*, which first appeared in 1893 and continued through five editions, is considered the first true textbook of anesthesia. In 1908, Hewitt developed an important appliance that would assist all anesthesiologists in managing an obstructed upper airway. He called his oral device an "air-way restorer," thus beginning the practice of inserting an airway to help ventilation during an anesthetic.

Late Nineteenth-Century Anesthesia in America

American clinicians of the second half of the 19th century failed to achieve the lasting recognition gained by their British colleagues. Several factors contributed to this disparity. Snow, Clover, and Hewitt were unique men of genius who had no peers in America. Ether remained the dominant anesthetic in America, where the provision of anesthesia was often a service relegated to medical students, junior house officers, nurses, and nonprofessionals. The subordinate status of anesthesia was reflected in American art. Thomas Eakins' great studies, "The Gross Clinic" of 1876 and "The Agnew Clinic" of 1889, both present the surgeon as the focus of attention, whereas the person administering the anesthetic is seen among the supporting figures.

During this period, however, Americans led the revival of nitrous oxide. Gardner Q. Colton, the "professor" who had first demonstrated the use of nitrous oxide to Horace Wells, developed the Colton Dental Association after he returned from the California gold rush. In several eastern cities he opened offices equipped with nitrous oxide generators and, perhaps profiting from Wells' unhappy experience, larger breathing bags of 30-L capacity. By 1869, his advertisements carried the intriguing slogan "31½ Miles Long." Colton had asked each patient to sign his name to a scroll, which then contained the names of 55,000 patients who had experienced painless extractions of teeth without hazard. He proposed that if this great number of patients were to march past in single file, the line would be extended for 31½ miles.²²

Colton gave brief exposures of nitrous oxide undiluted with air or oxygen, which raised concern that the gas was acting as an asphyxiant. The following year a Chicago surgeon, Edmund Andrews, experimented with an oxygen–nitrous oxide mixture and proved that nitrous oxide does not cause anesthesia by depriving the brain of oxygen. Although the oxygen–nitrous oxide mixture was safer, he identified a handicap to its use that was unique to that time when patients were attended in their homes. The large bag was conspicuous and awkward to carry whenever Andrews walked along busy streets. He observed that, "In city practice, among the higher classes, however, this is no obstacle as the bag can always be taken in a carriage, without attracting attention."²³ Four years later, Andrews was delighted to report the availability of liquefied nitrous oxide compressed under 750 lb of pressure, which allowed a supply sufficient for three patients to be carried in a single cylinder. Despite Andrews' early enthusiasm, few American surgeons relied on nitrous oxide until it was used in combination with regional anesthesia, the last great contribution to anesthetic practice achieved in the late 19th century.

The Discovery of Regional Anesthesia in the Nineteenth Century

Cocaine, an extract of the coca leaf, was the first effective local anesthetic. Its property of numbing mucous membranes and exposed tissues had been known for centuries in Peru, where folk surgeons performing trephinations of the skull chewed coca leaves and allowed their saliva to fall onto the surfaces of the wound. This was a unique situation in anesthesia; there are no other instances in which both the operator and his patient routinely shared the effects of the same drug. After Albert Niemann refined the active alkaloid and named it *cocaine*, it was used in experiments by a few investigators. It was noted that cocaine provided topical anesthesia and even produced local insensibility when injected, but these observations were not applied in clinical practice before 1884, when the significance of the action of cocaine was realized by Carl Koller, a Viennese surgical intern.

Carl Koller (1857–1944) appreciated what others had failed to recognize because of his past experience and his ambition to practice ophthalmology at a time when many operations on the eye were still being performed without anesthesia. Almost four decades after the discovery of ether, general anesthesia by mask had several limitations for ophthalmic surgery. The anesthetized patient could not cooperate with his surgeon. The anesthesiologist's apparatus interfered with surgical access. At that time, many surgical incisions on the eye were not closed, as fine sutures were not yet available. The high incidence of vomiting following the administration of chloroform or ether threatened the extrusion of the internal contents of the globe, with the risk of irrevocable blindness.

While a medical student, Koller had worked in a Vienna laboratory in a search for a topical ophthalmic anesthetic to overcome the limitations of general anesthesia. Unfortunately, the suspensions of morphine, chloral hydrate, and other drugs that he had used had been ineffectual.

In 1884, Koller's friend, Sigmund Freud, became interested in the cerebral-stimulating effects of cocaine and gave him a small sample in an envelope, which he placed in his pocket. When the envelope leaked, a few grains of cocaine stuck to Koller's finger, which he casually licked with his tongue. It became numb. At that moment, Koller realized that he had found the object of his search. He dashed to the laboratory and made a suspension of cocaine crystals. He and Gustav Gartner, a laboratory associate, observed its anesthetic effect on the eyes of a frog, a rabbit, and a dog before they dropped the solution onto their own corneas. To their amazement, their eyes were insensitive to the touch of a pin.²⁴

As an intern, Carl Koller could not afford to attend a Congress of German Ophthalmologists in Heidelberg on September 15, 1884; but, after a friend read his article, a revolution in ophthalmic surgery and other surgical disciplines was initiated. Within the next year, more than 100 articles supporting the use of cocaine appeared in European and American medical journals. Despite this gratifying success, Koller was not able to pursue his goal of gaining a residency position in Vienna. After a duel provoked by an anti-Semitic slur, Koller left Austria and, after studying briefly in Holland and Britain, immigrated in 1888 to New York, where he practiced ophthalmology for the remainder of his career.

American surgeons quickly developed new applications for cocaine. Its efficacy in anesthetizing the nose, mouth, larynx, trachea, rectum, and urethra was described in October 1884. The next month, the first reports of its subcutaneous injection were published. In December 1884, two young surgeons, William Halsted and Richard Hall, described blocks of the sensory nerves of the face and arm. Halsted even performed a brachial plexus block but did so under direct vision while the patient received an inhaled anesthetic. Unfortunately, self-experimentation with cocaine was hazardous, as both surgeons became addicted. Addiction was an ill-understood but frequent problem in the late 19th century, especially when cocaine and morphine were present in many patent medicines.

Other local anesthetic techniques were attempted before the end of the 19th century. The term *spinal anesthesia* was coined in 1885 by Leonard Corning, a neurologist who had observed Hall and Halsted. Corning wanted to assess the action of cocaine as a specific therapy for neurologic problems. After first assessing its action in a dog, producing a blockade of rapid onset that was confined to the animal's rear legs, he administered cocaine to a man "addicted to masturbation." Corning administered one dose without effect, then after a second dose, the patient's legs "felt sleepy." The man had impaired sensibility in his lower extremity after about

twenty minutes. He left Corning's office "none the worse for the experience."²⁵ Although Corning does not refer to the escape of cerebrospinal fluid (CSF) in either case, it is likely that the dog had a spinal anesthetic and that the man had an epidural anesthetic. No therapeutic benefit was described, but Corning closed his account and his attention to the subject by suggesting that cocainization might in time be "a substitute for etherization in genito-urinary or other branches of surgery."²⁶

Two other authors, August Bier and Theodor Tuffier, described authentic spinal anesthesia, with mention of cerebrospinal fluid, injection of cocaine, and an appropriately short onset of action. In a comparative review of the original articles by Bier, Tuffier, and Corning, it was concluded that Corning's injection was extradural, and Bier merited the credit for introducing spinal anesthesia.²⁵

INTO THE TWENTIETH CENTURY

Spinal Anesthesia

Fourteen years passed before spinal anesthesia was performed for surgery. In the interval, Heinrich Quincke of Kiel, Germany, described his technique of lumbar puncture. He proposed that it was most safely performed at the level of the third or fourth lumbar interspace, because an entry at that level would be below the termination of the spinal cord. Quincke's technique was used in Kiel for the first deliberate cocainization of the spinal cord in 1899 by a surgical colleague, August Bier. Six patients received small doses of cocaine intrathecally, but, because some cried out during surgery while others vomited and experienced headaches, Bier considered it necessary to conduct a clinical experiment.

Professor Bier permitted his assistant, Dr. Hildebrandt, to perform a lumbar puncture, but, after the needle penetrated the dura, Hildebrandt could not fit the syringe to the needle and a large volume of the professor's spinal fluid escaped. They were at the point of abandoning the study when Hildebrandt volunteered to be the subject of a second attempt. They had an astonishing success. Twenty-three minutes later, Bier noted: "A strong blow with an iron hammer against the tibia was not felt as pain. After 25 minutes: Strong pressure and pulling on a testicle were not painful."²⁷ They celebrated their success with wine and cigars. That night, both developed violent headaches, which they attributed at first to their celebration. Bier's headache was relieved after 9 days of bedrest. The house officer did not have the luxury of continued rest. Bier postulated that their headaches were due to the loss of large volumes of CSF and urged that this be avoided if possible. The high incidence of complications following lumbar puncture with wide-bore needles and the toxic reactions attributed to cocaine explain his later loss of interest in spinal anesthesia.

Surgeons in several other countries soon practiced spinal anesthesia. Many of their observations are still relevant. The first series from France of 125 cases was published by Theodor Tuffier, who later counseled that the solution should not be injected before CSF was seen. The first American report was by Rudolph Matas of New Orleans, whose first patient developed postanesthetic meningismus, a then-frequent complication that was overcome in part by the use of hermetically sealed sterile solutions recommended by E. W. Lee of Philadelphia and sterile gloves as advocated by Halsted. During 1899, Dudley Tait and Guidlo Cagliari of San Francisco performed experimental studies in animals and therapeutic spinals for orthopedic patients. They encouraged the use of fine needles to lessen the escape of CSF and urged that the skin and deeper tissues be infiltrated beforehand with local anesthesia, as had been urged earlier by William Halsted and the foremost advocate of infiltration anesthesia, Carl Ludwig Schleich of Berlin. An early American specialist in anesthesia, Ormond Goldman, published an anesthesia record appropriate for recording the course of "intraspinal cocainization" in 1900. In the same year, Heinrich Braun learned of a newly described extract of the adrenal gland, epinephrine, which he used to prolong the action of local anesthetics with great success. Braun developed several new nerve blocks, coined the term *conduction anesthesia*, and is remembered by European writers as the "father of conduction anesthesia." Braun was the first person to use procaine, which, along with stovaine, was one of the first synthetic local anesthetics produced to reduce the toxicity of cocaine. Further advances in spinal anesthesia followed the introduction of these and other synthetic local anesthetics.

Before 1907, several anesthesiologists were disappointed to observe that their spinal anesthetics were incomplete. Most believed that the drug spread solely by local diffusion before this phenomenon was investigated by Arthur Barker, a London surgeon.²⁸ Barker constructed a glass tube shaped to follow the curves of the human spine and used it to demonstrate the limited spread of colored solutions that he had injected through a T-piece in the lumbar region. Barker applied this observation to use solutions of stovaine made hyperbaric by the addition of 5% glucose, which worked in a more predictable fashion. After the injection was complete, Barker placed his patient's head on pillows to contain the anesthetic below the nipple line. Lincoln Sise acknowledged Barker's work in 1935 when he introduced the use of hyperbaric solutions of pontocaine. John Adriani advanced the concept further in 1946 when he used a hyperbaric solution to produce "saddle block," or perineal anesthesia. Adriani's patients remained seated after injection as the drug descended to the sacral nerves.

Tait, Jonnesco, and other early masters of spinal anesthesia used a cervical approach for thyroidectomy and thoracic procedures, but this radical approach was supplanted in 1928 by the lumbar injection of hypobaric solutions of "light" nupercaine by G. P. Pitkin. Although hypobaric solutions are now usually limited to patients in the jackknife position, their former use for thoracic procedures demanded skill and precise timing. The enthusiasts of hypobaric anesthesia devised formulas to attempt to predict the time in seconds needed for a warmed solution of hypobaric nupercaine to spread in patients of varying size from its site of injection in the lumbar area to the level of the fourth thoracic dermatome.

The recurring problem of inadequate duration of single-injection spinal anesthesia led a Philadelphia surgeon, William Lemmon, to report an apparatus for continuous spinal anesthesia in 1940.²⁹ Lemmon began with the patient in the lateral position. The spinal tap was performed with a malleable silver needle, which was left in position. As the patient was turned supine, the needle was positioned through a hole in the mattress and table. Additional injections of local anesthetic could be performed as required. Malleable silver needles also found a less cumbersome and more common application in 1942 when Waldo Edwards and Robert Hingson encouraged the use of Lemmon's needles for continuous caudal anesthesia in obstetrics. In 1944 Edward Tuohy of the Mayo Clinic introduced two important modifications of the continuous spinal techniques. He developed the now-familiar Tuohy needle as a means of improving the ease of passage of lacquered silk ureteral catheters through which he injected incremental doses of local anesthetic.³⁰

Epidural Anesthesia

In 1949, Martinez Curbelo of Havana, Cuba, used Tuohy's needle and a ureteral catheter to perform the first continuous epidural anesthetic. Silk and gum elastic catheters were difficult to sterilize and sometimes caused dural infections before being superseded by disposable plastics. Yet, deliberate single-injection peridural anesthesia had been practiced occasionally for decades before continuous techniques brought it greater popularity. At the beginning of the 20th century, two French clinicians experimented independently with caudal anesthesia. The neurologist Jean Athanase Sicard applied the technique for a nonsurgical purpose, the relief of back pain. Fernand Cathelin used caudal anesthesia as a less dangerous alternative to spinal anesthesia for hernia repairs. He also demonstrated that the epidural space terminated in the neck by injecting a solution of India ink into the caudal canal of a dog. The lumbar approach was first used solely for multiple paravertebral nerve blocks before the Pagés–Dogliotti single-injection technique became accepted. As they worked separately, the technique carries the names of both men. Captain Fidel Pagés prepared an elegant demonstration of segmental single-injection peridural anesthesia in 1921, but died soon after his paper appeared in a Spanish military journal.³¹ Ten years later, Achille M. Dogliotti of Turin, Italy, wrote a classic study that made the epidural technique well known.³² Whereas Pagés used a tactile approach to identify the epidural space, Dogliotti identified it by the loss-of-resistance technique still being currently taught.

Twentieth-Century Regional Anesthesia

Surgery on the extremities lent itself to other regional anesthesia techniques. At first, they were combined with general anesthesia. In 1902, Harvey Cushing coined the phrase "regional anesthesia" for his technique of blocking either the brachial or sciatic plexus under direct vision during general anesthesia to reduce anesthesia requirements and provide postoperative pain relief.³³ Fifteen years before his publication, a similar approach had been energetically advanced to reduce the stress and shock of surgery by George Crile, another dedicated advocate of regional and infiltration techniques during general anesthesia.

An intravenous regional technique with procaine was reported in 1908 by August Bier, the surgeon who had pioneered spinal anesthesia. Bier injected procaine into a vein of the upper limb between two tourniquets. Even though the technique is termed the *Bier block*, it was not used for many decades until it was reintroduced 55 years later by Mackinnon Holmes, who modified the technique by exsanguination before applying a single proximal cuff. Holmes used lidocaine, the very successful amide local anesthetic synthesized in 1943 by Lofgren and Lundquist of Sweden.

Several investigators achieved upper extremity anesthesia by percutaneous injections of the brachial plexus. In 1911, based on his intimate knowledge of the anatomy of the axillary area, Hirschel promoted a "blind" axillary injection. In the same year, Kulenkampff described a supraclavicular approach in which the operator sought out paresthesias of the plexus while keeping the needle at a point superficial to the first rib and the pleura. The risk of pneumothorax with Kulenkampff's approach led Mulley to attempt blocks more proximally by a lateral paravertebral approach, the precursor of what is now popularly known as the Winnie block.

Heinrich Braun wrote the earliest textbook of local anesthesia, which appeared in its first English translation in 1914. After 1922, Gaston Labat's *Regional Anesthesia* dominated the American market. Labat migrated from France to the Mayo Clinic, where he served briefly before taking a permanent position at the Bellevue Hospital in New York, where he worked with Hippolite Wertheim. They formed the first American Society for Regional Anesthesia. After Labat's death, Emery A. Rovenstine was recruited to Bellevue to continue Labat's work. Rovenstine created the first American clinic for the treatment of chronic pain, where he and his associates refined techniques of lytic and therapeutic injections, and used the American Society of Regional Anesthesia to further knowledge of pain management across the United

The development of the multidisciplinary pain clinic was one of many contributions to anesthesiology made by John J. Bonica, a renowned teacher of regional techniques. During his periods of military, civilian, and university service at the University of Washington, John Bonica formulated a series of improvements in the management of patients with chronic pain. His classic text, *The Management of Pain*, now in its third edition, is regarded as a classic of the literature of anesthesia.

THE QUEST FOR SAFETY IN ANESTHESIOLOGY

In many ways, the history of late 19th and 20th century anesthesiology is the quest for safer anesthetic agents and methods. The introduction of sophisticated monitoring is critical to the increase in patient safety during this time period. The advances in technology, including components of the anesthesia machine, which produced more accurate and thus safer anesthetics, have obsessed those in the specialty. In addition, the development and widespread use of better patient monitors, such as the electrocardiograph (ECG), arterial blood gas analyzer, and pulse oximeter, has reduced the morbidity and mortality of surgical procedures—and thus allowed patients with critical illnesses to safely undergo potentially life-saving procedures. Endotracheal intubation largely replaced mask ventilation, thereby permitting the anesthesiologist to attend to other aspects of patient care during general anesthesia. Progress in the realm of intraoperative pain control during the late 19th and 20th centuries therefore enhanced the quality of patient care and promoted the development of surgical techniques.

Critical to increasing patient safety was the development of a machine capable of delivering a calibrated amount of gas and volatile anesthetic. In the late 19th century freestanding anesthesia machines were manufactured in the United States and Europe. Three American dentist-entrepreneurs, Samuel S. White, Charles Teter, and Jay Heidbrink, developed the first series of U.S. instruments to use compressed cylinders of nitrous oxide and oxygen. Before 1900 the S. S. White Company modified Hewitt's apparatus and marketed its continuous-flow machine, which was refined by Teter in 1903. Heidbrink added reducing valves in 1912. In the same year other important developments were initiated by physicians. Water-bubble flow meters, introduced by Frederick Cotton and Walter Boothby of Harvard University, allowed the proportion of gases and their flow rate to be approximated. The Cotton and Boothby apparatus was transformed into a practical portable machine by James Tayloe Gwathmey of New York, who demonstrated it at a 1912 Medical Congress in London. The Gwathmey machine caught the attention of a London anesthetist, Henry E. G. "Cockie" Boyle, who acknowledged his debt to the American when he incorporated Gwathmey's concepts in the first of the series of "Boyle" machines that were marketed by Coxeter and British Oxygen Corporation. During the same period in Lubeck, Germany, Heinrich Draeger and his son, Bernhaard, adapted compressed-gas technology, which they had originally developed for mine rescue apparatus, to manufacture ether and chloroform-oxygen machines.

In the years after World War I, several U.S. manufacturers continued to bring forward widely admired anesthesia machines. Some companies were founded by dentists, including Heidbrink and Teter. Karl Connell and Elmer Gatch were surgeons. Richard von Foregger was an engineer who was exceptionally receptive to clinicians' suggestions for additional features for his machines. Elmer McKesson became one of the country's first specialists in anesthesiology in 1910 and developed a series of gas machines. In an era of inflammable anesthetics, McKesson carried nonflammable nitrous oxide anesthesia to its therapeutic limit by performing inductions with 100% nitrous oxide and thereafter adding small volumes of oxygen. If the resultant cyanosis became too profound, McKesson depressed a valve on his machine that flushed a small volume of oxygen into the circuit. Even though his techniques of primary and secondary saturation with nitrous oxide are no longer used, the oxygen flush valve is part of McKesson's legacy.

Carbon dioxide absorbance is important to the anesthetic machine. Initially, because it allows rebreathing of gas, it minimized loss of flammable gases into the room and the risk of explosion. Nowadays, it permits decreased utilization of anesthetic and reduced cost. The first use of carbon dioxide absorbers in anesthesia came in 1906 from the work of Franz Kuhn, a German surgeon. His use of canisters developed for mine rescues by Draeger was a bold innovation, but his circuit had unfortunate limitations—exceptionally narrow breathing tubes and a large dead space, which might explain its very limited use. Kuhn's device was ignored. A few years later, the first American machine with a carbon dioxide absorber was independently fabricated by Dennis Jackson.

In 1915, Jackson, a pharmacologist, developed an early technique of carbon dioxide absorption that permitted the use of a closed anesthesia circuit. He used solutions of sodium and calcium hydroxide to absorb carbon dioxide. As his laboratory was located in an area of St. Louis, Missouri, heavily laden with coal smoke, Jackson reported that the apparatus allowed him the first breaths of absolutely fresh air he had ever enjoyed in that city. The complexity of Jackson's apparatus limited its use in hospital practice, but his pioneering work in this field encouraged Ralph Waters to introduce a simpler device using soda lime granules 9 years later. Waters positioned a soda lime canister between a face mask and an adjacent breathing bag to which was attached the fresh gas flow. As long as the mask was held against the face, only small volumes of fresh gas flow were required and no valves were needed.³⁵

When Waters made his first "to-and-fro" device, he was attempting to develop a specialist practice in anesthesia in Sioux City, Iowa, and had achieved limited financial success. Waters believed that his device had advantages for both the clinician and the patient. Economy of operation was an important advance at a time when private patients and insurance companies were reluctant to pay not only for a specialist's services but even for the drugs and supplies he had purchased. Waters estimated that his new canister would reduce his costs for gases and soda lime to less than \$.50 per hour. This portable apparatus could be easily carried to the patient's home and, in residential or hospital settings, prevented the pollution of the operating environment with the malodorous and explosive vapors of ethylene. He even noted that the canister conserved body heat and humidified inspired gases.

An awkward element of Waters' device was the position of the canister close to the patient's face. Brian Sword overcame this limitation in 1930 with a freestanding machine with unidirectional valves to create a circle system and an in-circuit carbon dioxide absorber (Fig. 1-6).³⁶ James Elam and his co-workers at the Roswell Park Cancer Institute in Buffalo, New York, further refined the carbon dioxide absorber, maximizing the amount of carbon dioxide removed with a minimum of resistance for breathing.³⁷ Thus, the circle system introduced by Sword in the 1930s remains the most popular North American anesthesia circuit.

Figure 1-6. Brian Sword's closed-circle anesthesia machine (1930).

Alternative Circuits

A valveless device, the Ayre's T-piece, has found wide application in the management of intubated patients. Phillip Ayre practiced anesthesia in England when the limitations of equipment for pediatric patients produced what he describe as "a protracted and sanguine battle between surgeon and anaesthetist, with the poor unfortunate baby as the battlefield."³⁸ In 1937, Ayre introduced his valveless T-piece to reduce the effort of breathing in neurosurgical patients. The T-piece soon became particularly popular for cleft palate repairs, as the surgeon had free access to the mouth. Positive pressure ventilation could be achieved when the anesthetist obstructed the expiratory limb. In time, this ingenious, lightweight, nonrebreathing device evolved through more than 100 modifications for a variety of special situations. A significant alteration was Gordon Jackson Rees' circuit, which permitted improved control of ventilation by substituting a breathing bag on the outflow limb.³⁹

An alternative method to reduce the amount of equipment near the patient is provided by the coaxial circuit of the Bain-Spoerel apparatus.⁴⁰ This lightweight tube-within-a-tube has served very well in many circumstances since its Canadian innovators described it in 1972. However, the Bain-Spoerel circuit was not the first application of coaxial technology in anesthesia. A few 19th-century inhalers, including Hewitt's 1890 chloroform apparatus, used a tube-within-a-tube to lead air into the vaporizer and then back within a smaller tube to the patient.

A more recent precursor of the modern coaxial circuit was created during World War II by Richard Salt and Edgar Pask for tests undertaken by the Royal Air Force of types of life jackets. Many pilots who had survived "ditching" in the frigid North Sea succumbed to hypothermia and drowned after losing consciousness because the life jacket failed to keep the airman's head above water. To simulate an unconscious victim, Dr. Pask was anesthetized with ether *via* a nasal tracheal tube. The

unresponsive physician was then lowered into a swimming pool to become the passive subject as a series of life jackets were tested. Even though the tubing of the breathing circuit was many yards long, rebreathing was prevented by the circuit's coaxial design and by the position of the exhalation valve above the surface of the water. This design overcame the risk of pulmonary barotrauma even when the jacket failed and Pask sank to the bottom of the pool. Once the studies were completed, the coaxial circuit passed from use until its utility was recognized by Drs. Bain and Spoerel.

Flow Meters

As closed and semiclosed circuits became practical, gas flow could be measured with greater accuracy. Bubble flow meters were replaced with dry bobbins or ball-bearing flow meters, which, although they did not leak fluids, could cause inaccurate measurements if they adhered to the glass column. In 1910, M. Neu had been the first to apply rotameters in anesthesia for the administration of nitrous oxide and oxygen, but his machine was not a commercial success, perhaps because of the great cost of nitrous oxide in Germany at that time. Rotameters designed for use in German industry were first employed in Britain in 1937 by Richard Salt; but as World War II approached, the English were denied access to these sophisticated flow meters. After World War II rotameters became regularly employed in British anesthesia machines, although most American equipment still featured nonrotating floats. The now universal practice of displaying gas flow in liters per minute was not a uniform part of all American machines until more than a decade after World War II. Some anesthesiologists still in practice learned to calculate gas flows in the cumbersome proportions of gallons per hour.

Vaporizers

Uncalibrated glass vaporizers could be used with confidence for ether but were inadequate for more potent agents. Skilled practitioners gave chloroform with safety, but their success was dependent upon clinical expertise based upon subjective observations that were difficult to teach to neophytes. The art of a smooth induction with a potent anesthetic was a great challenge, particularly if the inspired concentration could not be determined with accuracy. This limitation was particularly true of chloroform, as an excessive rate of administration produced a lethal cardiac depression. Even the clinical introduction of halothane after 1956 might have been similarly thwarted except for a fortunate coincidence: the prior development of calibrated vaporizers. Two types of calibrated vaporizers designed for other anesthetics had become available in the half-decade before halothane was marketed. The prompt acceptance of halothane was in part due to an ability to provide it in carefully titrated concentrations.

The Copper Kettle was the first temperature-compensated, accurate vaporizer. It had been developed by Lucien Morris at the University of Wisconsin in response to Ralph Waters' plan to test chloroform by giving it in controlled concentrations.⁴¹ Morris achieved this goal by passing a metered flow of oxygen through a vaporizer chamber that contained a porex disk to separate the oxygen into minute bubbles. The gas became fully saturated with anesthetic vapor as it percolated through the liquid. The concentration of the anesthetic inspired by the patient could be calculated by knowing the vapor pressure of the liquid anesthetic, the volume of oxygen flowing through the liquid, and the total volume of gases from all sources entering the anesthesia circuit. Although experimental models of Morris' vaporizer used a water bath to maintain stability, the excellent thermal conductivity of copper was substituted in later models. When first marketed, the Copper Kettle did not feature a mechanism to indicate changes in the temperature (and vapor pressure) of the liquid. Shuh-Hsun Ngai proposed the incorporation of a thermometer, a suggestion that was later added to all vaporizers of that class.⁴²

Copper Kettle (Foregger Company) and Vernitrol (Ohio Medical Products) vaporizers were universal vaporizers—a property that remained a distinct advantage as new anesthetics were marketed. Universal vaporizers could be charged with any anesthetic liquid, and, provided that its vapor pressure and temperature were known, the inspired concentration could be calculated quickly. This feature gave an unanticipated advantage to American investigators. They were not dependent on the construction of new agent-specific vaporizers.

When halothane was first marketed in Britain, an effective temperature-compensated, agent-specific vaporizer had recently been placed in clinical use. It had been developed for domiciliary obstetric use as many British women were then delivered at home by midwives who required a safe, portable vaporizer with which to provide known concentrations of an inhaled analgesic. The TECOTA (TEmperature COmpensated Trichloroethylene Air) vaporizer had been created by engineers who had been frustrated by a giant corporation's unresponsiveness to their proposals and had formed a new company, Cyprane Limited. The TECOTA featured a bimetallic strip composed of brass and a nickel–steel alloy, two metals with different coefficients of expansion. As the anesthetic vapor cooled, the strip bent to move away from the orifice, thereby permitting more fresh gas to enter the vaporizing chamber. This maintained a constant inspired concentration despite changes in temperature and vapor pressure. After their TECOTA vaporizer was accepted by the Central Midwives Board, their company soon gained a much greater success by adapting their technologic advance to create the "Fluotec," the first of a series of agent-specific "tec" vaporizers for use in the operating room. All major manufacturers now offer a similar instrument.

Ventilators

Mechanical ventilators are now an integral part of the anesthesia machine. Patients are ventilated during general anesthesia by electrical or gas-powered devices that are simple to control yet sophisticated in their function. The history of mechanical positive pressure ventilation began with attempts to resuscitate victims of drowning by a bellows attached to a mask or tracheal tube. These experiments found little role in anesthetic care for many years. At the beginning of the 20th century, however, several modalities were explored before intermittent positive pressure machines evolved.

A series of artificial environments were created in response to the frustration experienced by thoracic surgeons who found that the lung collapsed when they incised the pleura. Between 1900 and 1910, continuous positive or negative pressure devices were created to maintain inflation of the lungs of a spontaneously breathing patient once the chest was opened. Brauer (1904) and Murphy (1905) placed the patient's head and neck in a box in which positive pressure was continually maintained. Sauerbruch (1904) created a negative pressure operating chamber encompassing both the surgical team and the patient's body and from which only the patient's head projected.

In 1907, the first intermittent positive pressure device, the Draeger "Pulmotor," was developed to rhythmically inflate the lungs. This instrument and later American models such as the E & J Resuscitator were used almost exclusively by firefighters and mine rescue workers. There are accounts that before 1940 in some American communities, surgeons occasionally called the fire department to assist in the ventilation of patients who had stopped breathing while in the operating room. At that time many hospitals lacked any resuscitation equipment.

A few European medical workers had an early interest in rhythmic inflation of the lungs. In 1934 a Swedish team developed the "Spiropulsator," which C. Crafoord later modified for use during cyclopropane anesthesia.⁴³ Its action was controlled by a magnetic control valve called the flasher, a type first used to provide intermittent gas flow for the lights of navigational buoys. When Trier Mørch, a Danish anesthesiologist, could not obtain a Spiropulsator during World War II, he fabricated the Mørch "Respirator," which used a piston pump to rhythmically deliver a fixed volume of gas to the patient. After World War II a motorcycle engineer in Britain developed the comparable prototype of the Blease "Pulmoflator" in which an electric motor provided compressed air to inflate the patient's lungs. In those days, when purpose-built miniature motors were unavailable, mechanics adapted automotive parts such as windshield blade motors and other devices for use in their early models.⁴⁴

A major stimulus to the development of ventilators came as a consequence of a devastating epidemic of poliomyelitis that struck Copenhagen, Denmark, in 1952. As scores of patients were admitted, the only effective ventilatory support that could be provided patients with bulbar paralysis was continuous manual ventilation *via* a tracheostomy employing devices such as Waters' "to-and-fro" circuit. This succeeded only through the dedicated efforts of hundreds of volunteers. Medical students served in relays to ventilate paralyzed patients. The Copenhagen crisis stimulated a broad European interest in the development of portable ventilators in anticipation of another epidemic of poliomyelitis.

At this time, the common practice in North American hospitals was to place polio patients with respiratory involvement in "iron lungs," metal cylinders that encased the body below the neck. Inspiration was caused by intermittent negative pressure created by an electric motor acting on a piston-like device occupying the foot of the chamber. During an epidemic, scores of iron lungs might be operated continuously in a single large room.

Some early American ventilators were adaptations of respiratory-assist machines originally designed for the delivery of aerosolized drugs for respiratory therapy. Two types employed the Bennett or Bird "flow-sensitive" valves. The Bennett valve was designed during World War II when a team of physiologists at the University of Southern California encountered difficulties in separating inspiration from expiration in an experimental apparatus designed to provide positive pressure breathing for aviators at high-altitude. An engineer, Ray Bennett, visited their laboratory, observed their problem, and resolved it with a mechanical flow-sensitive automatic valve. A second valving mechanism was later designed by an aeronautical engineer, Forrest Bird.

The use of the Bird and Bennett valves gained an anesthetic application when the gas flow from the valve was directed into a rigid plastic jar containing a breathing bag or bellows as part of an anesthesia circuit. These "bag-in-bottle" devices mimicked the action of the clinician's hand as the gas flow compressed the bag, thereby providing positive pressure inspiration. Passive exhalation was promoted by the descent of a weight on the bag or bellows. The functions of the components of some of the first ventilators to use these principles could be examined with ease through the plastic housing, whereas they are now concealed within the interior of the instrument. As a result, it is now possible to operate the ventilator of an anesthesia machine for years without becoming aware of the principles that direct its action and

protect against malfunction.

Anesthesia Machine and Equipment Monitors

The introduction of safety features was coordinated by the American National Standards Institute (ANSI) Committee Z79, which was sponsored from 1956 until 1983 by the American Society of Anesthesiologists. Since 1983, representatives from industry, government, and health care professions have met on Committee Z79 of the American Society for Testing and Materials. They establish voluntary goals that may become accepted national standards for the safety of anesthesia equipment.

Ralph Tovell voiced the first call for standards during World War II while he was the U.S. Army Consultant in Anesthesiology for Europe. Tovell found that, as there were four different dimensions for connectors, tubes, masks, and breathing bags, supplies dispatched to field hospitals might not match their anesthesia machines. As Tovell observed, "When a sudden need for accessory equipment arose, nurses and corpsmen were likely to respond to it by bringing parts that would not fit."⁴⁵ Although Tovell's reports did not gain an immediate response, after the war Vincent Collins and Hamilton Davis took up his concern and formed the ANSI Committee Z79. One of the committee's most active members, Leslie Rendell-Baker, wrote an account of the committee's domestic and international achievements.⁴⁶ He reported that Ralph Tovell, encouraged all manufacturers to select the now uniform orifice of 22 mm for all adult and pediatric face masks and to make every tracheal tube connector 15 mm in diameter. For the first time, a Z79-designed mask-tube elbow adapter would fit every mask and tracheal tube connector.

Other advances were introduced by the Z79 Committee. Tracheal tubes of nontoxic plastic bear a Z79 or IT (Implantation Tested) mark. The committee also mandated touch identification of oxygen flow control at Roderick Calverley's suggestion, which reduced the risk that the wrong gas would be selected before internal mechanical controls prevented the selection of an hypoxic mixture.⁴⁷ Pin indexing reduced the hazard of attaching a wrong cylinder in the place of oxygen. Diameter indexing of connectors prevented similar errors in high-pressure tubing. For many years, however, errors committed in reassembling hospital oxygen supply lines led to a series of tragedies before polarographic oxygen analyzers were added to the inspiratory limb of the anesthesia circuit.

Patient Monitors

Safer machines assured the clinician that an appropriate gas mixture was delivered to the patient. Other monitors were required to provide an early warning of acute physiologic deterioration before a patient suffered irrevocable damage. Every anesthesiologist who has remained in practice during the past 30 years has witnessed a great series of advances in monitoring with the advent of clinically employable forms of electrocardiography, arterial blood gas analysis, anesthetic gas analysis, computer-processed electroencephalography, and pulse oximetry.

Two American surgeons, George W. Crile and Harvey Cushing, developed a strong interest in measuring blood pressure during anesthesia. Both men wrote thorough and detailed examinations of blood pressure monitoring; however, Cushing's contribution is better remembered because he was the first American to apply the Riva Rocci cuff, which he saw while visiting Italy. Cushing introduced the concept in 1902 and had blood pressure measurements recorded on anesthesia records.⁴⁸ These improved records were an advance over the first recordings of the patient's pulse that Cushing and a colleague at Harvard Medical School, Charles Codman, had initiated in 1894 in an attempt to assess the course of the anesthetics they administered as students.

Anesthesiologists began to auscultate blood pressure after 1905 when Nicholai Korotkoff, a surgeon-in-training in St. Petersburg, Russia, gave an abbreviated report of the sounds that he heard distal to the Riva Rocci cuff as it was deflated. Although his one-paragraph account does not explain why he came to listen over a normal vessel (a novel approach now used universally for the clinical measurement of blood pressure), it may be that his commitment to vascular surgery caused him to auscultate before incising a mass that might be vascular and would, therefore, produce a bruit. Perhaps he happened to have his stethoscope positioned over a vessel as a cuff was deflated and fortuitously heard sounds never appreciated before. Cuffs and stethoscopes are now often replaced by automated blood pressure devices, which first appeared in 1936 and which operate on an oscillometric principle. The development of inexpensive microprocessors has promoted the routine use of these automatic cuffs in clinical settings.

The first precordial stethoscope was believed to have been used by S. Griffith Davis at Johns Hopkins University.⁴⁹ He adapted a technique developed by Harvey Cushing in a laboratory in which dogs with surgically induced valvular lesions had stethoscopes attached to their chest wall so that medical students might listen to bruits characteristic of a specific malformation. Davis' technique was forgotten but was rehabilitated by Dr. Robert Smith, an energetic pioneer of pediatric anesthesiology in Boston. A Canadian contemporary, Albert Codesmith, of the Hospital for Sick Children, Toronto, became frustrated by the repeated dislodging of the chest piece under the surgical drapes and fabricated his first esophageal stethoscope from urethral catheters and Penrose drains. His brief report heralded its clinical role as a monitor of both normal and adventitious respiratory and cardiac sounds.⁵⁰ An additional benefit was that the stethoscope could protect against the risk of disconnection of a paralyzed patient from the anesthesia circuit. In the era before audible alarms, the patient's survival depended upon the anesthesiologist's recognition of the sudden disappearance of breath sounds.

Electrocardiography, Pulse Oximetry, and Carbon Dioxide Measurement

Clinical electrocardiography began with Willem Einthoven's application of the string galvanometer in 1903. Within two decades, Thomas Lewis had described its role in the diagnosis of disturbances of cardiac rhythm, while James Herrick and Harold Pardee first drew attention to the changes produced by myocardial ischemia. After 1928, cathode ray oscilloscopes were available, but the risk of explosion owing to the presence of inflammable anesthetics forestalled the introduction of the electrocardiogram into routine anesthetic practice until after World War II. At that time the small screen of the heavily shielded "bullet" oscilloscope displayed only 3 seconds of data, but that information was highly prized. In some hospitals, priorities were established to determine where this expensive monitor was to be used. When an assistant was dispatched to bring the "bullet scope," everyone knew that a major anesthetic enterprise was about to begin.

Pulse oximetry, the optical measurement of oxygen saturation in tissues, is one of the more recent additions to the anesthesiologist's array of routine monitors. Severinghaus states, "Pulse oximetry is arguably the most important technological advance ever made in monitoring the well-being and safety of patients during anesthesia, recovery, and critical care."⁵¹ Although research in this area began in 1932, its first practical application came during World War II. An American physiologist, Glen Millikan, responded to a request from British colleagues in aviation research. Millikan set about preparing a series of devices to improve the supply of oxygen that was provided to pilots flying at high altitude in unpressurized aircraft. To monitor oxygen delivery and to prevent the pilot from succumbing to an unrecognized failure of his oxygen supply, Millikan created an oxygen sensing monitor worn on the pilot's earlobe, and coined the name *oximeter* to describe its action. Before his tragic death in a climbing accident in 1947, Millikan had begun to assess anesthetic applications of oximetry.

For the next three decades, oximetry was rarely used by anesthesiologists, and then primarily in research studies such as those of Faulconer and Pender. Refinements of oximetry by a Japanese engineer, Takuo Aoyagi, led to the development of pulse oximetry. As Severinghaus recounted the episode, Aoyagi had attempted to eliminate the changes in a signal caused by pulsatile variations when he realized that this fluctuation could be used to measure both the pulse and oxygen saturation. Severinghaus observed that this was "a classic example of the adage that 'one man's noise is another man's signal.'"⁵²

Although pulse oximetry gives second-by-second data about oxygen saturation, anesthesiologists have recognized a need for breath-by-breath measurement of respiratory and anesthetic gases. After 1954, infrared absorption techniques gave immediate displays of the exhaled concentration of carbon dioxide. Clinicians quickly learned to relate abnormal concentrations of carbon dioxide to threatening situations such as the inappropriate placement of a tracheal tube in the esophagus, abrupt alterations in pulmonary blood flow, and other factors. More recently, infrared analysis has been perfected to enable breath-by-breath measurement of anesthetic gases as well. This technology has largely replaced mass spectrometry, which initially had only industrial applications before Albert Faulconer of the Mayo Clinic first used it to monitor the concentration of an exhaled anesthetic in 1954.

Tracheal Intubation in Anesthesia

The development of techniques and instruments for intubation ranks among the major advances in the history of anesthesiology. The first tracheal tubes were developed for the resuscitation of drowning victims, but were not used in anesthesia until 1878. Although John Snow and others had already anesthetized patients by means of a tracheostomy, the first use of elective oral intubation for an anesthetic was undertaken by a Scottish surgeon, William Macewan. He had practiced passing flexible metal tubes through the larynx of a cadaver before attempting the maneuver on an awake patient with an oral tumor at the Glasgow Royal Infirmary, on July 5, 1878.⁵³ Because topical anesthesia was not yet known, the experience must have demanded fortitude on the part of Macewan's patient. Once the tube was correctly positioned, an assistant began a chloroform-air anesthetic *via* the tube. Once anesthetized, the patient soon stopped coughing. Macewan abandoned the practice following an unusual fatality. His last patient had been intubated while awake but the tube was removed before the anesthetic could begin. The patient later died while receiving chloroform by mask.

Although there was a sporadic interest in tracheal anesthesia in Edinburgh and other European centers after Macewan, a contemporary American surgeon is remembered for his extraordinary dedication to the advancement of tracheal intubation. Joseph O'Dwyer had witnessed the distressing death by asphyxiation of children with diphtheria and sought an alternative to the mutilation of a hasty tracheotomy. In 1885, O'Dwyer designed a series of metal laryngeal tubes, which he inserted blindly between the vocal cords of children suffering a diphtheritic crisis. Colleagues applauded his humanitarian efforts. Three years later, O'Dwyer designed a

second rigid tube with a conical tip that occluded the larynx so effectively that it could be used for artificial ventilation when applied with the bellows and T-piece tube of George Fell's apparatus.⁵⁴ The Fell–O'Dwyer apparatus was used during thoracic surgery by Rudolph Matas of New Orleans, who was so pleased with it that he predicted, "The procedure that promises the most benefit in preventing pulmonary collapse in operations on the chest is . . . the rhythmical maintenance of artificial respiration by a tube in the glottis directly connected with a bellows."⁵⁴ For several decades, this principle would be transiently rediscovered by other surgeons before Matas' prophecy was fully realized.

After O'Dwyer's death, the outstanding pioneer of tracheal intubation was Franz Kuhn, a surgeon of Kassel, Germany. From 1900 until 1912, Kuhn wrote a series of fine papers and a classic monograph, "*Die perorale Intubation*," which were not well known in his lifetime but have since become widely appreciated.⁵⁵ His work might have had a more profound impact if it had been translated into English. Kuhn described techniques of oral and nasal intubation that he performed with flexible metal tubes composed of coiled tubing similar to those now used for the spout of metal gasoline cans. After applying cocaine to the airway, Kuhn introduced his tube over a curved metal stylet that he directed toward the larynx with his left index finger (Fig. 1-7). While he was aware of the subglottic cuffs that had been used briefly by Victor Eisenmenger, Kuhn preferred to seal the larynx by positioning a supralaryngeal flange near the tube's tip before packing the pharynx with gauze. Kuhn even monitored the patient's breath sounds continuously through a monaural earpiece connected to an extension of the tracheal tube by a narrow tube. His writings reflect a mastery of intubation techniques unequalled for many years.

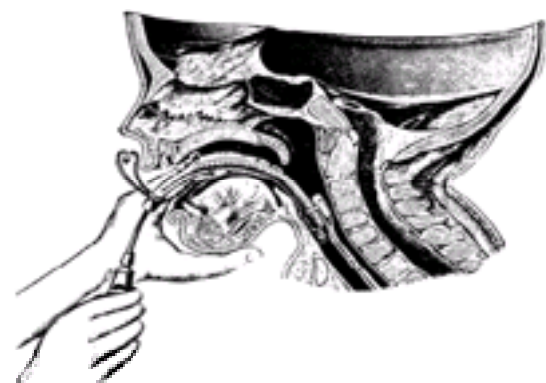

Figure 1-7. Kuhn's endotracheal tube. The tube and introducer were guided to the trachea by the fingers of the operator's left hand.

Intubation of the trachea by palpation was an uncertain and sometimes traumatic act. Even though the use of a mirror for indirect laryngoscopy antedated Macewan's intubations, the technique could not be adapted for use in anesthesia. For some years, surgeons even believed that it would be anatomically impossible to visualize the vocal cords directly. This misapprehension was overcome in 1895 by Alfred Kirstein in Berlin who devised the first direct-vision laryngoscope.⁵⁶ Kirstein was motivated by a friend's report that a patient's trachea had been accidentally intubated during esophagoscopy. Kirstein promptly fabricated a hand-held instrument that at first resembled a shortened cylindrical esophagoscope. He soon substituted a semicircular blade that opened inferiorly. Kirstein could now examine the larynx while standing behind his seated patient, whose head had been placed in an attitude approximating the "sniffing position" later recommended by Ivan Magill. Although Alfred Kristin's "autoscope" was not used by anesthesiologists, it was the forerunner of all modern laryngoscopes. Endoscopy was refined by Chevalier Jackson in Philadelphia, who designed a U-shaped laryngoscope by adding a hand grip that was parallel to the blade. The Jackson blade has remained a standard instrument for endoscopists but was not favored by anesthesiologists. Two laryngoscopes that closely resembled modern L-shaped instruments were designed in 1910 and 1913 by two American surgeons, Henry Janeway and George Dorrance, but neither instrument achieved lasting use despite their excellent designs.

Anesthesiologist Inspired Laryngoscopes

Early practitioners of intubation of the trachea were frustrated by laryngoscopes that were cumbersome, ill designed for the prevention of dental injury, and offered only a very limited view of the larynx. Before the introduction of muscle relaxants, intubation of the trachea was often a severe challenge. It was in that period, however, that two blades were invented that became the classic models of the straight and curved laryngoscope. Robert Miller of San Antonio, Texas, and Robert Macintosh of Oxford University created two blades that have maintained lasting popularity. Both laryngoscopes appeared within an interval of 2 years. In 1941, Miller brought forward a slender, straight blade with a slight curve near the tip to ease the passage of the tube through the larynx. Although Miller's blade was a refinement, the technique of its use was identical to that of earlier models as the epiglottis was lifted to expose the larynx.⁵⁷

The Macintosh blade, which passes in front of the epiglottis, was invented as an incidental result of a tonsillectomy, an operation that was then performed without intubation. Sir Robert Macintosh later described the circumstances of its discovery in an appreciation of the career of his technician, Mr. Richard Salt, who constructed the blade. As Sir Robert recalled, "A Boyle-Davis gag, a size larger than intended, was inserted for tonsillectomy, and when the mouth was fully opened the cords came into view. This was a surprise since conventional laryngoscopy, at that depth of anaesthesia, would have been impossible in those pre-relaxant days. Within a matter of hours, Salt had modified the blade of the Davis gag and attached a laryngoscope handle to it; and streamlined (after testing several models), the end result came into widespread use."⁵⁸ Sir Robert's observation of widespread use was an understatement; more than 800,000 Macintosh blades have been produced, and many special-purpose versions have been marketed.

These clever innovations may have failed to capture wide attention because intubating laryngoscopes lacked a wide market at a time when there were fewer than 100 anesthesiologists active in the United States. Many of those practitioners never attempted intubation throughout their career. Even after 1940, in some hospitals laryngologists were routinely called to intubate surgical patients while the attending anesthesiologist confined his attention to the anesthetic. In time, however, all anesthesiologists would learn the skills of atraumatic nasal and oral intubation by using the instruments and techniques developed by a few British and North American specialists.

The most distinguished pioneer of tracheal intubation was a self-trained British anaesthetist, Ivan (later, Sir Ivan) Magill.⁵⁹ In 1919, when serving in the Royal Army as a general medical officer, Magill was assigned to a military hospital near London. Although he had only a medical student's training in anesthesia, Magill was obliged to accept an assignment to the anesthesia service, where he was joined by another neophyte, Stanley Rowbotham.⁶⁰ They attended casualties disfigured by severe facial injuries who underwent repeated restorative operations. These procedures would be successful only if the surgeon, Harold Gillies, had unrestricted access to the face and airway. Some patients were formidable challenges, but both men became extraordinarily adept. Because they learned from fortuitous observations, they soon extended the scope of tracheal anesthesia.

Magill and Rowbotham's expertise with blind nasal intubation began after they learned to soften semirigid insufflation tubes that they passed through a nostril. Even though they originally planned to position the tips of the tubes only in the posterior pharynx, the slender tubes occasionally entered the trachea. Stimulated by this chance experience, they developed techniques of deliberate nasotracheal intubation. In 1920, Magill devised an aid to manipulating the catheter tip, the Magill angulated forceps, which are still manufactured according to his original design of 75 years ago.

After entering civilian practice, Magill set out to develop a wide-bore tube that would resist kinking but could be curved into a form resembling the contours of the upper airway. While in a hardware store, he found mineralized red rubber tubing which he cut, beveled, and smoothed to produce tubes that clinicians in all countries would come to call "Magill tubes." His tubes remained the universal standard for more than 40 years until rubber products were supplanted by inert plastics. Magill also rediscovered the advantage of applying cocaine to the nasal mucosa, a technique that he employed in developing his mastery of awake blind nasal intubation.

Magill's success in performing awake blind nasal intubation of the trachea excited the curiosity of other anaesthetists. Magill shared his principles at meetings attended by the few specialists in anesthesia, but few colleagues ever matched his control of the airway until muscle relaxants were introduced. Throughout much of his distinguished career, he continued to create new devices. Magill's innovations included tracheal tubes for children, an L-shaped laryngoscope, a tracheoscope, and a wire-tipped endobronchial tube for thoracic surgery.

In 1926, unaware of the prior work of Eisenmenger and Dorrance, Arthur Guedel began a series of experiments that led to the introduction of the cuffed tube.* His goal was to combine the safety of tracheal anesthesia with the safety and economy of the closed-circuit technique, recently refined by his close friend, Ralph Waters.⁶¹ Guedel transformed the basement of his Indianapolis home into a laboratory, where he subjected each step of the preparation and application of his cuffs to a vigorous review.⁶² He fashioned cuffs from the rubber of dental dams, condoms, and surgical gloves that were glued onto the outer wall of tubes. Using animal tracheas donated by the family butcher as his model, he considered whether the cuff should be positioned above, below, or at the level of the vocal cords. He recommended that the cuff be positioned just below the vocal cords to seal the airway and to prevent an accumulation of fluid below the cords but above the cuff. Ralph Waters later recommended that cuffs be constructed of two layers of soft rubber cemented together. These detachable cuffs were first manufactured by Waters' children, who sold

them to the Foregger Company.

Guedel sought ways to show the safety and utility of the cuffed tube. He first filled the mouth of an anesthetized and intubated patient with water and showed that the cuff sealed the airway. Even though this exhibition was successful, he searched for a more dramatic technique to capture the attention of those unfamiliar with the advantages of intubation. He reasoned that if the cuff prevented water from entering the trachea of an intubated patient, it should also prevent an animal from drowning, even if it were submerged under water. To encourage physicians attending a medical convention to use tracheal techniques, Guedel prepared the first of several “dunked dog” demonstrations (Fig. 1-8). An anesthetized and intubated dog, Guedel's own pet, “Airway,” was immersed in an aquarium. After the demonstration was completed, the anesthetic was discontinued before the animal was removed from the water. Airway awoke promptly, shook water over the onlookers, saluted a post, then trotted from the hall to the applause of the audience. By this novel demonstration, the cuffed tube gained wider use.

Figure 1-8. “The dunked dog.” Arthur Guedel demonstrated the safety of endotracheal intubation with a cuffed tube by submerging his anesthetized pet, Airway, in an aquarium while the animal breathed an ethylene–oxygen anesthetic through an underwater Waters' “to-and-fro” anesthesia circuit.

Endobronchial Tubes—The Next Step

Talented observers may recognize a therapeutic opportunity when presented with what at first appears to be a frustrating complication. After a patient experienced an accidental endobronchial intubation, Ralph Waters reasoned that a very long cuffed tube could be used to ventilate the dependent lung while the upper lung was being resected.⁶³ On learning of his friend's success with intentional one-lung anesthesia, Arthur Guedel proposed an important modification for chest surgery, the double-cuffed single-lumen tube, which was introduced by Emery Rovenstine. These tubes were easily positioned, an advantage over bronchial blockers that had to be inserted by a skilled bronchoscopist.

Following World War II, several double-cuffed single-lumen tubes were used for thoracic surgery, but after 1953, these were supplanted by double-lumen endobronchial tubes. The double-lumen tube currently most popular was designed by Frank Robertshaw of Manchester, England, and is prepared in both right- and left-sided versions. Robertshaw tubes were first manufactured from mineralized red rubber but are now made of extruded plastic, a technique refined by David Sheridan. Sheridan was also the first person to embed centimeter markings along the side of tracheal tubes, a safety feature that reduced the risk of the tube's being incorrectly positioned.

New Devices for Airway Management

Conventional laryngoscopes proved inadequate for some patients with a “difficult airway.” Two decades ago, if frustrated in intubating a patient whose airway was unexpectedly found to be difficult to visualize, clinicians fervently prayed for an instrument that would resolve their difficulty by permitting them to “look around the corner” or “create a space where no space exists.” A few clinicians credit harrowing experiences as their incentive for invention. The challenge of reintubating a patient hemorrhaging into the tissues of the neck following carotid endarterectomy led Cedric Bainton to devise the four-sided Bainton blade that “creates a space” by displacing edematous tissue to provide a direct view of previously obscured vocal cords. Roger Bullard desired a device to “look around the corner” when frustrated in attempts to visualize the larynx of a patient with Pierre-Robin syndrome. In response, he developed the Bullard laryngoscope, whose fiberoptic bundles lie beside a curved blade. The passage of flexible fiberoptic bronchoscopes has been aided by “intubating airways” such as those designed by Berman, Ovassapian, Augustine, Williams, Luomanen, and Patil. Patients requiring continuous oxygen administration during fiberoptic bronchoscopy may breathe through the Patil face mask, which features a separate orifice through which the scope is advanced. The Patil face mask is only one of an extensive series of aides to intubation created by the innovative “Vijay” Patil.

Dr. A. I. J. “Archie” Brain is respected by all clinician-inventors for his perseverance in creating the laryngeal mask airway (LMA). Dr. Brain first recognized the principle of the LMA in 1981 when, like many British clinicians, he provided dental anesthesia *via* a Goldman nasal mask. However, unlike any before him, he realized that just as the dental mask could be fitted closely about the nose, a comparable mask attached to a wide-bore tube might be positioned around the larynx. He not only conceived of this radical departure in airway management, which he first described in 1983,⁶⁴ but also spent years in single-handedly fabricating and testing scores of incremental modifications. Scores of Brain's prototypes are displayed in the Royal Berkshire Hospital, Reading, England, where they provide a detailed record of the evolution of the LMA. He fabricated his first models from Magill tubes and Goldman masks, then refined their shape by performing postmortem studies of the hypopharynx to determine the form of cuff that would be most functional. Before silicone rubber was selected, Brain had even mastered the technique of forming masks from liquid latex. Every detail of the LMA—the number and position of the aperture bars, the shape and the size of the masks—required repeated modification. Every clinician who has studied the Reading collection of LMA prototypes has gained a profound appreciation for Dr. Brain's achievement.

The Evolution of Inhaled Anesthetics During the Twentieth Century

As the mechanisms to deliver drugs were refined, entirely new classes of medications were also developed, with the intention of providing safer, more pleasant pain control. Ether and chloroform, the cornerstones of effective anesthesia for decades, were perceived as imperfect drugs. Ether was unpleasant to inhale; chloroform was shown to have serious toxic effects on the liver and heart. Both gases were volatile and were challenging to store and administer. Ethylene gas was the first alternative to ether and chloroform, but it too had major disadvantages. The rediscovery of ethylene in 1923 also came from an unlikely observation. After it was learned that ethylene gas had been used in Chicago greenhouses to inhibit the opening of carnation buds, it was speculated that a gas that put flowers to sleep might also have an anesthetic action on humans. Arno Luckhardt was the first to publish a clinical study in February 1923. Within a month, two other independent studies were presented, by Isabella Herb in Chicago and W. Easson Brown in Toronto. Ethylene was not a successful anesthetic because high concentrations were required and it was explosive. An additional significant shortcoming was a particularly unpleasant smell, which could only be partially disguised by the use of oil of orange or a cheap perfume. When cyclopropane was introduced, ethylene was abandoned.

There was a fortuitous element in the discovery of cyclopropane's anesthetic action in 1929.⁶⁵ W. Easson Brown and Velyien Henderson had previously shown that propylene had desirable properties as an anesthetic when freshly prepared; but after storage in a steel cylinder, it deteriorated to create a toxic material that produced nausea and cardiac irregularities in humans. Henderson, a professor of pharmacology at the University of Toronto, suggested to a chemist, George Lucas, that the toxic product be identified. After Lucas identified cyclopropane among the chemicals in the tank, the chemist prepared a sample in low concentration with oxygen and administered it to two kittens. The animals fell asleep quietly and recovered rapidly. Lucas saw that, rather than being a toxic contaminant, cyclopropane was a very potent anesthetic. After its effects in other animals were studied and cyclopropane proved to be stable after storage, human experimentation began.

Henderson was the first volunteer; Lucas followed. They then arranged a public demonstration in which Frederick Banting, already a Nobel laureate for his discovery of insulin, was anesthetized before a group of physicians. Despite this promising beginning, further research was abruptly halted for an illogical reason. The professor of surgery argued that since there had been three anesthetic deaths in Toronto attributed to ethyl chloride, no clinical trials of cyclopropane would be allowed despite its apparent safety. Rather than abandon the study, Velyien Henderson encouraged an American friend, Ralph Waters, to use cyclopropane at the University of Wisconsin. The Wisconsin group investigated the drug thoroughly and reported their clinical success in 1933. The slow pace of their research was due to the paucity of funding during the Great Depression.

By coincidence, external interference also frustrated the clinical trials of the first anesthetic to be created deliberately from a pharmacologist's knowledge of structure–activity relationships. In 1930, Chauncey Leake and MeiYu Chen performed successful laboratory trials of vinethene (divinyl ether) but were thwarted in its further development by a professor of surgery in San Francisco. Ironically, Canadians, who had lost cyclopropane to Wisconsin, learned of vinethene from Leake and

Chen in California and conducted the first human study in 1932 at the University of Alberta, Edmonton.

All potent anesthetics of this period were explosive save for chloroform, whose hepatic and cardiac toxicity limited its use in America. Anesthetic explosions remained a rare but devastating risk to both anesthesiologist and patient. To reduce the danger of explosion during the incendiary days of World War II, British anaesthetists turned to trichloroethylene. This noninflammable anesthetic found limited application in America, as it decomposed to release phosgene when warmed in the presence of soda lime. By the end of World War II, however, another class of noninflammable anesthetics was prepared for laboratory trials. Ten years later, fluorinated hydrocarbons revolutionized inhalation anesthesia.

Fluorinated Anesthetics

Fluorine, the lightest and most reactive halogen, forms exceptionally stable bonds. These bonds, although sometimes created with explosive force, resist separation by chemical or thermal means. For that reason, many early attempts to fluorinate hydrocarbons in a controlled manner were frustrated by the marked chemical activity of fluorine. In 1930, the first commercial application of fluorine chemistry was made in the production of a refrigerant, Freon. This was followed by the first attempt to prepare a fluorinated anesthetic, by Harold Booth and E. May Bixby in 1932. Although their drug, monochlorodifluoromethane, was devoid of anesthetic action, as were all other drugs produced by other investigators during that decade, their report accurately forecasts future developments. It began, "A survey of the properties of 166 known gases suggested that the best possibility of finding a new noncombustible anesthetic gas lay in the field of organic fluoride compounds. Fluorine substitution for other halogens lowers the boiling point, increases stability, and generally decreases toxicity."⁶⁶

The secret demands of the Manhattan Project for refined uranium-235 were the next impetus to an improved understanding of fluorine chemistry. Researchers learned that uranium might be refined through the creation of an intermediate compound, uranium hexafluoride. Part of this project was undertaken by Earl McBee of Purdue University, who had a long-standing interest in the fluorination of hydrocarbons. McBee also held a grant from the Mallinckrodt Chemical Works, a manufacturer of ether and cyclopropane, to prepare new fluorinated compounds, which were to be tested as anesthetics. By 1945, the Purdue team had created small amounts of 46 fluorinated ethanes, propanes, butanes, and an ether.

The value of these chemicals might not have been appreciated, however, if Mallinckrodt had not also provided financial support for pharmacology research at Vanderbilt University. At that time, the Vanderbilt anesthesia department was unique in that its first chairperson was a pharmacologist, Benjamin Robbins, who could assess the drugs more effectively than could any other anesthesiologist of that period. Robbins tested McBee's compounds in mice and selected the most promising for evaluation in dogs. Although none of these compounds found a place as an anesthetic, Robbins' conclusions on the effects of fluorination, bromination, and chlorination in his landmark report of 1946 encouraged later studies that would prove to be successful.⁶⁷

A team at the University of Maryland under Professor of Pharmacology John C. Krantz, Jr., investigated the anesthetic properties of dozens of hydrocarbons over a period of several years, but only one, ethyl vinyl ether, entered clinical use in 1947. Because it was inflammable, Krantz requested that it be fluorinated. In response, Julius Shukys prepared several fluorinated analogs. One of these, trifluorethyl vinyl ether, or fluoxene, became the first fluorinated anesthetic. Fluoxene was marketed from 1954 until 1974. As the drug was marginally inflammable, fluoxene had already been supplanted by more potent agents when it was withdrawn as a consequence of the delayed discovery of the action of a metabolite that was toxic to lower animals. Fluoxene is important not only for its historical interest as the first fluorinated anesthetic but also as a reminder of the importance of the continual surveillance of a drug's action—a process in which all clinicians play a significant role each day.⁶⁸

While American researchers were conducting a rather random search for new anesthetics, a team of British chemists applied a more direct approach. In 1951, Charles Suckling, a chemist of Imperial Chemical Industries who already had an expert understanding of fluorination, was asked to create a new anesthetic. Suckling began by asking clinicians to describe the properties of an ideal anesthetic. He learned from this inquiry that his search must consider several limiting factors, including the volatility, inflammability, stability, and potency of the compounds. Within 2 years, Charles Suckling created halothane. As a reflection of the planning that he had carried out beforehand, halothane was the sixth compound synthesized.

The limited number of chemicals produced for testing reflected Suckling's expert knowledge of the pharmacology of halogens and his ability to appreciate important physical relationships that apply to all anesthetics. His achievement was an extension of a principle that had been recognized in 1939 by his superior, James Ferguson, which Ferguson later learned had first been considered by John Snow in 1848. The principle was to relate the opioid actions of known anesthetics along a thermodynamic scale—the ratio of the partial pressure producing anesthesia over the saturated vapor pressure of the drug at the temperature of the experiment. The resulting ratios fall within a very narrow range, as opposed to the more than 200-fold variations seen when anesthetics are graphed by the inspired concentration required for anesthesia.⁶⁹

Suckling first determined that halothane had an anesthetic action by anesthetizing meal worms and houseflies before he forwarded it to a pharmacologist, James Raventos, along with an accurate prediction, based on Ferguson's principles, of the concentration that would be required for anesthesia in higher animals. After Raventos completed a favorable review, halothane was offered to Michael Johnstone, a respected anesthetist of Manchester, England, who recognized its great advantages over the other anesthetics available in 1956.

Halothane was followed in 1960 by methoxyflurane, an anesthetic that was popular until 1970. At that time, a dose-related nephrotoxicity following protracted methoxyflurane anesthesia was found to be caused by inorganic fluoride, released by the enzymatic cleavage of a monofluoro-carbon bond. As a consequence and because of a persisting concern that rare cases of hepatitis following anesthesia might be due to a metabolite of halothane, the search for newer inhaled anesthetics focused on the resistance of the molecule to metabolic degradation.

Two fluorinated liquid anesthetics, enflurane and its isomer isoflurane, were results of the search for increased stability. They were synthesized by Ross Terrell in 1963 and 1965, respectively. Because enflurane was easier to create, it preceded isoflurane. Its application was restricted after it was shown to be a marked cardiovascular depressant and to have some convulsant properties. Isoflurane was nearly abandoned because of difficulties in its purification, but after this problem was overcome by Louise Speers, a series of successful trials was published in 1971. The release of isoflurane for clinical use was delayed again for more than half a decade by calls for repeated testing in lower animals, owing to an unfounded concern that the drug might be a carcinogen. As a consequence, isoflurane was more thoroughly assessed before being offered to anesthesiologists than any other drug heretofore used in anesthesia. The era when an anesthetic could be introduced following a single fortuitous observation has given way to a cautious program of assessment and reassessment before a new inhaled agent, such as desflurane or sevoflurane, is advocated in routine practice.

Intravenous Anesthetics

A firm understanding of the circulation, along with adequate intravenous (iv) access, was necessary before drugs could be administered directly into a patient's bloodstream. Both of these aspects were firmly in place well before an appropriate iv anesthetic was devised. In 1909, a German, Ludwig Burkhardt, produced surgical anesthesia by intravenous injections of chloroform and ether. Seven years later, Elisabeth Bredenfeld of Switzerland reported the use of intravenous morphine and scopolamine. Those trials failed to show an improvement over inhaled techniques. None of the drugs had an action that was both prompt and sufficiently abbreviated.

The first barbiturate, barbital, was synthesized in 1903 by Fischer and von Mering. Phenobarbital and all other successors of barbital had very protracted action and found little use in anesthesia. After 1929, oral pentobarbital was used as a sedative before surgery, but when it was given in anesthetic concentrations, long periods of unconsciousness followed. The first short-acting oxybarbiturate was hexobarbital (Evipal), used clinically in 1932. Hexobarbital was enthusiastically received in Britain and America because its abbreviated induction time was unrivaled by any other technique. A London anesthetist, Ronald Jarman, found that it had a dramatic advantage over inhalation inductions for minor procedures. Jarman developed the "falling arm" sign. Immediately before induction, the patient was instructed to raise one arm above his head while Jarman injected hexobarbital into a vein of the opposite forearm. As soon as the upraised arm fell, indicating the onset of hypnosis, the surgeon began. Although this technique is now known to be hazardous, it was welcomed in 1933. Patients were also pleased by the barbiturates, because the onset of their action was so abrupt that many awoke unable to believe they had been anesthetized.*

Even though hexobarbital's prompt action had a dramatic effect on the conduct of anesthesia, it was soon replaced by two thiobarbiturates. In 1932, Donalee Tabern and Ernest H. Volwiler of the Abbott Company synthesized thiopental (Pentothal) and thiamylal (Surital). The sulfated barbiturates proved to be more satisfactory, potent, and rapid-acting than were their oxybarbiturate analogs. Thiopental was first administered to a patient at the University of Wisconsin in March 1934, but the successful introduction of thiopental into clinical practice was due to John S. Lundy and his colleagues at the Mayo Clinic, who began their intensive and protracted assessments of thiopental during June 1934.

When first introduced, thiopental was often given in repeated increments as the primary anesthetic for protracted procedures. Its hazards came to be appreciated over time. At first, depression of respiration was monitored by the simple expedient of observing the motion of a wisp of cotton placed over the nose. Only a few skilled practitioners were prepared to pass a tracheal tube if the patient stopped breathing. Such practitioners realized that thiopental without supplementation did not suppress airway reflexes, and they therefore encouraged the prophylactic provision of topical anesthesia of the airway beforehand. The cardiovascular effects of thiobarbiturates were widely appreciated only when the powerful vasodilating effect of thiopental caused fatalities among burned civilian and military casualties in World

War II. In response, fluid replacement was used more aggressively and thiopental administered with greater caution.

Muscle Relaxants

Many anesthesiologists regard the introduction of curare as being among the most important advances in anesthesia since the discovery of ether's action in 1846. Anesthesiologists who practiced before muscle relaxants came into use recall the terror they felt when a premature attempt to intubate the trachea under cyclopropane caused persisting laryngospasm. Before 1942, abdominal relaxation was possible only if the patient tolerated high concentrations of an inhaled anesthetic, which might bring profound respiratory depression and protracted recovery. Curare and the drugs that followed transformed anesthesia profoundly. Before this time, tracheal anesthesia was an art reserved for the expert; now it became a skill that all anesthesiologists could acquire. Because intubation of the trachea could now be taught in a deliberate manner, a neophyte could fail on a first attempt without compromising the safety of the patient. For the first time, abdominal relaxation could be attained when curare was supplemented by light planes of inhaled anesthetics or by a combination of intravenous agents providing "balanced anesthesia." New frontiers opened. A sedated and paralyzed patient could now undergo the major physiologic trespasses of cardiopulmonary bypass and deliberate hypothermia, and might receive long-term respiratory support after surgery.

The curares are alkaloids prepared from plants native to equatorial rain forests. The refinement of the harmless sap of several species of vines into toxins that were lethal only when injected was an extraordinary triumph introduced by paleopharmacologists in loincloths. Their discovery was the more remarkable because it was independently repeated on three separate continents—South America, Africa, and Asia. These jungle tribes also developed nearly identical methods of delivering the toxin by darts, which, after being dipped in curare, maintained their potency indefinitely until they were propelled through blowpipes to strike the flesh of monkeys and other animals of the treetops.

Curare was used in surgery in 1912, but the report was ignored for decades. Arthur Lawen, a physiologist/physician of Leipzig, used curare in his laboratory before boldly producing abdominal relaxation at a light level of anesthesia in a surgical patient. His report, written in German, was not appreciated for decades, nor could it have been until his fellow clinicians learned the skills of intubation of the trachea and controlled ventilation of the lungs.⁷¹

Curare remained a curiosity of laboratory practice until 1938 when Richard and Ruth Gill returned to New York from South America. They had collected 11.9 kg of crude curare near their Ecuadorian ranch for the Merck Company. Their motivation was a mixture of personal and altruistic goals. Some months before, while on an earlier visit to the United States, Richard Gill had been told by Dr. Walter Freeman that he had multiple sclerosis. Freeman mentioned that there was a possibility that curare might have a therapeutic role in the management of spastic disorders. When the Gills returned to the United States with their supply of crude curare, they were initially disappointed to learn that Merck's researchers had lost interest, but they were later able to share the curare with E. R. Squibb & Co. Squibb scientists soon offered a semirefined curare to two groups of American anesthesiologists, who assessed its action but soon abandoned their studies when it caused total respiratory paralysis in two patients and the death of laboratory animals.

Curare first entered clinical medicine through the actions of psychiatrists. In 1939, A. R. McIntyre refined a portion of Gill's curare. A. E. Bennett of Omaha, Nebraska, initially injected it into children with spastic disorders. After observing no persisting benefit, he administered it to patients about to receive metrazol, a precursor to electroconvulsive therapy. Because it eliminated seizure-induced fractures, they termed it a "shock absorber." By 1941, other psychiatrists followed this practice and, when they found that the action of curare was protracted, occasionally used neostigmine as an antidote.

Some months later, Harold Griffith, the chief anesthetist of the Montreal Homeopathic Hospital, learned of Bennett's successful use of curare and resolved to apply it in anesthesia. As Griffith was already a master of tracheal intubation, he was much better prepared than were most of his contemporaries to attend to potential complications. On January 23, 1942, Griffith and his resident, Enid Johnson, anesthetized and intubated the trachea of a young man before injecting curare early in the course of his appendectomy. Satisfactory abdominal relaxation was obtained as the surgery proceeded without incident. Griffith and Johnson's report of the successful use of curare in the 25 patients of their series launched a revolution in anesthetic care.⁷²

The successful use of curare prompted other studies that led to the introduction of other nondepolarizing and depolarizing relaxants. By 1948, gallamine and decamethonium had been synthesized. Metubine, a curare "rediscovered" in the 1970s, was used clinically in the same year. Succinylcholine was prepared by the Nobel laureate Daniel Bovet in 1949 and was in wide international use before historians noted that the drug had been synthesized and tested long beforehand. In 1906, Hunt and Taveaux prepared succinylcholine among a series of choline esters, which they had injected into rabbits to observe their cardiac effects. If their rabbits had not been previously paralyzed with curare, the depolarizing action of succinylcholine might have been known decades earlier.

Research in relaxants was rekindled in 1960, when researchers became aware of the action of maldetine, a relaxant from the Congo basin. It was remarkable in that it had a steroidal nucleus. Investigations of maldetine led to pancuronium and vecuronium. As these drugs provided new avenues for investigation, the pace of muscle relaxant research has accelerated.

Drugs After 1945

During the first decades following World War II, other classes of drugs were developed. Anesthesiologists learned a new vocabulary as words were coined to describe the actions of novel compounds. "Lytic cocktails," "dissociative anesthesia," and "neuroleptanalgesia" became common expressions. Intravenous mixtures concocted from a succession of analgesics and anxiolytics produced a state of euphoria, tranquility, and indifference when provided with care, or profound respiratory depression when presented carelessly. In 1966, the neologism "dissociative anesthesia" was created by Guenter Corssen and Edward Domino to describe the trance-like state of profound analgesia produced by ketamine. "Neuroleptanalgesia" was coined by a Belgian anesthesiologist, Juan de Castro, who performed the first clinical investigations of combinations of tranquilizers and opioids, synthesized under the direction of Paul Janssen.

Although many pharmacologists are remembered for the introduction of a single drug, Paul Janssen has brought more than 70 agents forward from among 70,000 chemicals created in his laboratory since 1953. His products have had profound effects on disciplines as disparate as parasitology and psychiatry. The pace of productive innovation in Janssen's research laboratory has been astonishing. Chemical R4263 (fentanyl), synthesized in 1960, was followed only a year later by R4749 (droperidol). Although the fixed combination (Innovar) in which they were introduced, is now less popular, Janssen's opioids, sufentanil and alfentanil, have come into common use.

Several induction agents have been brought forward to challenge the preeminence of thiopental. Of these only propofol has found great success. After its synthesis by Imperial Chemical Industries as ICI 35 868, it was first employed in clinical trials in 1977. Investigators found that it produced hypnosis quickly with minimal excitation and that patients awoke promptly once the drug was discontinued. Regrettably, cremaphor, the solvent with which it was formulated, was unsatisfactory. Once propofol was reformulated with egg lecithin, glycerol, and soybean oil, the drug gained great success. As it entered clinical practice in Britain almost coincidentally with the introduction of the LMA, it was soon noted that propofol suppressed pharyngeal reflexes to a degree that permitted the insertion of the LMA without a need for either muscle relaxants or potent inhaled anesthetics.

THE EVOLUTION OF PROFESSIONAL ANESTHESIOLOGY

Anesthesiology evolved slowly as a medical specialty in the United States in part because of the presence of a second group of anesthesia care providers, nurse anesthetists. During the late 19th century, small communities were often served by a single physician, who assigned a nurse to "drop" ether under his direction. In larger towns, doctors practiced independently and did not welcome being placed in what they perceived to be the subordinate role of anesthetist while their competitors enhanced their surgical reputations and collected the larger fees. Many American surgeons recalled the simple techniques they had practiced as junior house officers and regarded anesthesia as a technical craft that could be left to anyone. Some hospitals preferred to pay a salary to an anesthesia nurse while gaining a profit from the fees charged for that person's services. The most compelling argument to be advanced in favor of nurse anesthesia was that of skill: a trained nurse who administered anesthetics every working day was to be preferred to a physician who gave anesthesia only rarely.

Before the beginning of the 20th century, Mary Botsford and Isabella Herb were among the first Americans to become specialists in anesthesia. Both women were highly regarded as clinicians and also were influential in the formation of specialty societies. Dr. Mary Botsford is believed to have been the first woman to establish a practice as a specialist in anesthesia. In 1897, she became the anesthesiologist at a children's hospital in San Francisco. Following her example, several other Californian female physicians entered the specialty. Botsford later received the first academic appointment in anesthesia in the western United States when she became Clinical Professor of Anesthesia at the University of California, San Francisco. Botsford also served as the president of the Associated Anesthetists of the United States and Canada.

One of the first physicians to actually declare himself a "specialist in anesthesia" was Sydney Ormond Goldan of New York, who published seven articles in 1900, including an early description of the use of cocaine for spinal anesthesia. After studying Goldan's early career, Raymond Fink recognized in him some of the qualities of many modern anesthesiologists: "He was brimful of enthusiasm for anesthesia, an excellent communicator and a prolific writer, a gadgeteer and the owner of several patents of anesthesia equipment."⁷³ At a time when many surgeons considered that spinal anesthesia did away with their need for an anesthesiologist, Goldan was

particularly bold in his written opinions. He called for equality between surgeon and anesthesiologist and was among the first to state that the anesthesiologist had a right to establish and collect his own fee. Goldan regarded the anesthesiologist as being more important than the surgeon to the welfare of the patient. His forthright pronouncements may not have been well received, for he was not listed among the nine founding members of the Long Island Society of Anesthetists when the nation's first specialty society was founded on October 6, 1905, with annual dues of \$1.00.

Since the training of physician anesthetists around the turn of the century lacked uniformity, many prominent surgeons preferred nurse anesthetists and directed the training of the most able candidates they could recruit. The Mayo brothers' personal anesthetist was Alice Magaw. George W. Crile relied on the skills of Agatha Hodgins. During World War I, Agatha Hodgins, Geraldine Gerrard, Ann Penland, and Sophie Gran were among the more than 100 nurse anesthetists who attended thousands of American and Allied casualties in France. On their return to the United States, many developed schools of nurse anesthesia.⁷⁴ Physician anesthetists sought to obtain respect among their surgical colleagues by organizing professional societies and improving the quality of training.

Organized Anesthesiology

After 1911, the annual fee rose to \$3.00 when the Long Island Society became the New York Society of Anesthetists. Although the new organization still carried a local title, it drew members from several states and had a membership of 70 physicians in 1915. A second society with roots in the Midwest became the short-lived American Association of Anesthetists, which, by 1915, became the Interstate Association of Anesthetists. Almost all of the approximately 100 professional anesthesiologists in America belonged to both societies.

One of the most noteworthy figures in the struggle to professionalize anesthesiology was Francis Hoffer McMechan. McMechan had been a practicing anesthesiologist in Cincinnati until 1911, when he suffered a severe first attack of rheumatoid arthritis, which was to leave him confined to a wheelchair, and forced his retirement from the operating room in 1915. McMechan had been in practice only fifteen years, but he had written eighteen clinical articles in this short time. A prolific researcher and writer, McMechan did not permit his crippling disease to sideline his career. Instead of pursuing goals in clinical medicine, he applied his talents to establishing anesthesiology societies.⁷⁵

McMechan supported himself and his devoted wife through editing the *Quarterly Supplement* from 1914 until August 1922, when he became editor of the first journal devoted to anesthesia, *Current Researches in Anesthesia and Analgesia*, the precursor of *Anesthesia and Analgesia*, the oldest journal of the specialty. As well as fostering the organization of the International Anesthesia Research Society (IARS) in 1925, Francis and his wife Laurette McMechan became overseas ambassadors of American anesthesia. Since Laurette was French, it was understandable that McMechan combined his own ideas about anesthesiology with concepts from abroad.⁷⁶

In 1926, McMechan held the Congress of Anesthetists in a joint conference with the Section on Anaesthetics of the British Medical Association. Subsequently, he traveled throughout Europe, giving lectures and networking physicians in the field. Upon his final return to America, he was gravely ill and was confined to bed for two years. His hard work and constant travel paid dividends, however: in 1929, the IARS, which McMechan founded in 1922, had members not only from North America, but from several European countries, Japan, India, Argentina, and Brazil.⁷⁷

In the 1930s, McMechan expanded his mission from organizing anesthesiologists to promoting the academic aspects of the specialty. In 1931, work began on what would become the International College of Anesthetists. This body began to award fellowships in 1935. For the first time, physicians were recognized as specialists in anesthesiology. The certification qualifications were universal, and fellows were recognized as specialists in several countries. Although the criteria for certification were not strict, the College was a success in raising the standards of anesthesia practice in many nations. In 1939, McMechan finally succumbed to illness, and the anesthesia world lost their tireless leader.

Other Americans participated in the promotion of organized anesthesiology. Ralph Waters participated in the evolving anesthesia society; his greatest contribution to the specialty was raising its academic standards. After completing his internship in 1913, he entered medical practice in Sioux City, Iowa, where he gradually limited his practice to anesthesia. His personal experience and extensive reading were supplemented by the only postgraduate training available, a 1-month course conducted in Ohio by E. I. McKesson. At that time, the custom of becoming a self-proclaimed specialist in medicine and surgery was not uncommon. Waters, who was frustrated by low standards and who would eventually have a great influence on establishing both anesthesia residency training and the formal examination process, recalled that before 1920, "The requirements for specialization in many midwestern hospitals consisted of the possession of sufficient audacity to attempt a procedure and persuasive power adequate to gain the consent of the patient or his family."⁷⁸

In an effort to improve anesthetic care, Waters regularly corresponded with Dennis Jackson and other scientists. In 1925, he relocated to Kansas City with a goal of gaining an academic post at the University of Kansas, but the professor of surgery failed to support his proposal. The larger city did allow him to initiate his freestanding outpatient surgical facility, "The Downtown Surgical Clinic," which featured one of the first postanesthetic recovery rooms. In 1927, Erwin Schmidt, professor of surgery at the University of Wisconsin's medical school, encouraged Dean Charles Bardeen to recruit Waters.

In accepting the first American academic position in anesthesia, Waters described four objectives that have been since adopted by many other academic departments. His goals were as follows: "(1) to provide the best possible service to patients of the institution; (2) to teach what is known of the principles of Anesthesiology to all candidates for their medical degree; (3) to help long-term graduate students not only to gain a fundamental knowledge of the subject and to master the art of administration, but also to learn as much as possible of the effective methods of teaching; (4) to accompany these efforts with the encouragement of as much cooperative investigation as is consistent with achieving the first objectives."⁷⁹

Ralph Waters' personal and professional qualities impressed talented young men and women who sought residency posts in his department. He encouraged residents to initiate research interests in which they collaborated with two pharmacologists whom Waters had known previously, Arthur Loevenhart and Chauncey Leake, as well as others with whom he became associated in Madison. Clinical concerns were also investigated. As an example, anesthesia records were coded onto punch cards to form a data base that was used to analyze departmental activities. Morbidity and mortality meetings, now a requirement of all training programs, also originated in Madison. They were attended by members of the department and distinguished visitors from other centers. As a consequence of their critical reviews of the conduct of anesthesia, responsibility for an operative tragedy gradually passed from the patient to the physician. In more casual times, a practitioner could complain, "The patient died because he did not take a good anesthetic." Alternatively, the death might be attributed to a mysterious force such as "status lymphaticus," of which Arthur Guedel, a master of sardonic humor, observed, "Certainly status lymphaticus is at times a great help to the anesthetist. When he has a fatality under anesthesia with no other cleansing explanation he is glad to recognize the condition as an entity."⁷⁹ Through the instruction received from Ralph Waters and his colleagues, anesthesiologists in training learned to accept responsibility for their actions by realizing that the fault often was the responsibility of the provider and not the patient who was denied a voice in the clinical debate.

The University of Wisconsin became a regular destination for other specialists. In 1929, Ralph Waters helped organize the Anesthesia "Travel Club," whose members were leading American or Canadian teachers of anesthesia. Each year one member was the host for a group of 20 to 40 anesthesiologists who gathered for a program of informal discussions. There were demonstrations of promising innovations for the operating room and laboratory, which were all subjected to what is remembered as a "high-spirited, energetic, critical review." Even during the lean years of the Depression, international guests also visited. For Geoffrey Kaye of Australia, Torsten Gordth of Sweden, Robert Macintosh and Michael Nosworthy of England, and scores of others, Waters' department was their "mecca of anesthesia." It soon became the model for other academic departments in Europe, South America, and Asia.

Ralph Waters trained 60 residents during the 22 years he was the "chief." From 1937 onward, the alumni, who declared themselves the "Aqualumni" in his honor, returned annually for a professional and social reunion. Thirty-four "Aqualumni" took academic positions, and, of these, 14 became chairpersons of departments of anesthesia. They maintained Waters' professional principles and encouraged teaching careers for many of their own graduates. Sixty-five years after Waters arrived in Madison, more than 80 chairpersons or former chairpersons of academic departments could trace their professional lineage back to Ralph Waters. A great majority of the departments of anesthesia with residency programs in the United States have faculty members who were trained in a department led by a professional "descendant" of Ralph Waters.⁸⁰ His enduring legacy was once recognized by the dean who had recruited him in 1927, Charles Bardeen, who observed, "Ralph Waters was the first person the University hired to put people to sleep, but, instead, he awakened a world-wide interest in anesthesia."

Waters also had an important role in establishing organized anesthesia. He energetically supported the growth of physician anesthesia organizations. He supported Paul Wood's drive to give the pre-eminent New York Society of Anesthetists a title reflecting its national role. In 1936, the American Society of Anesthetists was formed from the New York Society in an effort to show the American Medical Association (AMA) that a national anesthesia society favored certification of specialists in the field. Combined with the American Society of Regional Anesthesia, whose president was Emery Rovenstein, the American Board of Anesthesiology (ABA) was organized as a subordinate board to the American Board of Surgery. With McMechan's death in 1939, the AMA favored independence for the ABA largely through the efforts of John Lundy. In 1940, independence was granted.

A few years later, the officers of the American Society of Anesthetists were challenged by Dr. M. J. Seifert, who wrote, "An Anesthetist is a technician and an Anesthesiologist is the specific authority on anesthesia and anesthetics. I cannot understand why you do not term yourselves the American Society of Anesthesiologists."⁸¹ Ralph Waters was declared the first president of the newly named ASA in 1945. In that year, when World War II ended, 739 (37%) of 1977 ASA

members were in the armed forces. In the same year, the ASA's first Distinguished Service Award (DSA) was presented to Paul M. Wood for his tireless service to the specialty, one element of which can be examined today in the extensive archives preserved in the Society's Wood Library Museum at ASA headquarters, Park Ridge, Illinois.⁸²

After World War II, specialties within the realm of anesthesiology began to thrive. Kathleen Belton was a superb pediatric specialist. In 1948, while working in Montreal, Belton and her colleague, Digby Leigh, wrote the classic text, *Pediatric Anesthesia*. At the same time, a second pediatric anesthesiologist, Margot Deming, was the Director of Anesthesia at the Children's Hospital of Philadelphia. Pediatric anesthesia also figured in the career of Doreen Vermeulen-Cranch, who had earlier initiated thoracic anesthesia in The Netherlands and pioneered hypothermic anesthesia. Obstetric anesthesia also figured prominently in the career of Virginia Apgar. After encountering severe financial and professional frustrations during her training and while serving as Director of the Division of Anesthesia at Columbia University, Apgar turned to obstetric anesthesia in 1949. She dedicated the next decade of her multifaceted career to the care of mothers and their infants.⁸³

THE SCOPE OF MODERN ANESTHESIOLOGY

This overview of the development of anesthesiology could be extended almost indefinitely by an exploration of each sub-specialty area, but an assessment of our current roles can be seen by a personal survey of the areas in which anesthesiologists serve in hospitals, clinics, and laboratories. The operating room and obstetric delivery suite remain the central interest of most specialists. Aside from being the location where the techniques described in this chapter find regular application, service in these areas brings us into regular contact with new advances in pharmacology and bioengineering.

After surgery, patients are transported to the postanesthesia care unit or recovery room, an area that is now considered the anesthesiologist's "ward." Fifty years ago, patients were carried directly from the operating room to a surgical ward to be attended only by a junior nurse. That person lacked both the skills and equipment to intervene when complications occurred. After the experiences of World War II taught the value of centralized care, physicians and nurses created recovery rooms, which were soon mandated for all major hospitals. By 1960 the evolution of critical care progressed through the use of mechanical ventilators. Patients who required many days of intensive medical and nursing management were cared for in a curtained corner of the recovery room. In time, curtains drawn about one or two beds gave way to fixed partitions and the relocation of those areas to form intensive care units. The principles of resuscitative and supportive care established by anesthesiologists transformed critical care medicine.

The future of anesthesiology is a bright one. The safer drugs that once revolutionized the care of patients undergoing surgery are constantly being improved upon. The role of the anesthesiologist continues to broaden, as physicians with backgrounds in the specialty have developed clinics for chronic pain control and outpatient surgery. Anesthesia practice will continue to increase in scope, both inside and outside of the operating suite, such that anesthesiologists will become an integral part of the entire perioperative experience.

* Deceased.

* Nineteenth-century "anesthetists" in America became 20th-century "anesthesiologists," but their British and Canadian counterparts (unchallenged by competition from nurses) remained "anaesthetists." The author of this chapter has adhered to this distinction.

* Guedel never recorded how he came to create his black rubber airway, but the event that precipitated the design of its most popular successor, the Berman airway, is known. In 1948, Robert Berman was shocked to observe a safety pin resting in his patient's pharynx as he removed a Guedel airway. He realized that the pin must have been dislodged from within the airway and so set about bivalving other airways to find other foreign bodies hidden from view. In response, he designed an open-sided airway that could be cleaned under direct vision. A friend fabricated the Berman airway from cellulose acetate butyrate and so created the first molded plastic anesthesia device.

* Soon after Evipal was introduced, Robert Macintosh administered it to Sir William Morris, the manufacturer of the Morris Garages (MG) automobiles. Macintosh secured a result that later changed the course of anesthesia.⁷⁰ When Morris awoke, he glanced at his watch and inquired as to why the operation had been postponed. On learning that his surgery was completed, he was amazed by this "magic experience," which he contrasted with his vivid recollections of the terror of undergoing a mask induction as a child in a dentist's office. So impressed was Morris (later, Viscount Nuffield) with the quality of anesthetic he had received and the potential for further discovery, that he insisted, over the objections of Oxford's medical establishment, on endowing a department of anesthesia for the university as a precondition of his support for a postgraduate medical center. In 1937, Sir Robert Macintosh became Oxford's first professor of anesthesiology and led the growth of the first university department in Europe from the first fully endowed Chair of Anaesthesia in the world. Fifty years later, on July 24, 1987, when the Nuffield Department of Anaesthetics celebrated its Golden Jubilee, Sir Robert greeted alumni who had returned from scores of countries. Morris' "magic experience" of barbiturate anesthesia had led to a result beyond his imagining—the creation of one of the world's most distinguished anesthesia centers.

The enormous changes in the practice of medicine that accelerated in the late 1990s are continuing in 2000. These changes have been occurring so quickly that treatises on practice management require constant updating. As a result, issues related to the mechanics, details, and finances of practice are demanding more attention and effort than at any previous time. Further, anesthesiologists traditionally have been little involved in the management of many components of practice that are beyond the strictly medical elements of applied physiology and pharmacology, pathophysiology, and therapeutics. This was, perhaps, somewhat understandable because anesthesiologists traditionally spent the vast majority of their time in a hospital operating room (OR) and thus were usually free of the concerns of running an office and managing a busy office-based practice. Very little formal teaching of or training in practice management of any kind occurred in anesthesiology residency programs. Word-of-mouth handing down of what was mostly folklore was often all an anesthesiology resident had to go on after completing training and beginning practice. Interestingly in this regard, the Anesthesiology Residency Review Committee of the Accreditation Council on Graduate Medical Education now requires that the didactic curricula of anesthesiology residencies include material on practice management. Today, most residency programs offer at least a cursory introduction to issues of practice management, but these can be insufficient to prepare satisfactorily the resident being graduated for the real business challenges of the practice of anesthesiology.

This chapter presents a wide variety of topics that, until very recently, were not in anesthesiology textbooks. Several basic components of the administrative, organizational, and financial aspects of anesthesiology practice are outlined. Included is mention of some of the issues associated with practice arrangements in the modern environment increasingly dominated by managed care. Although many of these issues are undergoing almost constant change, it is important to understand the basic vocabulary and principles of this dynamic field. Lack of understanding of these issues may put anesthesiologists at a disadvantage when attempting to forge practice arrangements and, particularly, lobby for a fair fraction of the fully capitated prospective payment health care dollar.

COMPONENTS COMMON TO ALL ANESTHESIOLOGY PRACTICES

Basic Operational Understandings

Practice arrangements and their implications for anesthesiology personnel are perceived as increasingly more important as medical care administration and reimbursement receive more scrutiny and emphasis. Certain basic underpinnings, albeit only a few, are very unlikely to face fundamental challenge. The American Society of Anesthesiologists (ASA) for many years has provided resource material to its members regarding practice in general and arrangements for its execution. These are updated regularly by the ASA through its committees and then its House of Delegates. Although these documents contain broad-brush generalities that must be interpreted in each individual's situation, they nonetheless stand as a solid foundation on which anesthesiology practice is based. In the past, many anesthesiologists were unaware of the existence of these resources and discovered them only when referred to them during an appeal to the ASA for help in resolving some significant practice problem. Prospective familiarity with these principles likely will help avoid some of the problems leading to calls for help. Further, many anesthesiologists do not know that, if members of the ASA, they receive copies of these and many related documents annually, because they are reprinted in the back of the ASA Directory of Members. A separate compilation of these and often very helpful related documents can be purchased.¹ The current atmosphere in American medicine, which creates the impression that "all of a sudden all the rules and understandings are changing," makes it virtually mandatory that anesthesiologists be familiar with the fundamental background of their profession. The ASA Guidelines for the Ethical Practice of Anesthesiology includes sections on the principles of medical ethics; the definition of medical direction of nonphysician personnel (including the specific statement that an anesthesiologist engaged in medical direction should not personally be administering another anesthetic); the anesthesiologist's relationship to patients and other physicians; the anesthesiologist's duties, responsibilities, and relationship to the hospital; and the anesthesiologist's relationship to nurse anesthetists and other nonphysician personnel. Further, the ASA publishes The Organization of an Anesthesia Department, and states through it that the ASA "has adopted a Statement of Policy, which contains principles that the Society urges its members to consider in structuring their own individual medical practices." This document has sections on physician responsibilities for medical care and on medicoadministrative organization and responsibilities. The ASA has been particularly proactive in helping its members keep up with rapidly changing areas of managed care and practice management, and now sponsors regular conferences specifically devoted to these issues. Additionally, practice management is becoming a regular feature of ASA regional refresher courses and of the annual meeting's refresher courses. In the past, some (probably many) anesthesiology residents finishing training felt unprepared, in a business and organizational sense, to enter the job market and had to learn through a self-taught crash course during negotiations for a position, sometimes to their detriment. Reference to the considerable body of material created and presented by the ASA (see also the section on [Practice Arrangements](#)) is a good starting point to help young anesthesiologists during residency to prepare for the increasing rigors of starting a career in the practice of anesthesiology.

The Internet

As of the advent of the year 2000, the Internet has become an important feature of many people's lives. Specifically, through the World Wide Web, more information is readily accessible to essentially any person at any location than at any other time in history. Anesthesiologists are no exception to this phenomenon, and, in fact, may utilize this means of information exchange more than other practitioners. Most anesthesiology societies now have Web locations, as do most journals. Several journals that exist only on the Internet are now in existence, and more are being rapidly developed. Electronic bulletin boards allow anesthesiology practitioners from around the world to immediately exchange ideas on diverse topics, both medical and administrative. Additionally, the body of medical literature is readily accessible to any practitioner, and it is reasonable to assume that practitioners may be held to a higher standard regarding knowledge of the latest published data, which may affect anesthesia practice. Even a superficial overview of the Internet and anesthesiology practice is far outside the scope of this chapter. A modern anesthesiology practice, however, cannot reasonably exist without an Internet connection. Numerous resources are available for further information on the Internet and anesthesiology, including books and journals dedicated specifically to this topic. The "gasnet" (www.gasnet.org) is one World Wide Web site that is particularly helpful. The Web site of

the ASA (www.asahq.org) is also a good starting point, as is the site of the Anesthesia Patient Safety Foundation (www.apsf.org).

The Credentialing Process and Clinical Privileges

The system of credentialing a health care professional and granting clinical privileges is motivated by a fundamental assumption that appropriate education, training, and experience, along with the absence of excessive numbers of poor patient outcomes, increase the chances that the individual will deliver acceptable-quality care. As a result, the systems have received considerably increased emphasis in recent years. The process of credentialing health care professionals has been the focus of considerable public attention (particularly in the mass media), in part the result of very rare incidents of untrained persons (impostors) infiltrating the health care system and sometimes harming patients. The more common situation, however, involves health professionals who exaggerate past experience and credentials or fail to disclose adverse past experiences. There has been some justified publicity concerning physicians who lost their licenses sequentially in several states and simply moved on each time to start practice elsewhere (which should be much, much more difficult now).

The patient–physician relationship also has changed radically, with a concomitant increase in suspicion directed toward the medical profession. There is now a pervasive public perception that physicians are inadequately policed, particularly by their own professional organizations and hospitals. Intense public and political pressure has been brought to bear on various law-making bodies, regulatory and licensing agencies, and health care institution administrations to discover and purge both (1) fraudulent, criminal, and deviant health care providers, and (2) incompetent or simply poor-quality practitioners whose histories show sufficient poor patient outcomes to attract attention, usually through malpractice suits. Identifying and avoiding or correcting an incompetent practitioner is the goal. Verification of appropriate education, training, and experience on the part of a candidate for a position rendering anesthesia care assumes special importance in light of the legal doctrine of *vicarious liability*, which can be described as follows: if an individual, group, or institution hires an anesthesia provider or even simply approves of that person (e.g., by granting clinical privileges through a hospital medical staff), those involved in the decision may later be held liable in the courts, along with the individual, for the individual's actions. This would be especially true if it were later discovered that the offending practitioner's past adverse outcomes had not been adequately investigated during the credentialing process.

Out of these various long-standing concerns has arisen the sometimes cumbersome process of obtaining state licenses to practice and of obtaining hospital privileges. It is somewhat analogous to passing through screening and metal detection devices at airports, which is tolerated by the individual in the interest of the safety of all. The stringent credentialing process is intended both to protect patients and to safeguard the integrity of the medical profession. Recently, central credentialing systems have been developed, including those affiliated with the American Medical Association, American Osteopathic Association, and the Federation of State Medical Boards. Perhaps one credentialing entity will become a virtual "universal metal detector" to make the process simpler while maintaining stringent standards and verification mechanisms. At this time, however, these have yet to be fully developed or universally accepted, and the current cumbersome system remains in force in most instances.

There are checklists of the requirements for the granting of medical staff privileges by hospitals.^{2,3} In addition, the National Practitioner Data Bank and reporting system administered by the U.S. government now has several years' worth of information in it. This data bank is a central repository of licensing and credentials information about physicians. Many adverse situations involving a physician—particularly instances of substance abuse, malpractice litigation, or the revocation, suspension, or limitation of that physician's license to practice medicine or to hold hospital privileges—must be reported (via the state board of medical registration/licensure) to the National Practitioner Data Bank. It is a statutory requirement that all applications for hospital staff privileges be cross-checked against this national data bank. The potential medicolegal liability on the part of a facility's medical staff, and the anesthesiology group in particular, for failing to do so is staggering. The Data Bank, however, is not a complete substitute for direct documentation and background checking. Often, practitioners reach negotiated solutions following medical staff problems, thereby avoiding the mandatory reporting. That is, a suspect physician may be given the option to resign medical staff privileges and avoid Data Bank reporting, rather than undergo full involuntary privilege revocation.

The documentation for the credentialing process for each anesthesia practitioner must be complete. Privileges to administer anesthesia must be officially granted and delineated in writing.^{1,2} This can be straightforward (and there are good models offered by the ASA⁴); or it can be more complex to accommodate institutional needs to identify practitioners qualified to practice in designated anesthesia subspecialty areas such as cardiac, infant/pediatric, obstetric, intensive care, or pain management. Specific documentation of the process of granting or renewing clinical privileges is required and, unlike some other records, the documentation is protected as confidential peer review information under the Federal Health Care Quality Improvement Act of 1986. A related 1988 U.S. Supreme Court decision questioning this confidentiality involved a case that occurred in 1981. The 1986 federal law is constructed so that it still applies now, even in light of the 1988 decision.

Verification of credentials and experience is mandatory. Because of another type of legal case, some examples of which have been highly publicized, medical practitioners may be hesitant to give an honest evaluation (or any evaluation at all) of individuals known to them who are seeking a professional position elsewhere. Obviously, someone writing a reference for a current or former co-worker should be honest. Sticking to clearly documentable facts is advisable. Stating a fact that is in the public record (such as a malpractice case lost at trial) should not justify an objection from the subject of the reference. Whether omitting such a fact is dishonest on the part of the reference writer is more of a gray area. Including positive opinions and enthusiastic recommendations, of course, is no problem. Some fear that including facts that may be perceived as negative (e.g., the lost malpractice case or personal problems such as a history of treatment for substance abuse) and negative opinions will provoke retaliatory lawsuits (such as for libel, defamation of character, or loss of livelihood) from the subject. As a result, many reference writers in these questionable situations confine their written material to brief, simple facts such as dates employed and position held.

Because there should be no hesitation for a reference writer to include positive opinions, receipt of a reference that includes nothing more than dates worked and position held should be a suggestion that there may be more to the story. Receipt of such a reference about a person applying for a position should always lead to a telephone call to the writer. A telephone call may be advisable in all cases, independent of whatever the written reference contains. Frequently, pertinent questions over the telephone can elicit more candid information. In rare instances, there may be dishonesty through omission by the reference giver even at this level. This may involve an applicant who an individual, a department or group, or an institution would like to see leave. The subject may have poor-quality practice, but there may also be reluctance by the reference giver(s) to approach licensing or disciplinary authorities (because of the unpleasantness and also out of concern about retaliatory legal action). This type of "sandbagging" is fortunately infrequent. The best way to avoid it is to telephone an independent observer or source (such as a former employer or associate who no longer has a personal stake in the applicant's success) when any question exists. Because the ultimate goal is optimum patient care, the subjects applying for positions generally should not object to such calls being made. Discovery of a history of unsafe practices and/or habits or of causing preventable anesthesia morbidity or mortality should elicit careful evaluation as to whether the applicant can be appropriately assigned, trained, and/or supervised to be maximally safe in the proposed new environment.

In all cases, new personnel in an anesthesia practice environment must be given a thorough orientation and checkout. Policy, procedures, and equipment may be unfamiliar to even the most thoroughly trained, experienced, and safe practitioner. This may occasionally seem tedious, but it is both sound and critically important safety policy. Being in the midst of a crisis situation caused by unfamiliarity with a new setting is not the optimal orientation session.

After the initial granting of clinical privileges to practice anesthesia, anesthesiologists must periodically renew their privileges within the institution or facility (e.g., annually or every other year). There are moral, ethical, and societal obligations on the part of the privilege-granting entity to take this process seriously. State licensing bodies often become aware of problems with health professionals very late in the evolution of the difficulties. An anesthesia provider's peers in the hospital or facility are much more likely to notice untoward developments as they first appear. However, privilege renewals are often essentially automatic and receive little of the necessary attention. Judicious checking of renewal applications and awareness of relevant peer review information is absolutely necessary. The physicians or administrators responsible for evaluating staff members and reviewing their practices and privileges may be justifiably concerned about retaliatory legal action by a staff member who is censured or denied privilege renewal. Accordingly, such evaluating groups must be thoroughly objective (totally eliminating any hint of political or financial motives) and must have documentation that the staff person in question is in fact practicing below the standard of care. Court decisions have found liability by a hospital, its medical staff group, or both when the incompetence of a staff member was known or should have been known and was not acted upon.³

A major issue in the granting of clinical privileges, especially in procedure-oriented specialties such as anesthesiology, is whether it is reasonable to continue the common practice of "blanket" privileges. This process in effect authorizes the practitioner to attempt any treatment or procedure normally considered within the purview of the applicant's medical specialty. These considerations may have profound political and economic implications within medicine, such as which type of surgeon should be doing carotid endarterectomies or lumbar discectomies. More important, however, is whether the practitioner being evaluated is qualified to do everything traditionally associated with the specialty. Specifically, should the granting of privileges to practice anesthesia automatically approve the practitioner to handle pediatric cardiac cases, critically ill newborns (such as a day-old infant with a large diaphragmatic hernia), ablative pain therapy (such as an alcohol celiac plexus block under fluoroscopy), high-risk obstetric cases, and so forth? This question raises the issue of procedure-specific or limited privileges. The quality assurance (QA) and risk management considerations in this question are weighty if inexperienced or insufficiently qualified practitioners are allowed or even expected, because of peer or scheduling pressures, to undertake major challenges for which they are not prepared. The likelihood of complications will be higher, and the difficulty of defending the practitioner against a malpractice claim in the event of catastrophe will be significantly increased.

There is no clear answer to the question of procedure-specific credentialing and granting of privileges. Ignoring issues regarding qualifications to undertake complex and challenging procedures has clear negative potential. On the other hand, stringent procedure-specific credentialing is impractical in smaller groups, and in larger groups encourages many small "fiefdoms," with a consequent further atrophy of the clinical skills outside of the practitioner's specific areas. Each anesthesia

department or group needs to address these issues. At the very least, the common practice of every applicant for privileges (new or renewal) checking off every line on the printed list of anesthesia procedures should be reviewed. Additionally, board certification is now essentially a standard of quality assurance of the minimum skills required for the consultant practice of anesthesiology. Subspecialty boards, such as those in pain management, critical care, and transesophageal echocardiography further objectify the credentialing process. This will become even more significant in the year 2000, when newly issued board certification by the American Board of Anesthesiology will become time-limited and subject to periodic testing and recertification. Finally, the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) mandates a minimum of 150 hours of AMA category 1 continuing medical education every three years for anesthesiologists. Documentation of meeting this standard again acts as a quality assurance mechanism for the individual practitioner, while providing another objective credentialing measurement.

Medical Staff Participation and Relationships

All medical care facilities and practice settings depend on their medical staffs, of course, for daily activities of the delivery of health care; but, very importantly, they also depend on those staffs to provide administrative structure and support. Medical staff activities are increasingly important in achieving favorable accreditation status (e.g., from the JCAHO) and in meeting a wide variety of governmental regulations and reviews. Principal medical staff activities involve sometimes time-consuming efforts, such as duties as a staff officer or committee member. Anesthesiologists should be participants in—in fact, should play a significant role in—credentialing, peer review, tissue review, transfusion review, OR management, and medical direction of same-day surgery units, postanesthesia care units (PACUs), intensive care units (ICUs), and pain management units. Also, it is very important that anesthesiology personnel be involved in fund-raising activities, benefits, community outreach projects sponsored by the facility, and social events of the facility staff.

The role these and related activities play in anesthesia practice management may not be obvious at first glance, but this is a reflection of the unfortunate fact that, all too often, anesthesiologists have chosen to have very little or no involvement in such efforts. Of course, there are exceptions in specific settings. However, it is an unmistakable reality that anesthesiologists as a group have a reputation for lack of involvement in medical staff and facility issues due to lack of interest. In fact, anesthesiology personnel are all too often perceived as the ones who slip in and out of the facility anonymously (dressed very casually or even in the pajama-like comfort of scrub suits) and virtually unnoticed. This is an unfortunate state of affairs, and it is starting to come back to haunt those who have not been involved, or even noticed. Anesthesiology personnel sometimes respond that the demands for anesthesiology service are so great that they simply never have the time or the opportunity to become involved. If this is really true, it is likely that more providers of anesthesia care are needed.

In any case, anesthesiologists simply must make the time to be involved in medical staff affairs, both in health care facilities and as part of the organization, administration, and governance of the comparatively large multispecialty physician groups that provide entities with which managed care organizations (MCOs) and health care facilities can negotiate for physician services. The types and styles of these organizations vary widely and are discussed extensively below. The point here is simple. If anesthesiologists are not involved and not perceived as interested, dedicated “team players,” they will be shut out of critical negotiations and decisions. Although the most obvious instance in which others will make decisions for anesthesiologists is the distribution of capitated fee income collected by a central “umbrella” organization, there are many such situations; and anesthesiologists will have to comply with the resulting mandates. In the most basic terms, absence from the bargaining table and/or being seen as not involved in the welfare of the large group virtually ensure that anesthesiologists will not receive their “fair share of the pie.”

Similarly, involvement with a facility, a medical staff, or a multispecialty group goes beyond formal organized governance and committee activity. Collegial relationships with physicians of other specialties and with administrators are central to maintenance of a recognized position and avoidance of the situation of exclusion described above. Being readily available for formal and informal consults, particularly regarding preoperative patient workup and the maximally efficient and certain way to get surgeons' patients to the OR in a timely, expedient manner, is extremely important. No one individual can be everywhere all the time, but an anesthesiology group or department should strive to be always responsive to any request for help from physicians or administrators. It often appears that anesthesiologists underappreciate just how great a positive impact a relatively simple involvement (starting an intravenous line for a pediatrician, helping an internist manage an ICU ventilator, or helping a facility administrator unclog a jammed recovery room) may have. Unfortunately, anesthesiologists in a great many locations have a negative stereotype to overcome and must work to maintain the perception that they deserve an equal voice regarding the impact of the current changes in the health care system.

Establishing Standards of Practice and Understanding the Standard of Care

Given all the current and future changes in the anesthesiology practice environment, it is more important than ever that anesthesiologists genuinely understand what is expected of them in their clinical practice. The increasing frequency of “production pressure,”⁵ with the tacit (or even explicit) directive to anesthesia personnel to “go fast” no matter what and to “do more with less,” creates situations in which anesthesiologists may conclude that they must cut corners and compromise maximally safe care just to stay in business. This type of pressure has become even greater with the implementation of more and more protocols or parameters for practice, some from professional societies such as the ASA and some mandated by or developed in conjunction with purchasers of health care (insurance companies or MCOs). Many of these protocols are devised to fast-track patients through the medical care system, especially when an elective procedure is involved, in as absolutely little time as possible, thus minimizing costs. Do these fast-track protocols constitute standards of care that health care providers are mandated to implement? What are the implications of doing so? Of not doing so?

To better understand answers to such questions, it is important to have a basic background in the concept of the *standard of care*. Anesthesiology personnel are fortunate in this regard because for at least a decade American anesthesiology has been recognized as one of the significant leaders in establishing practice standards intended to maximize the quality of patient care and help guide personnel at times of difficult decisions, including the risk–benefit and cost–benefit decisions of specific practices. Another important component of this issue is the unique legal system in the United States, in which the potential liability implications of most decisions must be considered. Businesses, groups, and individuals have had their entire public existences destroyed by staggering legal settlements and judgments allowed by the U.S. legal system. Major attempts at reform of this system have occurred and will continue to occur. However, although a very positive restructuring of the tort liability system could alleviate some of the catecholamine-generating “sword over the head” mentality exhibited by some physicians, it will not relieve anesthesiology personnel of the responsibility to provide maximally safe care for their patients. Integration of systems and protocols to help maximize the quality of patient care, whether from formal standards or not, is an important component of managing an anesthesiology practice.

The *standard of care* is the conduct and skill of a prudent practitioner that can be expected by a reasonable patient. This is a very important medicolegal concept because a bad medical result due to failure to meet the standard of care is malpractice. Extensive discussions have attempted to establish exactly the applicable standard of care. Courts have traditionally relied on medical experts knowledgeable about the point in question to give opinions as to what is the standard of care and if it has been met in an individual case. This type of standard is somewhat different from the standards promulgated by various standard-setting bodies regarding, for example, the color of gas hoses connected to an anesthesia machine or the inability to open two vaporizers on that machine simultaneously. However, ignoring the equipment standards and tolerating an unsafe situation is a violation of the standard of care. Promulgated standards, such as the various safety codes and anesthesia machine specifications, rapidly become the standard of care because patients (through their attorneys, in the case of an untoward event) expect the published standards to be observed by the prudent practitioner.

Understanding the concept of the standard of care is the key to integrating the numerous standards, guidelines, practice parameters, and suggested protocols applicable to American anesthesiology practice in the unfortunately necessary constant undercurrent of concern about potential legal liability. Ultimately, the standard of care is what a jury says it is. However, it is possible to anticipate, at least in part, what knowledge and actions will be expected. There are two main sources of information as to exactly what is the expected standard of care. Traditionally, the beliefs offered by expert witnesses in medical liability lawsuits regarding what was being done in real life (*de facto* standards of care) were the main input juries had in deciding what was reasonable to expect from the defendant. The resulting problem is well known: except in the most egregious cases, it is usually possible for the lawyers to find experts who will support each of the two opposing sides, making the process more subjective than objective. (Because of this, there are even official ASA Guidelines for Expert Witness Qualifications and Testimony.⁶) Of course, there can be legitimate differences of opinion among thoughtful, insightful experts, but even in these cases the jury still must decide who is more believable, looks better, or sounds better. The second, much more objective, source for defining certain component parts of the standard of care has developed over the past decade or so in anesthesiology. It is the published standards of care, guidelines, practice parameters, and protocols now becoming more common. These serve as hard evidence of what can be reasonably expected of practitioners and can make it easier for a jury evaluating whether a malpractice defendant failed to meet the applicable standard of care. Several types of documents exist and have differing implications.

Anesthesiology may be the medical specialty most involved with published standards of care. It has been suggested that the nature of anesthesia practice (having certain central critical functions relatively clearly defined and common to all situations and having an emphasis on technology) makes it the most amenable of all the fields of medicine to the use of published standards. The original intraoperative monitoring standards⁷ are a classic example. The ASA first adopted its own set of basic intraoperative monitoring standards in 1986 and has modified them several times (Table 2-1). This document includes clear specifications for the presence of personnel during an anesthetic episode and for continual evaluation of oxygenation, ventilation, circulation, and temperature. The rationale for these monitoring standards is simple; it was felt that functionally mandating certain behaviors oriented toward providing the maximum possible warning of threatening developments during an anesthetic should help minimize intraoperative catastrophic patient injury. These ASA monitoring standards very quickly became part of the accepted standard of care in anesthesia practice. This means they are important to practice management because they have profound medicolegal implications: a catastrophic accident occurring while the standards are being actively ignored is very difficult to defend in the consequent malpractice suit, whereas an accident that occurs during well-documented full compliance with the standards will automatically have a strong defense because the standard of care was being met. Several states in the United States have made compliance with these ASA standards mandatory under state regulations or even statutes. Various malpractice insurance companies offer discounts on malpractice insurance policy premiums for compliance with these standards, something quite natural to insurers because they are familiar with the idea of managing

known risks to help minimize financial loss to the company. The ASA monitoring standards have been widely emulated in other medical specialties and even in fields outside of medicine. Although there are definite parallels in these other efforts (such as in obstetrics and gynecology), no other group has pursued the same degree of definition.

Table 2-1. AMERICAN SOCIETY OF ANESTHESIOLOGISTS STANDARDS FOR BASIC ANESTHETIC MONITORING

Many of the same management questions that led to the intraoperative monitoring standards have close parallels in the immediate preoperative and postoperative periods in the PACU. With many of the same elements of thinking, the ASA has adopted Basic Standards for Preanesthesia Care (Table 2-2) and Standards for Postanesthesia Care (Table 2-3). For the latter, there was consideration of and collaboration with the very detailed standards of practice for PACU care published by the American Society of Post Anesthesia Nurses (another good example of the sources of standards of care).

Table 2-2. AMERICAN SOCIETY OF ANESTHESIOLOGISTS BASIC STANDARDS FOR PREANESTHESIA CARE

Table 2-3. AMERICAN SOCIETY OF ANESTHESIOLOGISTS STANDARDS FOR POSTANESTHESIA CARE

A slightly different situation exists with regard to the standards for conduct of anesthesia in obstetrics. These standards were originally passed by the ASA in 1988, in the same manner as the other ASA standards, but the ASA membership eventually questioned whether they reflected a realistic and desirable standard of care. Accordingly, the obstetric anesthesia standards were downgraded in 1990 to guidelines (Table 2-4), specifically to remove the mandatory nature of the document. Because there was no agreement as to what should be prescribed as the standard of care, the medicolegal imperative of published standards has been temporarily set aside. From a management perspective, this makes the guidelines no less valuable, because the intent of optimizing care through the avoidance of complications is no less operative. However, in the event of the need to defend against a malpractice claim in this area, it is clear from this sequence of events that the exact standard of care is debatable and not yet finally established. A new ASA document, Practice Guidelines for Obstetrical Anesthesia, of a new type with more detail and specificity as well as an emphasis on the meta-analytic approach was published in 1999.⁸

Table 2-4. AMERICAN SOCIETY OF ANESTHESIOLOGISTS GUIDELINES FOR REGIONAL ANESTHESIA IN OBSTETRICS

The newest type of related document is the practice parameter. This has some of the same elements as a standard of practice but is more intended to guide judgment, largely through algorithms with some element of guidelines, in addition to directing the details of specific procedures as would a formal standard. A good example of a set of practice parameters came some years ago from the cardiologists and addressed the indications for cardiac catheterization. Beyond the details of the minimum standards for carrying out the procedure, these practice parameters set forth algorithms and guidelines for helping to determine under what circumstances and with what timing to perform it. Understandably, purchasers of health care (insurance companies and MCOs) with a strong desire to limit the costs of medical care have great interest in practice parameters as potential vehicles for helping to eliminate “unnecessary” procedures and limit even the necessary ones.

The ASA has been very active in creating and publishing practice parameters. The first published parameter concerned the use of pulmonary artery (PA) catheters.⁹ It

considered the clinical effectiveness of PA catheters, public policy issues (costs and concerns of patients and providers), and recommendations (indications and practice settings). The next month, the ASA Difficult Airway Algorithm was published.¹⁰ This thoughtful document synthesized a strategy summarized in a decision tree diagram for dealing acutely with airway problems. It has great clinical value, and it is reasonable to anticipate that it will be used to help many patients. However, all these documents are readily noticed by plaintiffs' lawyers, the difficult airway parameter from the ASA being an excellent example. An important and so-far undecided question is whether guidelines and practice parameters from recognized entities such as the ASA *define* the standard of care. There is no simple answer. This will be decided over time by practitioners' actions, debates in the literature, mandates from malpractice insurers, and, of course, court decisions. Some guidelines, such as the FDA preanesthetic apparatus checkout, are accepted as the standard of care. There will be debate among experts, but the practitioner must make the decision as to how to apply practice parameters such as those from the ASA. Practitioners have incorrectly assumed that they *must* do everything specified. This is clearly not true, yet there is a valid concern that these will someday be held up as defining the standard of care. Accordingly, prudent attention within the bounds of reason to the principles outlined in guidelines and parameters will put the practitioner in at least a reasonably defensible position, whereas radical deviation from them should be based on obvious exigencies of the situation at that moment or clear, defensible alternative beliefs (with documentation).

The ASA has many other task forces charged with the development of practice parameters. Several aspects of pain management, transesophageal echocardiography, policies for sedation by nonanesthesia personnel, preoperative fasting, and others have been published and will likely have at least the same impact as those noted above.

On the other hand, practice protocols, such as those for the fast-track management of coronary artery bypass graft patients, that are handed down by MCOs or health insurance companies are a different matter. Even though the desired implication is that practitioners must observe (or at least strongly consider) them, they do not have the same implications in defining the standard of care as the other documents. Practitioners must avoid getting trapped. It may well not be a valid legal defense to justify action or the lack of action because of a company protocol. Difficult as it may be to reconcile with the payer, the practitioner still is subject to the classic definitions of standard of care.

The other type of standards associated with medical care are those of the JCAHO, the best-known medical care quality regulatory agency. As noted earlier, these standards were for many years concerned largely with structure (*e.g.*, gas tanks chained down) and process (*e.g.*, documentation complete), but in recent years they have been expanded to include reviews of the outcome of care. JCAHO standards also focus on credentialing and privileges, verification that anesthesia services are of uniform quality throughout an institution, the qualifications of the director of the service, continuing education, and basic guidelines for anesthesia care (need for preoperative and postoperative evaluations, documentation, and so forth). Full JCAHO accreditation of a health care facility is usually for 3 years. Even the best hospitals and facilities receive some citations of problems or deficiencies that are expected to be corrected, and an interim report of efforts to do so is required. If there are enough problems, accreditation can be conditional for 1 year, with a complete reinspection at that time. Preparing for JCAHO inspections involves a great deal of work, but because the standards usually do promote high-quality care, the majority of this work is highly constructive and of benefit to the institution and its medical staff.

Another type of regulatory agency is the peer review organization. Professional standards review organizations (PSROs) were established in 1972 as utilization review/QA overseers of the care of federally subsidized patients (Medicare and Medicaid). Despite their efforts to deal with quality of care, these groups were seen by all involved as primarily interested in cost containment. Various negative factors led to the PSROs' being replaced in 1984 with the peer review organization (PRO).¹¹ There is a PRO in each state, many being associated with a state medical association. The objectives of a PRO include 14 goals related to hospital admissions (*e.g.*, to shift care to an outpatient basis as much as possible) and 5 related to quality of care (*e.g.*, to reduce avoidable deaths and avoidable complications). The PROs comprise full-time support staff and physician reviewers paid as consultants or directors. Ideally, PRO monitoring will discover suboptimal care, and this will lead to specific recommendations for improvement in quality. There is a perception that quality of care efforts are hampered by the lack of realistic objectives and also that these PRO groups, like others before them, will largely or entirely function to limit the cost of health care services.

The practice management implications have become clear. Aside from the as-yet unrealized potential for quality improvement efforts and the occasional denial of payment for a procedure, the most likely interaction between the local PRO and anesthesiology personnel will involve a request for perioperative admission of a patient whose care is mandated to be outpatient surgery. If the anesthesiologist feels, for example, that either (1) preoperative admission for treatment to optimize cardiac, pulmonary, diabetic, or other medical status or (2) postoperative admission for monitoring of labile situations such as uncontrolled hypertension will reduce clear anesthetic risks for the patient, an application to the PRO for approval of admission must be made and vigorously supported. All too often, however, such issues surface a day or so before the scheduled procedure in a preanesthesia screening clinic or even in a preoperative holding area outside the OR on the day of surgery. This will continue to occur until anesthesia providers educate their constituent surgeon community as to what types of associated medical conditions may disqualify a proposed patient from the outpatient (ambulatory) surgical schedule. If adequate notice is given by the surgeon, such as at the time an elective case is booked for the OR, the patient can be seen far enough in advance by an anesthesiologist to allow appropriate planning.

In the circumstance in which the first knowledge of a questionable patient comes 1 or 2 days before surgery, the anesthesiologist can try to have the procedure postponed, if possible, or can undertake the time-consuming task of multiple telephone calls to get the surgeon's agreement, get PRO approval, and make the necessary arrangements. Because neither alternative is particularly attractive, especially from administrative and reimbursement perspectives, there may be a strong temptation to "let it slide" and try to deal with the patient as an outpatient even though this may be questionable. In almost all cases, it is likely that there would be no adverse result. However, the patient would be exposed to an avoidable risk. Both because of the workings of probability and because of the inevitable tendency to let sicker and sicker patients slip by as lax practitioners repeatedly "get away with it" and are lulled into a false sense of security, sooner or later there will be an unfortunate outcome or some preventable major morbidity or even mortality.

The situation is worsened when the first contact with a questionable ambulatory patient is preoperatively on the day of surgery. There may be intense pressure from the patient, the surgeon, or the OR administrator and staff to proceed with a case for which the anesthesia practitioner believes the patient is poorly prepared. The arguments made regarding patient inconvenience and anxiety are valid. However, they should not outweigh the best medical interests of the patient. Although this is a point in favor of screening all outpatients before the day of surgery, the anesthesiologist facing this situation on the day of operation should state clearly to all concerned the reasons for postponing the surgery, stressing the issue of avoidable risk and standards of care, and then help with alternative arrangements (including, if necessary, dealing with the PRO).

Potential liability exposure is the other side of the standard of care issue. Particularly regarding questions of postoperative admission of ambulatory patients who have been unstable in some worrisome manner, it is an extremely poor defense against a malpractice claim to state that the patient was discharged home, only later to suffer a complication because the PRO deemed that operative procedure outpatient and not inpatient surgery. As bureaucratically annoying as it may be, it is a prudent management strategy to admit the patient if there is any legitimate question, thus minimizing the chance for complications, and later haggle with the PRO or directly with the involved third-party payer.

Policy and Procedure

Management of an anesthesiology practice involves business, organizational, and clinical issues. One important organizational point that is often overlooked is the need for a complete policy and procedure manual. Such a compilation of documents is necessary for all practices, from the largest departments covering multiple hospitals to a single-room outpatient facility with one anesthesia provider. Contemplation of this compilation of documents may evoke a collective groan from anesthesiology personnel, and maintaining this manual may be misperceived as a bureaucratic chore. Quite the contrary, such a manual can be extraordinarily valuable, as, for example, when it provides crucial information during an emergency. Some suggestions for the content of this compendium exist, but, at minimum, organizational and procedural elements must be included.

The organizational elements that should be present include a chart of organization and responsibilities that is not just a call schedule but a clear explanation of who is responsible for what functions of the department and when, with attendant details such as expectations for the practitioner's presence within the institution at designated hours, telephone availability, pager availability, the maximum permissible distance from the institution, and so forth. Experience suggests it is especially important for there to be an absolutely clear specification of the availability of qualified anesthesiology personnel for emergency cesarean section, particularly in practice arrangements in which there are several people on call covering multiple locations. Sadly, these issues often are only considered after a disaster has occurred that involved miscommunication and the mistaken belief by one or more people that someone else would take care of a problem.

The organizational component of the policy and procedure manual should also include a clear explanation of the orientation and checkout procedure for new personnel, continuing medical requirements and opportunities, the mechanisms for evaluating personnel and for communicating this evaluation to disaster plans (or reference to a separate disaster manual or protocol), QA activities of the department, and the format for statistical record keeping (number of procedures, types of anesthetics given, types of patients anesthetized, number and types of invasive monitoring procedures, number and type of responses to emergency calls, and the like).

The procedural component of the policy and procedure manual should give both handy practice tips and specific outlines of proposed courses of action for particular circumstances; it also should store little-used but valuable information. Reference should be made to the statements, guidelines, and standards appearing in the back of the ASA's Directory of Members as well as to ASA practice parameters. Also included should be references to or specific protocols for the areas mentioned in the JCAHO standards: preanesthetic evaluation, immediate preinduction re-evaluation, safety of the patient during the anesthetic period, release of the patient from any

PACU, recording of all pertinent events during anesthesia, recording of postanesthesia visits, guidelines defining the role of anesthesia services in hospital infection control, and guidelines for safe use of general anesthetic agents. Other appropriate topics include the following:

1. Recommendations for preanesthesia apparatus checkout, such as from the U.S. Food and Drug Administration (FDA)¹³ (see [Appendixes](#), Chapter 22)
2. Guidelines for minimal monitoring and duration of stay of an infant, child, or adult in the PACU
3. Procedures for transporting patients to/from the OR, PACU, or ICU
4. Policy on ambulatory surgical patients—*e.g.*, screening, use of regional anesthesia, discharge home criteria
5. Policy on evaluation and processing of same-day admissions
6. Policy on recovery room admission and discharge
7. Policy on ICU admission and discharge
8. Policy on physicians responsible for writing orders in recovery room and ICU
9. Policy on informed consent and its documentation
10. Policy on the use of patients in clinical research
11. Guidelines for the support of cadaver organ donors and its termination
12. Guidelines on environmental safety, including pollution with trace gases and electrical equipment inspection, maintenance, and hazard prevention
13. Procedure for change of personnel during an anesthetic
14. Procedure for the introduction of new equipment, drugs, or clinical practices
15. Procedure for epidural and spinal narcotic administration and subsequent patient monitoring (*e.g.*, type, minimum time, nursing units)
16. Procedure for initial treatment of cardiac or respiratory arrest
17. Policy for handling patient's refusal of blood or blood products, including the mechanism to obtain a court order to transfuse
18. Procedure for the management of malignant hyperthermia
19. Procedure for the induction and maintenance of barbiturate coma
20. Procedure for the evaluation of suspected pseudocholinesterase deficiency
21. Protocol for responding to an adverse anesthetic event

Individual departments may add to the above suggestions as dictated by their specific needs. A thorough, carefully conceived policy and procedure manual is a valuable tool. The manual should be reviewed and updated as needed but at least annually, with a particularly thorough review preceding each JCAHO inspection. Each member of a group or department should review the manual at least annually and sign off in a log indicating familiarity with current policies and procedures.

Meetings and Case Discussion

There must be regularly scheduled departmental or group meetings. Although didactic lectures and continuing education meetings are valuable and necessary, there also must be regular opportunities for open clinical discussion about interesting cases and problem cases. Also, the JCAHO requires that there be at least monthly meetings at which risk management and QA activities are documented and reported. Whether these meetings are called case conferences, morbidity and mortality conferences, or deaths and complications, the entire department or group should gather for an interchange of ideas. More recently these gatherings have been called QA meetings. An open review of departmental statistics should be done, including all complications, even those that may appear trivial. Unusual patterns of small events may point toward a larger or systematic problem, especially if they are more frequently associated with one individual practitioner.

A problem case presented at the departmental meeting might be an overt accident, a near accident (critical incident), or an untoward outcome of unknown origin. Honest but constructive discussion, even of an anesthetist's technical deficiencies or lack of knowledge, should take place in the spirit of peer review. The classic question "What would you do differently next time?" is a good way to start the discussion. There may be situations in which inviting the surgeon or the internist involved in a specific case would be advantageous. The opportunity for each type of provider to hear the perspective of another discipline is not only inherently educational, but also can promote communication and cooperation in future potential problem cases.

Records of these meetings must be kept for accreditation purposes, but the enshrining of overly detailed minutes (potentially subject to discovery by a plaintiff's attorney at a later date) may inhibit true educational and corrective interchanges about untoward events. In the circumstance of discussion of a case that seems likely to provoke litigation, it is appropriate to be certain that the meeting is classified as official "peer review" and possibly even invite the hospital attorney or legal counsel from the relevant malpractice insurance carrier.

Support Staff

There is a fundamental need for support staff in every anesthesia practice. Even independent practitioners rely in some measure on facilities, equipment, and services provided by the organization maintaining the anesthetizing location. In large, well-organized departments, reliance on support staff is often very great. The need for adequate staff and the inadvisability of scrimping on critical support personnel to cut costs is obvious. What is often overlooked, however, is a process analogous to that of credentialing and privileges for anesthesiologists, although at a slightly different level. The people expected to provide clinical anesthesia practice support must be qualified and must at all times understand what they are expected to do and how to do it. It is singularly unfortunate to realize only after an anesthesia catastrophe has occurred that basic details of simple work assignments, such as the changing of carbon dioxide absorbent, were routinely ignored. This indicates the need for supervision and monitoring of the support staff by the involved practitioners. Further, such support personnel are favorite targets of cost-cutting administrators who do not understand the function of anesthesia technicians or their equivalent. In the modern era, administrators seem driven almost exclusively by the "bottom line" and cannot appreciate the connection between valuable workers such as these and the "revenue stream." Even though it is obvious to all who work in an OR that the anesthesia support personnel make it possible for there to be patients flowing through the OR, it is their responsibility to convince the facility's fiscal administrator that elimination of such positions is genuinely false economy because of the attendant loss in efficiency, particularly in turning over the room between surgeries. Further, it is also false economy to reduce the number of personnel below that genuinely needed to retrieve, clean, sort, disassemble, sterilize, reassemble, store, and distribute the tools of daily anesthesia practice. Inadequate attention to all these steps truly creates "an accident waiting to happen." When there is threatened loss of budget funding from a health care facility for the salaries of needed anesthesia support personnel, the practitioners involved must not simply stand by and see the necessary functions thrown into a "hit-or-miss" status by a few remaining heavily overburdened workers. Vigorous defense (or initiation of and agitation for new positions if the staff is inadequate) by the anesthesia practitioners should be undertaken, always with the realization that it may be necessary in some circumstances for them to supplement the budget from the facility with some of their practice income to guarantee an adequate complement of competent workers.

Business and organizational issues in the management of an anesthesia practice are also critically dependent on the existence of a sufficient number of appropriately trained support staff. One frequently overlooked issue that contributes to the negative impression generated by some anesthesiology practices centers on being certain there is someone available to answer the telephone at all times during the hours surgeons, other physicians, and OR scheduling desks are likely to telephone. This seemingly trivial component of practice management is important to the success of an anesthesiology practice as a business whose principal customers are the surgeons. Certainly there is a commercial server-client relationship both with the patient and the purchaser of health care; however, the uniquely symbiotic nature of the relationship between surgeons and anesthesiologists is such that availability even for simple "just wanted to let you know" telephone calls is genuinely important. The person who answers the telephone is the representative of the practice to the world and must take that responsibility seriously. From a management standpoint, significant impact on the success of the practice as a business often hinges on such details. Further, anesthesiologists should always have permanent personal electronic pagers to facilitate communications from other members of the department or group and from support personnel. This may sound intrusive, but the unusual position of anesthesiologists in the spectrum of physicians mandates this feature of managing an anesthesiology practice. Anesthesiology personnel should have no hesitation about spending their own practice income to do so. The symbolism is obvious.

Anesthesia Equipment and Equipment Maintenance

Problems with anesthesia equipment have been discussed for some time.^{14,15} However, compared to human error, overt equipment failure very rarely causes intraoperative critical incidents¹⁶ or deaths resulting from anesthesia care.¹⁷ Aside from the obvious human errors involving misuse of or unfamiliarity with the equipment, when the rare equipment failure does occur, it appears often that correct maintenance and servicing of the apparatus has not been done. These issues become the focus of anesthesia practice management efforts because there can often be confusion or even disputes about precisely who is responsible for maintaining the anesthesia equipment—the facility or the practitioners who use it and collect practice income from that activity. In many cases, the facility assumes the responsibility. In situations in which that is not true, however, it is necessary for the practitioners to venture into usually unfamiliar territory.

Programs for anesthesia equipment maintenance and service have been outlined.^{18,19 and 20} A distinction is made between failure due to progressive deterioration of equipment, which should be preventable because it is observable and should provoke appropriate action, and catastrophic failure, which often practically cannot be predicted. Preventive maintenance for mechanical parts is critical and involves periodic performance checks every 4–6 months. Also, an annual safety inspection of each anesthetizing location and the equipment itself is necessary. For equipment service, an excellent mechanism is a relatively elaborate cross-reference system to identify both the device needing service and also the mechanism to secure the needed maintenance or repair.

Equipment handling principles are straightforward. Before purchase, it must be verified that a proposed piece of equipment meets all applicable standards, which will

usually be true when dealing with recognized major manufacturers. On arrival, electrical equipment must be checked for absence of hazard (especially leakage of current) and compliance with applicable electrical standards. Complex equipment such as anesthesia machines and ventilators should be assembled and checked out by a representative from the manufacturer or manufacturer's agent. There are potential adverse medicolegal implications when relatively untrained personnel certify a particular piece of equipment as functioning within specification, even if they do it perfectly. It is also very important to involve the manufacturer's representative in pre- and in-service training for those who will use the new equipment. On arrival, a sheet or section in the master equipment log must be created with the make, model, serial number, and in-house identification for each piece of capital equipment. This not only allows immediate identification of any equipment involved in a future recall or product alert, but also serves as the permanent repository of the record of every problem, problem resolution, maintenance, and servicing occurring until that particular equipment is scrapped. This log must be kept up-to-date at all times. There have been rare but frightening examples of potentially lethal problems with anesthesia machines leading to product alert notices requiring immediate identification of certain equipment and its service status.

Who should maintain and service major anesthesia equipment has been widely debated. There are significant management implications. Equipment setup and checkout have been mentioned. After that, some groups or departments rely on factory service representatives for all attention to equipment, others engage independent service contractors, and still other (often larger) departments have access to personnel (either engineers and/or technicians) in their facility. Needs and resources differ. The single underlying principle is clear: the person(s) doing preventive maintenance and service must be qualified. Anesthesia practitioners may wonder how they can assess these qualifications. The best way is to unhesitatingly ask pertinent questions about the education, training, and experience of those involved, including asking for references and speaking to supervisors and managers responsible for those doing the work. Whether an engineering technician who spent a week at a course at a factory can perform the most complex repairs depends on a variety of factors, which can be investigated by the practitioners ultimately using the equipment in the care of patients. Failure to be involved in this oversight manner exposes the practice to increased liability in the event of an untoward outcome associated with improperly maintained or serviced equipment.

Determining when anesthesia equipment becomes obsolete and should be replaced is another question that is difficult to answer. Replacement of obsolete anesthesia machines and monitoring equipment is a key element of a risk modification program. Ten years is often cited as an estimated useful life for an anesthesia machine, but although an ASA statement repeats that idea, it also notes that the ASA promulgated a Policy for Assessing Obsolescence in 1989 that does not subscribe to any specific time interval. Anesthesia machines considerably more than 10 years old do not meet certain of the safety standards now in force for new machines (such as vaporizer lockout, fresh gas ratio protection, and automatic enabling of the oxygen analyzer) and, unless extensively retrofitted, do not incorporate the new technology that advanced very rapidly during the 1980s, much of it directly related to the effort to prevent untoward incidents. Further, it appears that this technology will continue to advance, particularly due to the adoption of anesthesia workstation standards by the European Economic Union that are expected to affect anesthesia machine design worldwide. Note that some anesthesia equipment manufacturers, anxious to minimize their own potential liability, have refused to support (with parts and service) some of the oldest of their pieces (particularly gas machines) still in use. This disowning of equipment by its own manufacturer is a very strong message to practitioners that such equipment must be replaced as soon as possible.

Should a piece of equipment fail, it must be removed from service and a replacement substituted. Groups, departments, and facilities are obligated to have sufficient backup equipment to cover any reasonable incidence of failure. The equipment removed from service must be clearly marked with a prominent label (so it is not returned into service by a well-meaning technician or practitioner) containing the date, time, person discovering, and the details of the problem. The responsible personnel must be notified so they can remove the equipment, make an entry in the log, and initiate the repair. As indicated in the protocol for response to an adverse event, a piece of equipment involved or suspected in an anesthesia accident must be immediately sequestered and not touched by anybody—particularly not by any equipment service personnel. If a severe accident occurred, it may be necessary for the equipment in question to be inspected at a later time by a group consisting of qualified representatives of the manufacturer, the service personnel, the plaintiff's attorney, the insurance companies involved, and the practitioner's defense attorney. The equipment should thus be impounded following an adverse event and treated similarly to any object in a forensic "chain of evidence," with careful documentation of parties in contact with and responsible for securing the equipment in question following such an event. Also, major equipment problems may, in some circumstances, reflect a pattern of failure due to a design or manufacturing fault. These problems should be reported to the FDA's Medical Device Problem Reporting system via the Device Experience Network (telephone 800-638-6725).²¹ This system accepts voluntary reports from users and requires reports from manufacturers when there is knowledge of a medical device being involved in a serious incident. Whether or not filing such a report will have a positive impact in subsequent litigation is impossible to know, but it is a worthwhile practice management point that needs to be considered in the unlikely but important instance of a relevant event.

Malpractice Insurance

All practitioners need liability insurance coverage specific for the specialty and role in which they are practicing. Premium rates depend on specialty, subspecialty, and whether the insured performs procedures that the insurance company's experience suggests may be more likely to result in a malpractice lawsuit. It is absolutely critical that applicants for medical liability insurance be completely honest in informing the insurer what duties and procedures they perform. Failure to do so, either from carelessness or from a foolishly misguided desire to reduce the resulting premium, may well result in retrospective denial of insurance coverage in the event of an untoward outcome from an activity the insurer did not know the insured engaged in.

Proof of adequate insurance coverage is usually required to secure or renew privileges to practice at a health care facility. The facility may specify certain minimum policy limits to limit its liability exposure. It is difficult to suggest specific dollar amounts for policy limits because the details of practice vary so much among situations and locations. The malpractice crisis of the 1980s has eased significantly for anesthesiologists, largely due to the decrease in number and severity of malpractice claims resulting from anesthesia catastrophes as anesthesia care in the United States became safer.^{22,23} and ²⁴ The exact analysis of this phenomenon can be debated, but it is a simple fact that malpractice insurance premiums for anesthesiologists have not been increased at the same rate as for other specialties over the past several years and, in many cases, have actually decreased. This does not mitigate the need for adequate coverage, however. In the late 1990s, coverage limits of \$1 million/\$3 million would seem the minimum advisable. This specification usually means that the insurer will cover up to \$1 million liability per claim and up to \$3 million per year, but this terminology is not necessarily universal. Therefore, anesthesiology personnel must be absolutely certain what they are buying when they apply for malpractice insurance. In parts of the United States known for a pattern of exorbitant settlements and jury verdicts, liability coverage limits of \$2 million/\$5 million may be prudent and well worth the moderate additional cost. An additional feature in this regard is the potential to employ "umbrella" liability coverage above the limits of the base policy, as noted below.

The fundamental mechanism of medical malpractice insurance has changed significantly in recent years because of the need for insurance companies to have better ways to predict what their losses (amounts paid in settlements and judgments) might be. Traditionally, medical liability insurance was sold on an "occurrence" basis, meaning that if the insurance policy was in force at the time of the occurrence of an incident resulting in a claim, whenever that claim might be filed, the practitioner would be covered. Occurrence insurance was somewhat more expensive than the alternative "claims made" policies, but was seen as worth it by some practitioners. These policies created some open-ended exposure for the insurer that sometimes led to unexpected large losses, even some large enough to threaten the existence of the insurance company. As a result, medical malpractice insurers have converted almost exclusively to claims-made insurance, which covers claims that are filed while the insurance is in force. Premium rates for the first year a physician is in practice are relatively low because there is less likelihood of a claim coming in (a majority of malpractice suits are filed 1–3 years after the event in question). The premiums usually increase yearly for the first 5 years and then the policy is considered mature. The issue comes when the physician later, for whatever reason, must change insurance companies (e.g., because of relocation to another state). If the physician simply discontinues the policy and a claim is filed the next year, there will be no insurance coverage. Therefore, the physician must secure "tail coverage," sometimes for a minimum number of years (e.g., 5) or sometimes indefinitely to guarantee liability insurance protection for claims filed after the physician is no longer primarily covered by the insurance policy. It may be possible in some circumstances to purchase tail coverage from a different insurer than was involved with the primary policy, but by far the most common thing done is to simply extend the existing insurance coverage for the period of the tail. This very often yields a bill for the entire tail coverage premium, which can be quite sizable, potentially staggering a physician who simply wants to move to another state where his existing insurance company is not licensed to do business. The issue of how to pay this premium is appropriately the subject of management attention and effort within the anesthesia practice. Individual situations will vary widely, but it is reasonable for anesthesiologists organized into a fiscal entity to consider this issue at the time of the inception of the group, rather than facing the potentially difficult question of how to treat one individual later. Other strategies have occasionally been employed when insuring the tail period, including converting the previous policy to part-time status for a period of years, and purchasing "nose" coverage from the new insurer—that is, paying an initial higher yearly premium with the new insurer, who then will cover claims that may occur during the tail period.

Another component to the liability insurance situation is consideration of the advisability of purchasing yet another type of insurance called "umbrella coverage," which is activated at the time of the need to pay a claim that exceeds the limits of coverage on the standard malpractice liability insurance policy. Because such an enormous claim is extremely unlikely, many practitioners are tempted to forgo the modest cost of such insurance coverage in the name of economy. As before, it is easy to see that this is potentially a very false economy—if there is a huge claim. Practitioners should consult with their financial managers, but it is likely that it would be considered wise management to purchase umbrella liability insurance coverage.

Medical malpractice insurers are becoming increasingly active in trying to prevent incidents that will lead to insurance claims. They often sponsor risk-management seminars to teach practices and techniques to lessen the chances of liability claims and, in some cases, suggest (or even mandate) specific practices, such as strict observation of the ASA Standards for Basic Anesthetic Monitoring. In return for attendance at such events and/or the signing of contracts stating that the practitioner will follow certain guidelines or standards, the insurer often gives a discount on the liability insurance premium. Clearly, it is sound practice management strategy for practitioners to participate maximally in such programs. Likewise, some insurers make coverage conditional on the consistent implementation of certain strategies such as minimal monitoring, stipulating that the practitioner will not be covered if it is found that the guidelines were being ignored at the time of an untoward event. Again, it

is obviously wise from a practice management standpoint to cooperate fully with such stipulations.

Response to an Adverse Event

In spite of the decreased incidence of anesthesia catastrophes, even with the very best of practice, it is likely that each anesthesiologist at least once in his or her professional life will be involved in a major anesthesia accident. (See “[What to Do When Sued](#),” Chapter 5.) Precisely because such an event is rare, very few are prepared for it. It is probable that the involved personnel will have no relevant past experience regarding what to do. Although an obvious resource is another anesthetist who has had some exposure or experience, one of these may not be available either. Various authors have discussed what to do in that event.^{25,26 and 27} Cooper *et al* have thoughtfully presented the appropriate immediate response to an accident in a straightforward, logical, compact format²⁸ that should periodically be reviewed by all anesthesiology practitioners and should be included in all anesthesia policy and procedure manuals. Unfortunately, however, the principal personnel involved in a significant untoward event may react with such surprise or shock as to temporarily lose sight of logic. At the moment of recognition that a major anesthetic complication has occurred or is occurring, help must be called. A sufficient number of people to deal with the situation must be assembled on site as quickly as possible. For example, in the unlikely but still possible event that an esophageal intubation goes unrecognized long enough to cause a cardiac arrest, the immediate need is for enough skilled personnel to conduct the resuscitative efforts, including making the correct diagnosis and replacing the tube into the trachea. Whether the anesthesiologist apparently responsible for the complication should direct the immediate remedial efforts will depend on the person and the situation. In such a circumstance, it would seem wise for a senior or supervising anesthesiologist quickly to evaluate the scenario and make a decision. This person becomes the incident supervisor and has responsibility for helping prevent continuation or recurrence of the incident, for investigating the incident, and for ensuring documentation while the original and helping anesthesiologists focus on caring for the patient. As noted, involved equipment must be sequestered and not touched.

If the accident is not fatal, continuing care of the patient is critical. Measures may be instituted to help limit damage from brain hypoxia. Consultants may be helpful and should be called without hesitation. If not already involved, the chief of anesthesiology must be notified as well as the facility administrator, risk manager, and the anesthesiologist's insurance company. These latter are critical to allow consideration of immediate efforts to limit later financial loss. (Likewise, there are often provisions in medical malpractice insurance policies that might limit or even deny insurance coverage if the company is not notified of any reportable event immediately.) If there is an involved surgeon of record, he or she probably will first notify the family, but the anesthesiologist and others (risk manager, insurance loss control officer, or even legal counsel) might appropriately be included at the outset. Full disclosure of facts as they are best known—with no confessions, opinions, speculation, or placing of blame—is the best presentation. Any attempt to conceal or shade the truth will later only confound an already difficult situation. Obviously, comfort and support should be offered, including, if appropriate, the services of facility personnel such as clergy, social workers, and counselors.

The primary anesthesia provider and any others involved must document relevant information. Never change any existing entries in the medical record. Write an amendment note if needed with careful explanation of why amendment is necessary, particularly stressing explanations of professional judgments involved. State only facts as they are known. Make no judgments about causes or responsibility and do not “point fingers.” The same guidelines hold true for the filing of the incident report in the facility, which should be done as soon as is practical. Further, all discussions with the patient or family should be carefully documented in the medical record. Also, it is likely that it will be recommended at that time that the involved clinical personnel sit down as soon as practical and write out their own personal notes, which will include opinions and impressions as well as maximally detailed accounts of the events as they unfolded. These personal notes are not part of the medical record or the facility files. If written while the involved person is still in the facility, these notes should be taken out of the facility that same day and, in all circumstances, given immediately to each involved person's attorney, even if this is not the defense attorney secured by the malpractice insurance company. This strategy guarantees that the notes are attorney–client work product, and thus not subject to forced discovery (revelation) by other parties to the case.

Follow-up after the immediate handling of the incident will involve the primary anesthesiologist but should again be directed by a senior supervisor, who may or may not be the same person as the incident supervisor. The follow-up supervisor verifies the adequacy and coordination of ongoing care of the patient and facilitates communication among all involved, especially with the risk manager. Lastly, it is necessary to verify that adequate post-event documentation is taking place.

Of course, it is expected that such an adverse event will be discussed in the applicable morbidity and mortality meeting. This is good and appropriate. It is necessary, however, to coordinate this activity with the involved risk manager and attorney so as to be completely certain that the contents and conclusions of the discussion are clearly considered peer review activity, and thus are shielded from discovery by the plaintiffs' attorney.

Unpleasant as it is to contemplate, it is better to have a plan and execute it in the event of an accident causing injury to a patient. Vigorous immediate intervention may improve the outcome for all concerned.

OPERATING ROOM MANAGEMENT

One of the significant issues for anesthesiologists raised by the many recent changes in the organization of the health care system is that of the most effective, most appropriate role for anesthesiologists. Anesthesiologists are becoming increasingly involved in and oriented to expanded roles beyond exclusive attention to what is and will always be the mainstay of their practice, administering anesthetics for surgery. One of these expanded roles is into OR management. The complexity and demands of organizing a modern operating suite will no longer allow the comparatively casual approach seen in some institutions in the past, in which things were taken care of in reasonable time, but with little attention paid to whether the first case of the day started at 7:30 A.M. or 7:50 A.M., how long it took to assemble the special instruments, or whether there was a brief delay in transporting a patient from the preoperative staging area so that the appropriate paperwork could be completed by the one overworked nurse. The current urgent drive for efficiency, cost control, and cost reduction clearly will not tolerate obvious inefficiency and wastefulness. A cooperative approach to these issues by all involved clearly is desirable. However, it has been demonstrated in real life and taught in management courses that strong leadership is necessary in the efforts to achieve maximum efficiency and cost reduction. Representatives of the key constituent groups—anesthesiologists, surgeons, OR nurses and techs, and (in some cases) professional administrators/managers—clearly can debate the question of who is best qualified to be a leader in a given OR environment. Many OR suites have looked to anesthesiologists to head, or at least be key players on, the leadership team. Of course, the different groups have different perspectives. It is clear, however, that anesthesiologists of necessity see and deal with the “big picture” as much as or more than the others on the team. This ability to achieve an overview is the main reason anesthesiologists are almost uniquely qualified to provide leadership in an OR.

In the past, as noted above, some anesthesiologists have avoided involvement in administrative and leadership roles in their work environment, the OR in particular, for a variety of reasons. This has contributed to the sometimes negative perception of anesthesiologists among other health care professionals and workers as well as facility administrators. Such abdication of responsibility has always been unfortunate and inappropriate. However, now, with all the pressures on the health care delivery system, it is overtly dysfunctional. Anesthesiologists who have not done so must step forward and actively seek involvement at the highest possible level in management of the OR(s) in which they practice. Clinical anesthesiologists can very profitably apply their unique insights into the process of OR function and significantly help meet the demands for efficiency and cost reduction while still maintaining high-quality patient care. The associated recognition and appreciation from the other constituent groups will emphasize the value and contributions of anesthesiologists as concerned physicians genuinely interested in the welfare of the entire institution, far beyond their own personal incomes. Failure to be involved not only further aggravates the negative image of anesthesiologists as simply greedy technicians rather than involved physicians practicing medicine, but also likely will contribute to accelerated loss of practice autonomy and the associated reimbursement.

An OR suite is a mini-society with various constituent groups, societal dynamics, and tensions determining the tone, pace, and flow of events. The key groups are the anesthesia providers, the surgeons, the OR staff (which usually comprises nursing, scrub techs, and support personnel), and professional administrators, who usually do not share backgrounds with any of the other three groups. As difficult as it may occasionally seem, it is possible and important for these groups not only to get along, but also to work constructively together to create a friendly, efficient work environment that promotes high-quality patient care. It is difficult to outline anything more than the broadest of general points regarding OR management because there is an extremely wide spectrum of OR types, from the largest inner-city teaching hospitals to the smallest freestanding ambulatory surgery specialty centers, with each particular facility having its own needs and characteristics.

Organization

Because both the anesthesia and surgical components of the OR milieu usually involve physicians who are not employees of the institution, there usually is not one central authority to which all the personnel involved must answer. Even when the physicians are employees, they report through their chiefs of service to the chief of the medical staff, who likely is not the hospital administrator. Therefore, even before considering the relationships between anesthesiologists and surgeons, it must be recognized that there is a natural division between the physicians and the OR staff. In this environment, anesthesia providers often find themselves trying to balance the needs of both the OR staff and the surgeons with what is possible and desirable from an anesthesia standpoint. This balancing act is a significant part of the art of anesthesia practice.

Anesthesia practitioners and surgeons have a symbiotic relationship. Without surgeons, there is no need for anesthesia services and without anesthesia providers, surgeons cannot work. In most circumstances, both groups recognize this and also the common goals of having surgery performed in an expeditious, safe manner. One of the biggest organizational sticking points can involve the age-old question “Who is in charge of the OR?” Sometimes, there can be no real answer because the interrelationships in the OR environment are so many and so complex. If there is a professional OR manager whose sole job it is to be an organizer, this person may have enough authority to be genuinely recognized as in charge. Further, some institutions have a position that carries the title Medical Director of the OR. The

implications to surgeons of an anesthesiologist in that position and vice versa are potentially contentious enough so that some institutions have simply abandoned that title. There does need to be some dispute-resolving and policy-setting authority from the physician perspective, however. If there is no medical director with authority to make relevant decisions and make these decisions stick, the physician authority usually resides with the Operating Room Committee. When there are major policy and financial decisions to be made, this committee becomes a microcosm political system with lobbying and campaigning for votes. No matter what it is called or how it is structured, there will be a forum for this type of activity in every OR in which standard tactics of diplomacy and negotiation will be carried out regularly.

Lines of authority parallel lines of responsibility. Who has hire/fire power over whom and who pays whom will determine a great deal about the organization of an individual OR. A classic example involves perfusionists for cardiac surgery. In some circumstances, they are employed by the hospital; in others, by the cardiac surgeons; in a few, by the anesthesiologists; and occasionally, by no one in that they function as completely independent contractors. The organizational implications of each of the above scenarios are relatively clear as they relate to standard issues such as work and call schedules, policy and procedures for bypass operations, equipment purchases, and so forth. Each institution develops its own tradition, often by trial and error, or by default based on the availability of various resources, including the perfusionists themselves. In some cases, the system that evolves never works well or does and then deteriorates over time. At such a juncture, one of the constituent components of the OR environment that has been out of power steps forward and offers to take (or seizes) control of the perfusionists. Then the cycle begins anew, under new management, and the process starts again. This is essentially healthy because an OR that has no cycles or problems and runs like a finely tuned machine because of a very strong central authority often is an unappealing workplace. There is significant intensity and consequent stress working in an OR simply because of the nature of surgery and its implications for the human condition. This is little appreciated by outsiders, but is also underappreciated by those who work there because to them it becomes routine and even boring—until they stop and reflect for a moment. Therefore, an effort to create a maximally collegial work environment will pay many significant dividends for all involved.

Other issues involving lines of responsibility can greatly affect the daily functioning of the OR. Very often, the OR staff are hospital/facility employees. Often, it is perceived that the hospital is more concerned with limiting the cost of salaries than providing as many personnel as the OR supervisor, surgeons, and anesthesia providers feel are necessary. The topic of adequate nursing and technical support staffing frequently is a never-ending discussion with the hospital administration. If there are genuine issues that cannot be resolved, it is not unreasonable in the appropriate settings for the anesthesiologists, for example, to contribute some of their practice income to hire the additional anesthesia technicians that have been needed. Likewise, surgeons who feel limited by the availability of scrub techs and/or nurses can get together and fund positions of this type from their practice income. This spirit of support and cooperation for the ultimate benefit of all would be both refreshing and most productive.

A central issue for the anesthesia providers in an OR is who among them will be the primary organizational person to interact with the OR. In situations in which all the anesthesia providers are independent contractors, there may be a titular chief of anesthesia who, by default, becomes the contact person. Larger groups or departments that function as a single entity and make their own assignments of personnel often have a clinical director whose job it is to be the contact person with the system and constitute the voice of the anesthesia department on OR organizational matters. Usually there is one anesthesia person supervising the schedule or “running the board” daily in the OR for the group. One of the virtues of this person being the clinical director (as opposed to rotating this responsibility among all the anesthesiologists) is that he or she likely has a better day-to-day perspective on the resources and demands related to both anesthesia and OR services. An additional benefit is that a comparative level of consistency in the application of policies, particularly regarding the scheduling of cases, can be more easily applied. One of the most frustrating things to both surgeons and OR staff is inconsistency and unpredictability of decision-making from the anesthesia department. A patient who may be deemed unacceptable for surgery by Anesthesiologist X running the schedule on Monday might well be considered, in exactly the same condition, a routine preop by Anesthesiologist Y on Tuesday. Some of this type of occurrence is unavoidable in a group, but the more there is, the more difficult OR life becomes for the surgeons and the OR staff. Without stifling individual practice styles and philosophies, some measure of consistency applied to similar situations, whether through a clinical director or not, will facilitate OR function considerably.

The availability of the tools of anesthesia administration is another component of OR organization. Usually, the anesthesia service staffs, maintains, and runs an anesthesia work room that contains all the supplies and equipment unique to anesthesia practice, which most often are chosen and ordered by the anesthesia providers and paid for either by the hospital/facility budget or by the practice revenue. There must be coordination with the OR staff as to who will be responsible for the routine equipment not necessarily unique to anesthesia, such as syringes and needles, intravenous fluids, and pulmonary artery catheters. An important goal is the avoidance of duplication and waste. Decisions as to what brands of supplies to buy and regarding major equipment purchases for the anesthesia side of the OR may be the subject of negotiations between the anesthesiologists and the facility administration, but may also reside with the physician members of the Operating Room Committee or its equivalent.

Scheduling Cases

Anesthesiologists need to be involved in the scheduling of OR cases in their institution or facility. In some circumstances, the “booking office” and the associated clerical personnel will reside within the department of anesthesiology. More often, however, this function will be part of the OR staff's responsibility, most likely under the direct control of the OR supervisor, who is usually a nurse. In this case, there needs to be a clear mechanism for input from the anesthesia providers to the case scheduling process, both on a daily basis and from the policy management aspect. This is important even in situations in which all the anesthesia providers are independent contractors and not really associated in any way. In such situations, the titular chief of anesthesia should be the one to coordinate schedules to guarantee after-hours coverage and to help plan for program changes, such as the addition of a new group of surgeons to the hospital staff.

When there is an anesthesia department that functions as a cohesive unit, its chairman, clinical director, or appointed representative will be the person who meets with the OR supervisor and surgeons as necessary to establish policies regarding the scheduling of OR cases. There are as many different ways to do this as there are operating suites. Most hospitals and facilities have evolved traditions that attempt to meet the needs of their operating suites. Despite this, OR scheduling remains universally one of the most difficult areas in medical practice. Acknowledging that it will be impossible to fully satisfy everyone, the anesthesia department should attempt to smooth the process as much as possible. First, the anesthesia department should listen sympathetically to the surgeons' desires and matching them to the OR staff's abilities to provide rooms, equipment, and personnel. Second, the anesthesia department should attempt to establish a schedule of anesthesia services and coverage to mesh realistically with the other two groups.

Regarding scheduling, surgeons are basically divided into two groups: the large majority who want first-in-the-morning operating time for elective cases, and the others—those who will operate essentially any time they can get their cases scheduled and do not understand why the OR cannot run full-tilt 24 hours a day 7 days a week. Neither group can be fully accommodated, and therein lies the need for extensive compromise. Anesthesiologists who approach these disparate desires calmly and with as little confrontation as possible will facilitate the compromise process considerably. There will always be some element of politics involved in these decisions, particularly if the OR uses block time (preassigned guaranteed time for a surgeon or a surgical service to book or post cases before a cutoff time a day or so ahead of the day in question) instead of open scheduling (first-come, first-served for all ORs), and the goal of the anesthesia department should be to appear as neutral as possible while being realistic about what can be accomplished in light of the number of rooms open and the length of the operating day.

Even in small operating suites, case scheduling will be greatly facilitated by some type of computerized scheduling system. Computerized scheduling is simpler and much faster than using a large ledger book. Juggling cases from room to room and trying various possibilities is much simpler on a computer than mass erasing and rewriting of hand entries. Conflicts of personnel or equipment can be instantly identified. Also, most systems of this type will produce reports and statistics automatically. One extremely valuable component of many such programs is automatic assignment of projected case duration based on historical precedent. Suppose Dr. X or service Y has an 8-hour block on a given day and wants to book (or post) four cases. The scheduling program determines what procedures are to be done (such as by CPT-4 code), looks back at past examples of how long that surgeon or service took to do such cases, and then automatically assigns a projected length for each of the cases booked. If the computer concludes that the first three cases will consume the entire available block of time, it will not accept the fourth case into that room's schedule on that day. Once the surgeons' initial resistance is overcome and they get in the habit of either making more realistic time estimates or accepting those from the computer, the scheduling process will become much smoother and far fewer midafternoon disputes will arise between the anesthesia and OR staffs about whether the last case scheduled can actually be done.

In general, there are a great many contributing variables in the scheduling process. The nature of the institution and the patient population served has a great impact. An ambulatory surgery center in an upscale suburban neighborhood doing mostly cosmetic surgery can schedule OR cases of fairly predictable length and complexity well in advance and be relatively certain that the vast majority of patients will appear in appropriate condition, ready to go, at the appointed day and hour. But a large inner-city teaching hospital serving a largely indigent population and receiving mostly acute problems and trauma patients will find it very difficult to schedule the OR much more than a day in advance, if that. In the latter circumstance, maximal cooperation and flexibility from the anesthesiology department (within the limitations of available resources) is mandatory in trying to accommodate the surgeons' requests and the OR staff's ability to do cases. These are two extreme examples from opposite ends of the spectrum. Most situations fall somewhere in between. In all circumstances, however, open communication and honest discussion among the three principal groups involved in OR scheduling about realistic requests and realistic estimates of what is possible will be the key to the smoothest possible functioning of the OR. It is very important to attempt to overcome the “us versus them” attitudes often seen in the OR. Surgeons may be perceived by anesthesia providers as having totally unrealistic expectations or demands for operating time. Anesthesiologists may be perceived by surgeons as arbitrarily canceling or refusing to do cases in an attempt to avoid work. This contentious atmosphere need not prevail. If each of the three groups (plus administrators where applicable) involved in OR scheduling tries hard to understand the positions and thinking of the other two and realizes that all need to be working together toward a common goal—safe, efficient, expedient patient care—then the OR working environment need not be the most difficult in the hospital.

Scheduling Personnel

Except in unusual circumstances, scheduling anesthesia providers is a continual juggling act. Even with independent contractors who make themselves available on lists at various hospitals and depend on surgeons (or OR staff acting at the direction of surgeons) to contact them directly regarding availability and consequent scheduling, there are time conflicts and, conversely, unwanted idle time. When departments or groups accept responsibility for providing anesthesia services for an OR suite, they then have to make sure that there are enough providers to staff the rooms scheduled on any given day. Ideally, a department or group would hire enough people so that there would always be more providers available beyond the minimum needed to run regular rooms during the day and cover the call schedule. In reality, however, this usually does not happen (at least not for long) because it is clearly financially disadvantageous for all to have too many people with no clinical activity. Therefore, there is usually an attempt to have just the right number of providers available, which may work well until someone is out with a family problem or an extended illness. In academic departments, anesthesia attending faculty and residents may be assigned nonclinical time intended for research, teaching, and administration. These people may provide a buffer to help deal with day-to-day variations in the number of people available to work in the OR, but repeated pulling of personnel away from their academic time to provide clinical service quickly undermines the academic programs of a teaching department and also leads to resignations that eventually eliminate that buffer. Accordingly, those responsible for scheduling anesthesia personnel ideally need to anticipate both reasonable needs and available personnel far enough in advance (at least 6 months) to hire accordingly. Doing this, however, has become increasingly difficult. With the sudden major realignments of large segments of the health care system and the advent of managed care systems and the consequent bidding for contracts to care for patients, it may be totally impossible to anticipate the patient load of an OR 6 months hence. There is no easy answer to this and no significant suggestions other than acknowledgment that in all these new arrangements, negotiations, and machinations, data confer power. MCOs must, of necessity, predict OR utilization rates for the groups they cover to allow reasonable negotiating of prospective payments. A great deal of actuarial effort goes into these predictions, and it is reasonable to hope for some degree of accuracy. Therefore, if a health care facility or an organized group of physicians obtains a contract to provide surgery and anesthesia services, it is likely that some reasonable prediction of the need for personnel can be generated.

Again, there are as many different types of situations as there are places to have them. Each operating suite evolves its own system. There needs to be very close coordination between the responsible anesthesia person and the OR supervisor as to how many ORs can be used on any given day and how late in the afternoon or evening they can be open. Inevitably, some cases take much longer than planned and emergency or add-on cases are booked/posted during the day, leading to the need to run more rooms than anticipated at the end of the afternoon and into the evening. The anesthesiology personnel who are thus stuck staying late, whether or not they are being paid overtime, may accept such a situation as a matter of course occasionally, but not routinely. These practitioners become exhausted and also resentful of being abused in general and of the time away from their outside lives. If the practice environment is such that there almost always are rooms that run significantly late, it is likely a worthwhile investment to have additional anesthesia personnel on late call who come in fresh at noon or 1 P.M. with the intention of giving lunch breaks and then staying that evening until all the scheduled cases from the day are finished and there has been a good start on the add-ons, which will then be completed by the anesthesia call personnel.

Scheduling after-hours anesthesia coverage is similarly difficult. In this consideration, the variation among facilities is greater still. Whether or not anesthesia residents, nurse anesthetists, and attending staff need to take in-hospital calls overnight depends on the nature of the institution and workload. Major referral centers for high-risk obstetrics and trauma, for example, need primary providers in-house 24 hours a day and, if these are residents and/or nurse anesthetists, also the attending staff to supervise them. In other settings, primary providers may be in-house with the attending staff taking call from home or both may take calls from home (assuming this is close enough to guarantee arrival in the OR within some agreed-upon interval, such as 30 minutes in the case of a stat cesarean section). The number of people needed on call is always a question. Should the call team be staffed for the minimum, average, or maximum expected load? Often the easiest answer to this is to anticipate an average load and acknowledge that there will be some idle time unused and other instances when the need will outstrip the available personnel. Of course, if that circumstance becomes commonplace rather than unusual, the number of personnel on call needs to be increased.

There are important medicolegal concerns related to this issue. In a small community hospital, for example, if there are three anesthesiologists on staff who do their own cases with no nurse anesthetists involved, they likely will agree that each will cover every third weekend, with the other two being off call and not obligated to the OR. If that one anesthesiologist is administering an anesthetic and cannot safely leave the room and another emergency patient comes into the OR suite with a major acute problem, what should happen? If the other two anesthesiologists are legitimately unavailable and unreachable, should the anesthesiologist in the OR leave the anesthetized patient with, for example, a circulating nurse to watch the monitors and ventilator to tend to the emergency patient in the OR next door? There is no easy answer and, obviously, those on the scene at the time must assess the relative risks and benefits and make hard choices. This example only serves to illustrate the difficulties of trying to provide call coverage to deal with all possible contingencies in the OR.

A related scheduling question is whether anesthesiology personnel who have worked overnight while on call should work in the OR the following day. Again, the individual practice environment will largely dictate the answer. If call almost never means a long night's work, leaving residual fatigue and stress in the morning, it is reasonable for a provider to be scheduled in the OR the following day with the understanding that on the rare occasion when there has been all-night activity, that practitioner will be dismissed as early as possible. Alternatively, if the calls usually do involve extensive night work, there should be no assignment for the next morning. In the rare circumstance that the provider does sleep the night, then he or she is an unexpected extra helper the next day for as long as needed. Common sense and reason guide this thinking. In the same vein, even if there is no indication that fatigue played a role, should an anesthesia catastrophe occur with a practitioner who was up all the previous night, the defense of the resultant malpractice suit may be difficult.

PRACTICE ARRANGEMENTS

The "Job Market" for Anesthesiologists

In the mid-1990s, for the first time, turmoil and uncertainty faced residents finishing anesthesiology training. The long-standing belief that there would be desirable, suitable practice opportunities for the considerable number of residents being graduated yearly finally came to an end. Three main factors contributed to this situation.

A main cause was the number of residents being trained compared to the number of practice opportunity openings. Before about 1993, with the exception of a very few of the most popular cities, finishing residents could first decide where they wanted to live and then seek an anesthesiology practice to join or simply start one themselves. Although a maldistribution of anesthesiologists in the United States existed (and still exists, with underserved rural and core-city areas that may never have had physician anesthesia services), the routine desirable jobs in urban, suburban, and midsize-town private practice groups or facilities began to dry up, particularly starting in 1994. In part, they were simply filled with anesthesiologists who had finished training recently enough to have no intention or desire to move or cut back their practice.

The second significant contributing factor was the proposal in 1993 by the U.S. administration to radically restructure American health care delivery. Although this proposal was eventually abandoned as too radical, it introduced an element of uncertainty that persisted long after it had been dismissed. This element of uncertainty led anesthesiologists and facilities to adopt a "wait and see" attitude about hiring new anesthesiologists, especially in 1994, thus further sharply reducing the number of practice opportunities open that year. (For the first time in recent memory, the Placement Service function at the annual meeting of the ASA was cancelled in October 1994 due to lack of interest from locations seeking to hire or add anesthesiologists. This has subsequently been re-instituted on a smaller scale, and is now more of a computerized journal classified ad section.)

The third major factor is related to the first two. It is the marketplace forces that have been and continue to induce significant changes in the U.S. health care system independent of any government proposal for change. Put as simply as possible, the business community, employers who provide health care insurance for their employees, and government entities that fund programs such as Medicare and Medicaid have stated that it is impossible for them to continue to fund the rapidly increasing expenditures necessary to provide health care coverage. As a result, an entire new industry, managed care, has appeared. The managed care concept is built on the idea that traditional fee-for-service health care has no incentive for health care providers, principally physicians, to limit expenditures. In fact, physicians, health care workers, and health care facilities were financially rewarded the more health care was "consumed" or rendered to patients. Accordingly, MCOs came into being, saying to business and government that a new administrative layer was needed to control (reduce) what physicians and health care facilities spend. This management of care by outside, independent reviewers and decision-makers who determine what care can and should be rendered to the patient is intended to replace the traditional fee-for-service indemnity system (bills submitted by physicians based on what they decide is necessary that are then paid after the fact by a health plan or insurance company) and thereby significantly reduce the cost for health care to employers and governments. Because one of the main themes of managed care plans is that there will be much less surgery in the future, there has been an impact on the plans of groups and facilities to add new anesthesiologists. Thus, in a very short period of time, the job market for anesthesiologists underwent a radical change. Discussions occurred both within and outside organized anesthesiology about components of this situation,^{29,30 and 31} but, predictably, no definitive answers are possible. By 1998 the situation had reversed somewhat, as medical students could rapidly read that changing conditions of 1994 and simply stopped choosing anesthesiology as a career. Rapidly, residency programs were faced with a dearth of applicants and many of even the most prominent programs in the nation were unable to fill their allocated resident slots. At the time of this writing the situation seems to be returning, at least somewhat, to conditions similar to the late 1980s with an overall shortage of practitioners and multiple attractive job offers for each resident graduated. The situation is evolving and fluid, but there will always be surgery, no matter what health system changes take place. Moreover, anesthesiologists do more than just OR anesthesia (increasingly so in the future). Therefore, it is appropriate to consider the multitude of issues concerning practice

arrangements in anesthesiology.

Types of Practice

With the “alphabet soup” of new practice arrangements for physicians (IPA, PPO, PHO, MCO, MSO, HMO) and the rapidly evolving forces of the health care marketplace, as well as the intermittent appearance of major governmental initiatives to institute radical reform of the health care system, it is difficult to outline the details of all the possible types of opportunities for anesthesiologists. Rather, it is reasonable to provide basic background information and also suggestions of sources of further information.

At least into the first decade of the 21st century, residents finishing anesthesiology training will still need to choose among three fundamental possibilities: academic practice in a teaching hospital environment; a practice exclusively of patient care in the private practice marketplace; and a practice exclusively of patient care as an employee of a health care system, organization, or facility.

Teaching hospitals with anesthesiology residency programs constitute only a very small fraction of the total number of institutions and facilities requiring anesthesia services. These academic departments tend to be among the largest, but the aggregate fraction in academic practices out of the entire anesthesiologist population is also small. It is interesting, however, that most residents finishing their training have almost exclusively been exposed only to academic anesthesiology. Accordingly, finishing residents in the past often were comparatively unprepared to evaluate and enter the anesthesiology job market. As noted, the Anesthesiology Residency Review Committee now requires teaching of job acquisition skills and practice management as part of the residency didactic curriculum.

Specialty certification by the American Board of Anesthesiology (ABA) is likely the goal of most anesthesia residency graduates. Some finishing residents who know they are eventually headed for private practice have started their attending careers as junior faculty. This allows them to obtain some supervisory experience and offers them the opportunity to prepare for the ABA examinations in the nurturing, protected academic environment with which they are familiar. Most, however, do not become junior faculty; they accept practice positions immediately. But such newly trained residents should take into account the need to become ABA-certified and build into their new practice arrangements the stipulation that there will be time and consideration given toward this goal. The hectic and unsettling time of embarking on a new career, possibly moving one's home and family, and getting acclimated to a new professional and financial environment may inhibit optimum performance on the examinations. The possibilities to avoid this disruption may be comparatively limited, but awareness of the problem can help. At the very least, it may lead to the forging of arrangements that will maximize the probability of success.

Academic Practice

For those who choose to stay in academic practice, the first question is whether to consider staying at one's training institution. On the one hand, “the devil you know is better than the devil you don't know.” On the other hand, however, fear of the unknown should not inhibit investigation of all possibilities. Aside from obvious personal preferences such as area of the country, size of city, and climate, a number of specific characteristics of academic anesthesia departments can be used as screening questions.

How big is the department? Junior faculty can get lost in very big departments and be treated as little better than glorified senior residents. On the other hand, the availability of subspecialty service opportunities and significant research and educational resources can make large departments extremely attractive. In smaller academic departments, there may be fewer resources, but the likelihood of being quickly accepted as a valued, contributing member of the teaching faculty (and research team, if appropriate) may be higher. In very small departments, the number of expectations, projects, and involvements could potentially be overwhelming. Additionally, a small department may lack a dedicated research infrastructure, so it may be necessary for the faculty in this situation to collaborate with other, larger departments to accomplish meaningful work.

What exactly is expected of junior faculty? If teaching one resident class every other week is standard, the candidate must enthusiastically accept that assignment and the attendant preparation work and time up front. Likewise, if it is expected that junior faculty will, by definition, be actively involved in publishable research, specific plans for projects to which the candidate is amenable must be made. In such situations, clear stipulations about startup research funding and nonclinical time to carry out the projects should be obtained. Particularly important is determining what the expectation is concerning outside funding—it can be a rude shock to realize that projects will suddenly halt after, for example, 2 years if extramural funding has not been secured.

What are the prospects for advancement? Most new junior faculty directly out of residency start with medical school appointments as instructors unless there is something else in their background that immediately qualifies them as assistant professors. It is wise to understand from the beginning what it takes in that department and medical school to facilitate academic advancement. There may be more than one track; the tenure track, for example, is usually dependent on published research whereas the clinical or teacher track relies more heavily on one's value in patient care and as a clinical educator. The criteria for promotion may be clearly spelled out by the institution—number of papers needed, involvement and recognition at various levels, grants submitted and funded, and so on—or the system may be less rigid and depend more heavily on the department chairman's evaluation and recommendation. In either case, careful inquiry before accepting the position can avert later surprise and disappointment.

How much does it pay? Traditionally, academic anesthesiologists have not earned as much as those in private practice—in return for the advantage of more predictable (and maybe less strenuous) schedules, continued intellectual stimulation, and the intangible rewards of academic success. As is clear from this chapter, there is now great activity and attention concerning reimbursement of anesthesiologists, and it is difficult to predict future income for any anesthesiology practice situation. However, all of the forces influencing payment for anesthesia care may significantly diminish the traditional income differential between academic and private practice. This is not a small issue. Anesthesiologists justifiably can expect to live reasonably well. Income is also a valid consideration both because anesthesiologists are frequently at least 30 years old when they finish training and are thus starting well behind their age-mates in lifetime earnings and because most physicians have substantial educational loans to repay when finishing residency. The compensation arrangements in academic practice vary widely in structure. In some cases, a faculty member is exclusively an employee of the institution, which bills and collects or negotiates group contracts for the patient care rendered by the faculty member, and then pays a negotiated amount (either an absolute dollar figure or a floating amount based on volume and/or collections) that constitutes the faculty person's entire income. Under other arrangements, the faculty members themselves can bill and collect or negotiate contracts for their clinical work. Some institutions have a (comparatively small) academic salary from the medical school for being on the faculty, but many do not; and, of these, some channel variable amounts of money into the academic practice (so-called Part A payments) in recognition of teaching and administration. This salary from the medical school, if extant, is then supplemented significantly by the practice income. Usually, the faculty will be members of some type of group or practice plan (either for the anesthesia department alone or the entire faculty as a whole) that bills and collects or negotiates contracts and then distributes the practice income to the faculty under an arrangement that must be examined by the candidate. An important corollary issue is that of the source of the salaries of the department's primary anesthesia providers—residents and, in some cases, nurse anesthetists. Although the hospital usually pays for at least some of these, arrangements vary, and it is important to ascertain whether the faculty practice income is also expected to cover the cost of the primary providers.

Private Practice in the Marketplace

As noted, some residents finish their anesthesia training never having seen a private practice anesthesia setting or even talked to an anesthesiologist who has been in private practice. These candidates are ill-equipped to seek a position in the private practice marketplace. Obviously, rotations to a private practice hospital in the third year of anesthesia residency could help greatly in this regard, but not all residency programs offer such opportunities. In that case, the finishing resident who is certain about going into private practice must find educational opportunities on career development and mentors from the private sector.

Armed with as much information as possible, one fundamental initial choice is between independent individual practice and a position with a group (either a sole proprietorship, partnership, or corporation) that functions as a single financial entity. Independent practice may become increasingly less viable in many locations because of the need to be able to bid for contracts with managed care entities. However, where it is possible, it usually first involves attempting to secure clinical privileges at a number of hospitals or facilities in the area in which one chooses to live. This may not always be easy, and this issue has been the subject of many (frequently unsuccessful) antitrust suits over recent years (see [Antitrust Considerations](#)). Then the anesthesiologist makes it known to the respective surgeon communities that he or she is available to render anesthesia services and waits until there is a request for his or her services. The anesthesiologist obtains the requisite financial information from the patient and then either individually bills and collects for services rendered or employs a service to do billing and collection for a percentage fee [which will vary depending on the circumstances, especially the volume of business; for billing (without scheduling services) it would be unlikely to be more than 7% or, at the most, 8% of actual collections]. How much of the needed equipment and supplies will be provided by the hospital or facility and how much by the independent anesthesiologist varies widely. If an anesthesiologist spends considerable time in one operating suite, he or she may purchase an anesthesia machine exclusively for his or her own use and move it from room to room as needed. It is likely to be impractical to move a fully equipped anesthesia machine from hospital to hospital on a day-to-day basis. Among the features of this style of practice are the collegiality and relationships of a genuine private practice based on referrals and also the ability to decide independently how much time one wants to be available to work. The downside is the potential unpredictability of the demand for service and the time needed to establish referral patterns and obtain bookings sufficient to generate a livable income.

Acknowledging that the issues presented above may at some times render components of these suggestions moot, it is reasonable for the finishing resident to know

that when seeking a position with a private group, the applicant should search for potential practice opportunities through word of mouth, recruiting letters sent to the training program supervisor, journal advertisements, and placement services (either commercial or professional, such as that provided at the ASA annual meeting). Some of the screening questions are the same as for an academic position, but there must be even more emphasis on the exact details of clinical expectations and financial arrangements. Some residents finish residency and even more so fellowship training very highly skilled in complex, difficult anesthesia procedures. They can be surprised to find that in some private practice group situations, the juniormost anesthesiologist must wait some time, perhaps even years, before being eligible to do, for example, open heart anesthesia and in the meantime will mostly be assigned more routine or less challenging anesthetics. Of course, this is not always the circumstance, but the applicant needs to investigate thoroughly to be certain that the opportunity satisfies the desire for professional challenge.

Financial arrangements in private group practices vary. Some groups are loose organizational alliances of independent practitioners who bill and collect separately and rotate clinical assignments and call for mutual convenience. Many groups act also as a fiscal entity, and there are many possible variations on this theme. In many circumstances in the past, new junior members started out as functional employees of the group for a probationary interval before being considered for full membership or partnership. This is not a classic employment situation because it is intended to be temporary as a prelude to full financial participation in the group. However, there have been enough instances of established groups abusing this arrangement that the ASA includes in its fundamental Statement of Policy the proviso: "Exploitation of anesthesiologists by other anesthesiologists is improper."¹ This goes on to say that after a reasonable trial period, income should reflect services rendered. Unfortunately, these statements have very little meaning or impact on groups in the marketplace today. Some groups have a history of demanding excessively long trial periods during which the junior anesthesiologist's income is artificially low and then denying partnership and terminating the relationship to go on to employ a new probationer and start the cycle over again. Accordingly, new junior staff attempting to join groups should try to have such an arrangement spelled out carefully in the agreement drafted by an expert representing the anesthesiologist. Another variation of this, in an attempt to disguise the fundamentally unethical nature of the practice, is to employ anesthesiologists on a fixed salary with the false incentive of no night or weekend call. This is disingenuous, as the vast majority of income is generated during routine scheduled day work, for which the anesthesiologist-employee is poorly compensated. Yet another usurious scheme is for a group to employ an anesthesiologist for a period of years at a low salary and then require a further cash outlay to purchase partnership in the corporation. As the cash outlay can be quite substantial, it is frequently borrowed from the corporation, leading to a sophisticated form of indentured servitude. Sadly, when the job market conditions are poor as they were a few years ago, the tendency is for there to be less likelihood of securing a prospective commitment of partnership at a specified future time. This is especially true in the more desirable areas of California and the Northeast United States where stories of abuse of junior partners are rife. Whether this should substantially affect an applicant's interest in or willingness to accept a position is a highly individual matter that must be evaluated by each applicant.

Private Practice as an Employee

There has been some trend toward anesthesiologists becoming permanent employees of any one of various fiscal entities. The key difference is that there is no intention or hope of achieving an equity position (share of ownership, usually of a partnership, thus becoming a full partner). Hospitals, outpatient surgery centers, multidisciplinary clinics, other facilities tied to a specific location where surgery is performed, physician groups that have umbrella fiscal entities specifically created to serve as the employer of physicians, and even surgeons may seek to hire anesthesiologists as permanent employees. The common thread in this system is that these fiscal entities see the anesthesiologists as additional ways of generating profits. Again, these employees are rarely paid a salary that is commensurate with their production of receivables. That is, the fiscal entity will pay a salary substantially below collections generated. These arrangements are particularly favored by many large managed care organizations that view anesthesiologists simply as expensive burdens that prevent hospitals from realizing maximum profit. Some anesthesiologists have predicted that this trend will continue to grow, and that eventually most physicians in the support specialties of anesthesiology, radiology, pathology, and emergency medicine will be outright permanent employees of an organized entity of some type. Although some current information might suggest this, it is impossible to speculate on the future in this regard. Other anesthesiologists believe that the future is extraordinarily bright and that anesthesiology will expand its role, predicting that anesthesiologists will increasingly assume positions of central authority, making decisions about hiring physicians of other specialties.

Negotiating for a position as a permanent employee is somewhat simpler and more straightforward than it is in marketplace private practice. It parallels the usual understandings that apply to most regular employer-employee situations: job description, role expectations, working conditions, hours, pay, and benefits. The idea of anesthesiologists functionally becoming shift workers disturbs many in the profession. On the other hand, the major upheaval in the health care delivery system is promoting reorganization that, until very recently, was unheard of. Again, the complex nature and multiple levels of such considerations make it a personal issue that must be carefully evaluated by each individual.

Billing and Collecting

In practices in which anesthesiologists are directly involved with the financial management, they need to understand as much as possible about the complex world of health care reimbursement. This not-small task has been made easier by the ASA, which has added a significant component to its Washington, D.C., office by adding a practice management coordinator to the staff. One of the associated assignments is helping ASA members understand and work with the sometimes confusing and convoluted issues of effective billing for anesthesiologists' services.

There continue to be proposals for significant changes in billing for anesthesiology care. However, the basics have changed only slightly in recent years. It is important to understand that many of the most contentious issues, such as the reimbursement for medical direction of nurse anesthetists, apply almost exclusively to Medicare and, in some states, Medicaid. Thus, the fraction of the patient population covered by these payers is important in any consideration. Different practice situations have different arrangements regarding the financial relationships between anesthesiologists and nurse anesthetists, and this can affect the impact of the rules regarding the ability of nurse anesthetists to bill for their services independently. The nurses may be employees of a hospital, of the anesthesiologists who medically direct them, or of no one in that they are independent contractors billing separately. As of 1998, the Health Care Financing Administration (HCFA) mandated that an anesthesia care team of a nurse anesthetist medically directed by an anesthesiologist could bill as a team no more than 100% of the fee that would apply if the anesthesiologist did the case alone. The implications of this change are complex and variable among anesthesiology practices, particularly because there is another trend—for health care facilities that traditionally had employed nurse anesthetists to seek to shift total financial responsibility for them to the anesthesiologist practice group. In the late 1990s there was also a suggestion from HCFA that CRNAs be allowed to bill for practice without anesthesiologist supervision as independent contractors. Such care would thus be under the medical direction of the surgeon, rather than the anesthesiologist. Obviously, this has caused much consternation among various parties, including the ASA membership, with vigorous lobbying efforts from all sides. At the time of this writing, it appears that the matter has been tabled, but is likely to become active at some future date. Further, the implications of all this for billing payers other than Medicare and Medicaid are exceedingly complex. Obviously, careful consideration of these issues and seeking out advice from knowledgeable resources is critical to fiscal stability in modern anesthesiology practice.

There has been significant consideration of the mechanism of billing for anesthesiology. There have been many suggestions that so-called schedule fees (a single predetermined fee for an anesthetic, independent of its length or complexity) will become more common. Further, there is pressure from some quarters to bundle together all the physicians' fees for one procedure into a single global fee that would pay the surgeon, anesthesiologist, radiologist, pathologist, and so on for one case, such as a laparoscopic cholecystectomy. Further, all of this concern about billing for specific procedures will become irrelevant in systems with prospective capitated payments for large populations of patients, in which each group of involved physicians in a system would receive a fixed amount per enrolled member per month (PMPM) and agree, except in the most unusual circumstances, to provide whatever care is needed by that population for that prospective payment. These are intended to be large-scale operations involving at least tens of thousands of people ("covered lives") in each organization.

At least for the moment, there is still some utility in some places for the traditional method of billing for anesthesiology services. In this system, each anesthetic generates a value of so many units, which represent effort and time. A conversion factor translates the value of a unit into dollars. Each anesthetic has a base value number of units (e.g., 8 for a cholecystectomy) and then the time taken for the anesthetic is divided into units, usually 15 minutes per unit. In some practice settings, it may be allowed to add modifiers, such as extra units for complex patients with multiple problems as reflected by an ASA physical status classification of 3-5 or for insertion of an arterial or pulmonary artery catheter. The sum is the total billing unit value. Determining the base value for an anesthetic in units depends on full and correct understanding of what operation was done. Although this sounds easy, it is the most difficult component of traditional anesthesia billing. The process of determining the procedure done is known as coding because the procedure name listed on the anesthesia record is assigned an identifying code number from the universally used CPT-4 coding book. This code is then translated through the ASA Relative Value Guide, which assigns a base unit value to the type of procedure identified by the CPT-4 code. In the past, some anesthesiologists failed to understand the importance of correct coding to the success of the billing process. Placing this task in the hands of someone unfamiliar with the system and with surgical terminology can easily lead to incorrect coding. This can fail to capture charges and income to which the anesthesiologist is entitled or, worse, can systematically overcharge the payers, which will bring sanctions, penalties and, in certain cases, criminal prosecution. In 2000, the prevailing official attitude is that there are no simple, innocent coding errors. All upcoding is considered to be *prima facie* evidence of fraud and subject to severe disciplinary and legal action. All practices should have detailed compliance programs in place to ensure correct coding for services rendered.³² Outside expert help (such as from a health care law firm that specializes in compliance programs) is highly desirable for the process of formulating and implementing a compliance plan.

Once the information has been secured, a mechanism must be employed to generate the actual bill and communicate it to the payer (on paper, on disk, or directly computer-to-computer). The potential arrangements for doing this vary widely. Ultimately, the entity actually submitting the bill will verify that it has been paid (posting of receipts) and may or may not actually handle the incoming money. Very often, anesthesia practices or individuals who use a billing service will arrange that the payments go directly to a bank lockbox, which is a post office box (better individual than shared, even if more expensive) to which the payments come and then go directly into a bank account. This system avoids the situation of having the people who generate the bill actually handle the incoming receipts, a practice that has led to

theft and fraud. Eventual decisions about how hard to try to collect from payers who deny coverage and then from patients directly will depend on the circumstances.

Anesthesia billing and collecting are among the most complex challenges in the medical reimbursement field. The experience of many people over the years has suggested that it often is well advised to deal with an entity that is not only well experienced in anesthesia billing, but also does anesthesia billing exclusively or as a large fraction of its efforts. It is very difficult for an anesthesiologist or a family member to do billing and collecting on the side. This has led to inefficient and inadequate efforts in many cases, illustrating the value of paying a reasonable fee to a professional who will devote great time and energy to the endeavor.

Antitrust Considerations

Although it is true that there are many potential antitrust implications of business arrangements involving anesthesiologists—particularly with all the realignments, consolidations, mergers, and contracts associated with the advent of managed care—it is also true that the applicable statutes and regulations are poorly understood. Contrary to popular belief, the antitrust laws do not involve the rights of individuals to engage in business. Rather, the laws are concerned solely with the preservation of competition within a defined marketplace and the rights of the consumer, independent of whether any one vendor or provider of service is involved. This misunderstanding has been the source of confusion. When an anesthesiologist has been excluded from a particular hospital's staff or anesthesia group and then sues based on an alleged antitrust violation, the anesthesiologist loses virtually automatically. This is because there is still significant competition in the relevant marketplace and competition in that market is not threatened by the exclusion of one physician from one staff.

In essence, if there are *several* hospitals offering relatively similar services to an immediate community (the market), denial of privileges to one physician by one hospital is not anticompetitive. If, on the other hand, there is only *one* hospital in a smaller market, then the same act, the same set of circumstances, would be seen very differently. In that case, there would be a limitation of competition because the hospital dominates and, in fact, may control the market for hospital services. Exclusion of one physician, then, would limit access by the consumers to alternative competing services and hence would likely be judged an antitrust violation.

The Sherman Antitrust Act is a federal law more than 100 years old. Section 1 deals with contracts, combinations, conspiracy, and restraint of trade. By definition, two or more separate economic entities must be involved in an agreement that is challenged as illegal for this section to apply. Section 2 prohibits monopolies or conspiracy to create a monopoly, and it is possible that this could apply to a single economic entity that has illegally gained domination of a market. Consideration of possible monopolistic domination of a market involves a situation in which a single entity controls at least 50% of the business in that market. The stakes are high in that the antitrust legislation provides for triple damages if a lawsuit is successful. The U.S. Department of Justice and the Federal Trade Commission are keenly interested in the current rapid evolution in the health care industry, and thus are actively involved in evaluating situations of possible antitrust violations. There are two ways to judge violations. Under the *per se* rule, which is applied relatively rarely, conduct that is obviously limiting competition in a market is automatically illegal. The other type of violation is based on the rule of reason, which involves a careful analysis of the market and the state of competition. The majority of complaints against physicians are judged by this rule. The more competitors there are in a market, the less likely that any one act is anticompetitive.

In the current era of rapidly evolving managed care arrangements, the antitrust laws are important. If physicians (individuals or groups) who normally would be competitors because they are separate economic entities meet and agree on the prices they will charge or the terms they will seek in a managed care contract, that can be anticompetitive, monopolistic, and hence possibly illegal. Note that sharing a common office and common billing service alone is not enough to constitute a true group. If, on the other hand, the same physicians join in a true economic partnership to form a new group (total integration) that is a single economic entity (and meets certain other criteria) that will set prices and negotiate contracts, that is perfectly legal. The other criteria are critical. There must be capital investment and also risk sharing (if there is a profit or loss, it is distributed among the group members)—*i.e.*, total integration into a genuine partnership. This issue is very important in considering the drive for new organizations to put together networks of physicians that then seek contracts with major employers to provide medical care. Sometimes, hospitals or clinics attempt to form a network comprising all the members of the medical staff so that the resulting entity can bid globally for total care contracts. Any network is a joint venture of independent practitioners. If the participating physicians of one specialty in a network are separate economic entities and the network advertises one price for their services, this would seem to suggest an antitrust violation (horizontal price fixing). In the past, if a network involved fewer than 20% of one type of medical specialist in a market, that was called a “safe harbor,” meaning that it was permissible for nonpartners to get together and negotiate prices. The federal government has tried to encourage formation of such networks to help reduce health care costs and, as a result, announced in late 1994 some relevant exceptions to the application of these rules. As long as the network is nonexclusive (other non-network physicians of a given specialty are free to practice in the same facilities and compete for the same patients), the network can comprise up to 30% of the physicians of one specialty in a market. Note specifically that this does not allow a local specialty society in a big city to serve as a bargaining agent on fees for its members, because it is very likely that more than 30% of the specialists in an area will be members of the society. The only real exception to this provision is in thinly populated rural areas where there may be just one physician network. In such cases (which are, so far, rare because the major managed care and network activity has occurred in heavily populated urban areas), there is no limit on how many of one specialty can become network members and have the network negotiate fees, as long as the network is nonexclusive.

Clearly, these issues are very complex. Relevant legislation, regulations, and court actions all happen rapidly and often. Mergers among anesthesiology groups in a market area for the purposes of both efficiency and strength in negotiating fees have been very popular as a response to the rapidly changing marketplace. A list of questions must be answered to determine if such a merger would have anticompetitive implications. Although compendia of relevant information are available to anesthesiologists,^{33,34} they cannot substitute for expert advice and help. Obviously, anesthesiologists contemplating a merger or facing any one of a great number of other new situations in the modern health care arena must secure assistance from professional advisors, usually attorneys, whose job it is to be aware of the most recent developments, how they apply, and how best to forge agreements in formal contracts. Anesthesiologists hoping to find reputable advisors can start their search with word-of-mouth referrals from colleagues who have used such services. Local or state medical societies frequently know of attorneys who specialize in this area. Finally, the ASA Washington, D.C., office has compiled a state-by-state list of advisors who have worked successfully with anesthesiologists in the past.

Exclusive Service Contracts

Until recently, one of the larger issues faced by anesthesiologists seeking to define practice arrangements was whether an exclusive contract with a health care facility to provide anesthesia services was desirable. An exclusive contract states that anesthesiologists seeking to practice at a given facility must be members of the group holding the exclusive contract and, usually, that members of the group will practice nowhere else. A hospital may want to give an exclusive contract in return for a guarantee of coverage as part of the contract. Also, the hospital may believe that such a contract can help ensure the quality of practitioner because the contract can contain credentialing and performance criteria. It is important to understand that the hospital likely will exercise a degree of control over the anesthesiologists with such a contract in force, such as requiring them to participate as providers in any contracts the hospital makes with third-party payers and also tying hospital privileges to the existence of the contract (the so-called “clean sweep provision” that bypasses any due process of the medical staff should the hospital terminate the contract). Certain of these types of provisions constitute *economic credentialing*, which is defined as the use of economic criteria unrelated to the quality of care or professional competency of physicians in granting or renewing hospital privileges (such as the acceptance of below-market fees associated with a hospital-negotiated care contract or even requiring financial contributions in some form to the hospital). The ASA has issued a statement condemning economic credentialing.³⁵ The anesthesiologists involved may accept such an exclusive services contract to guarantee that they alone will get the business from the surgeons on staff at that hospital, and hence the resulting income. There may be other considerations on both sides, and these have been outlined in an extensive relevant ASA publication that also includes a sample contract for information purposes only.³² Although many exclusive contracts with anesthesiology groups are in force, the sentiment in the relevant literature, particularly from the ASA, is against them. As has been stated, it is critical that anesthesiologists faced with important practice management decisions such as whether to enter into an exclusive contract must seek outside advice and counsel. There are a great many nuances to these issues,³³ and anesthesiologists are at risk attempting to negotiate such complex matters alone, just as patients would be at risk if a contract attorney attempted to induce general anesthesia.

Denial of hospital privileges as a result of the existence of an exclusive contract with the anesthesiologists in place at the facility has been the source of many lawsuits, including the well-known Louisiana case of *Hyde v. Jefferson Parish*. In that case, the court found for the defendant anesthesiologists and the hospital, saying that there was no antitrust violation because there was no real adverse effect on competition as far as patients were concerned because there were several other hospitals within the market to which they could go, and therefore they could exercise their rights to take advantage of competition in the relevant market. Thus, existence of an exclusive contract only in the rare setting where anticompetitive effects on patients can be proved might lead to a legitimate antitrust claim by a physician denied privileges.

Managed Care and New Practice Arrangements

As noted, managed care systems for health care delivery fundamentally exist as a mechanism to control and then reduce health care costs by having independent reviewers and decision-makers who are not the physicians rendering the care limit the health care services delivered to large groups of patients. These ideas represent a huge change for American physicians. These changes appear inescapable, not necessarily because of government initiatives, but because of marketplace forces that result from the business community and government entities simply refusing to continue to pay ever-increasing sums for health care. The degree of penetration of managed care into market areas around the country is highly variable. Areas such as Minneapolis, San Diego, eastern Massachusetts, and several other northern cities were the first to become mature managed care markets with a significant majority of the population enrolled in one or another managed care health plan. Other parts of the country with very sparsely populated areas such as sections of the deep South and the far West will be the last to experience the managed care revolution. The impact in these areas is difficult to predict because the organizers of managed care may not be able to enroll enough people to make it worth the effort to create and operate a system. An MCO attempts to secure health care provision contracts with employers who provide health plan coverage and with government agencies

(e.g., Medicaid) responsible for the health care of large populations. Each worker or covered head of a household may have dependents covered by the plan. Each person covered is referred to as a *covered life*. An MCO probably needs contracts for at least 10,000 covered lives and preferably many more to make a legitimate entry into the marketplace. The MCO then enrolls physicians or physician groups and hospitals as providers and contracts to send its enrolled patients (the covered lives) to the health care providers under contract. The central issue is finances. The MCO seeks to enroll covered lives by offering the lowest prices possible. In turn, it seeks to contract with providers (individuals and facilities) for the lowest possible fees for medical care in return for sending large volumes of patient business to those providers.

In the initial stages of the evolution of a managed care marketplace, the MCOs usually seek contracts with providers based on discounted fee-for-service arrangements. This preserves the basic traditional idea of production-based physician reimbursement (do more, bill more) but the price of each act of services is lower (the providers are induced to give deep discounts with the promise of significant volumes of patients) and, also, the MCO gatekeeper primary care physicians and the MCO reviewers are strongly encouraged to limit complex and costly services as much as possible. There are other features intermittently along the way, such as global fees and negotiated fee schedules (agreed-upon single prices for individual procedures, independent of length or complexity). Further, another element is introduced to encourage the providers, both gatekeepers and specialists, to reduce costs. In an application of the concept of risk-sharing (spend too much for patient care and lose income), this usually is initially manifest in the form of “withholds,” the practice of the MCO holding back a fraction of the agreed-upon payment to the providers (e.g., 10 or 15%) and keeping this money until the end of the fiscal year. At that time, if there is any money left in the risk pool or withhold account after all the (partial) provider fees and MCO expenses are paid, it is distributed to the providers in proportion to their degree of participation during the year. This is a clever and powerful incentive to providers to reduce health care expenses. It is not as powerful as the stage of full risk-sharing, however. As the managed care marketplace matures and MCOs grow and succeed, the existing organizations and, especially, any new ones, shift to prospective capitated payments for providers.

This eventual reimbursement arrangement constitutes an entirely new world to the providers, involving prospective capitated payments for large populations of patients, in which each group of providers in the MCO receives a fixed amount per enrolled covered life per month (PMPM) and agrees, except in the most unusual circumstances, to provide whatever care is needed by that population for that prospective payment. The most unusual circumstances involve “carve-out” arrangements in which specific very costly and unusual conditions or procedures (such as the birth of a child with disastrous multiple congenital anomalies) are covered separately on a discounted fee-for-service basis. With full capitation, the entire financial underpinning of American medical care does a complete about-face from the traditional rewards for doing more to new rewards for doing less. Some managed care contracts contain other features intended to protect the providers against unexpected overutilization by patients that would stretch the providers beyond the bounds of the original contract with the MCO. The provisions setting the boundaries are called “risk corridors,” and the “stop-loss clauses” add some discounted fee-for-service payment for the excess care beyond the risk corridor (capitated contract limit). Providers who were used to getting paid more for doing more suddenly find themselves getting paid a fixed amount no matter how much or how little they do with regard to a specified population—hence the perceived incentive to do, and consequently spend, less. If the providers render too much care within the defined boundary of the contract, they essentially will be working for free, the ultimate in risk-sharing. There are clearly potential internal conflicts in such a system,³⁷ and how patients react to this potential radical change in attitude on the part of physicians has not yet been fully established and may well eventually play a significant role in how managed care evolves.

Health care providers (physicians, health care workers, and facilities), in turn, are allying themselves in a wide variety of organizations to create strength and desirable resources to present to the MCOs in contract negotiations. Some of these alliances have been formed very quickly, almost in a panic, because of fears by providers that they might get left out of the managed care marketplace and thus deprived of major sources of income or, someday, any income at all. Management service organizations (MSOs) are joint venture network arrangements that do not involve true economic integration among the practitioners, but merely offer common services to physicians who may, as a loosely organized informal group, elect to seek MCO contracts. Preferred provider organizations (PPOs) are network arrangements of otherwise economically independent physicians who form a new corporate entity to seek managed care contracts in which there are significant financial incentives to patients to use the network providers and financial penalties for going to out-of-network providers. Physician-hospital organizations (PHOs) are similar entities but involve understandings between groups of physicians and a hospital so that a large package or bundle of services can be constructed as essentially one-stop points of care. Independent practice associations (IPAs) are like PPOs but are specifically oriented toward capitated contracts for covered lives with significant risk-sharing by the providers. Groups (or clinics) without walls are collections of practitioners who fully integrate economically into a single fiscal entity (true partnership) and then compete for MCO contracts on the basis of risk-sharing incentives among the partners. Fully integrated groups or health maintenance organizations (HMOs) house the group of partner provider physicians and associated support staff at a single location for the convenience of patients, a big selling point when they seek MCO contracts.

The questions anesthesiologists face when addressing this alphabet soup of organizations are many and complex,³⁵ even more complex than those faced by office-based primary care or specialty physicians, because of the interdependent relationships with health care facilities as practice locations and with surgeons. The era of solo independent practitioners may be ending in many locations. Small groups of anesthesiologists may find themselves at a competitive disadvantage unless they become part of a vertically integrated (multispecialty) or horizontally integrated (with other anesthesiologists) organization. An extensive compendium of relevant information has been prepared by the ASA.³³ Because it appears likely that at least most, if not all, anesthesiologists in the United States will be affected by managed care, the central themes of this compendium and other publications^{38,39} are very important. Negotiations with MCOs require expert advice, probably even more so than the traditional exclusive contracts with hospitals noted above. Before any negotiation can even be considered, the MCO must provide significant amounts of information about the covered patient population. The projected health care utilization pattern of a large group of white-collar workers (and their families) from major upscale employers in an urban area will be quite different from that of a rural Medicaid population. Specific demographics and past utilization histories are absolutely mandatory for each proposed population to be covered, and this information should go directly to the advising experts for evaluation, whether the proposed negotiation is for discounted fee-for-service, a fee schedule, global bundled fees, or full capitation.

Significant questions have also been raised about the reimbursement implications for anesthesiologists of the managed care revolution. Again, the ASA has assembled a great deal of relevant information, the understanding of which is essential to successful negotiations.^{33,40} Table 2-5 is a list of information an anesthesia practice should have about its activities, and Table 2-6 is a sample “capitation checklist.” Initial consideration of a capitated contract should involve an attempt to take all the data about the existing practice and the proposed MCO-covered population and translate back from the proposed capitated rate to income figures that would correlate with the existing practice structure, to allow a comparison and an understanding of the relationship of the projected work to projected income. It is, of course, impossible to suggest dollar values for capitated rates for anesthesiology care because details and conditions vary so widely. One ASA publication⁴⁰ used examples, purely for illustrative purposes, involving \$2.50 or \$4.00 PMPM, but there have been unconfirmed reports of capitated rates as low as \$0.75 PMPM. Discounted fee-for-service arrangements are easier for anesthesiologists to understand because these are directly referable to existing fee structures. Reports of groups instituting 10–50% discounts off the starting point of 80% of usual and customary reimbursement in various practice circumstances have been circulated at national meetings of anesthesiologists. Although it seems likely that average income for anesthesiologists will decrease from past levels under all managed care systems, it also appears that anesthesiologists will continue to have very comfortable incomes, still among the higher figures for all physicians.

Table 2-6. CAPITATION CHECKLIST

Expansion into Perioperative Medicine, Hospital Care, and Hyperbaric Medicine

As the role of the anesthesiologist changes, in part due to the realities of workforce statistics and to the potential for decreased clinical workloads due to the success of managed care health systems, new opportunities should be explored. One set of ideas that has been circulating for some time has led to serious suggestions that the name of the profession of anesthesiology be changed to “perioperative medicine and pain management.” This suggestion illustrates that one prospective significant anesthesiology practice management strategy can be more formal organization of responsibilities for patients in the pre- and postoperative periods.

Many anesthesiologists now function at least some of the time in preoperative screening clinics because of the great fraction of OR patients who do not spend the night before surgery in the hospital or who do not come to a hospital at all. In such settings, these anesthesiologists frequently assume a role analogous to that of a primary care physician, planning and executing a work-up of one or more significant medical or surgical problems before the patient can reasonably be expected to undergo surgery. More formalized arrangements of this type would involve the creation of designated perioperative clinics operated and staffed by anesthesiologists. Ophthalmologists and orthopedists, for example, would no longer need to try to manage their surgical patients' medical problems themselves or send their patients proposed for surgery to an internist or other primary care provider for “preop clearance.” The anesthesiologist would assume that role at the same time the patient is undergoing preoperative evaluation for anesthesia care.

Likewise, this concept would be excellent for the postoperative period. An anesthesiologist, completely free of OR or other duties, could not only make at least twice-daily rounds on patients after surgery and provide exceedingly comprehensive pain management service, but also could follow the surgical progress and make virtually continuous reports (likely *via* e-mail) to the surgeon's office or alphanumeric pocket communicator. Surgeons would have a much better handle on their patients' progress while having more time to tend to other new patients in the office or OR. The utilization review and fast-track protocol administrators would have a contact person who is not tied up in an OR or office continuously available. Patients would receive much more physician attention and perceive this as actually a significant improvement in their care. Equivalent outpatient or recuperative center services could easily be established. In this regard, some anesthesiologists function as hospitalists for the care of both surgical and medical patients. A fundamental aspect of the practice of anesthesiology is the management of acute problems in the hospital setting. It is logical that anesthesiologists would be among the physicians best suited to provide primary care for patients in the hospital setting. Although the comfort level of anesthesiologists varies in the fields of internal medicine and pediatrics, it is likely that this trend will continue among those interested and competent in hospital care.

Finally, anesthesiologists are becoming increasingly involved in the practice of hyperbaric medicine and wound care. This is likely related to the familiarity of anesthesiologists with concepts of gas laws and physics, along with their constant presence in the hospital. The treatment of various medical conditions by the application of oxygen under increased pressure, usually 2–3 atmospheres absolute, is one of the most rapidly growing hospital services. Anesthesiologists are among the leaders of this field, with unlimited opportunities for clinical care, teaching, and research. Again, even a brief discussion is outside the scope of this chapter and interested readers are referred to the Undersea and Hyperbaric Medical Society (www.umhs.org).

Creative exploration of new opportunities involving these and other ideas will open new avenues for anesthesiology (or whatever it is eventually called) practice.

CONCLUSION

Practice management in anesthesiology today is more complex and more important than ever before. Attention to details that previously either did not exist or were deemed unimportant can likely make the difference between success and failure in anesthesiology practice.

Outlined here are basic descriptions and understandings of many different administrative, organizational, and financial components and factors in the practice of anesthesiology. Ongoing significant changes in the health care system will provide a continuing array of challenges. Application of the principles presented here will allow anesthesiologists to creatively extrapolate from these basics to their own individual circumstances and forge ahead.

INTRODUCTION

Medical journals are replete with numbers. These include weights, lengths, pressures, volumes, flows, concentrations, counts, temperatures, rates, currents, energies, and forces. For five decades, anesthesia journals have exhorted the researcher to collect, analyze, and interpret these numbers more carefully. The analysis and interpretation of these numbers require the use of statistical techniques; the design of the experiment to acquire these numbers is also part of statistical competence. The need for these statistical techniques is mandated by the nature of our universe, which is both orderly and random at the same time. For example, the anesthesiologist knows that halothane has a dose-response pharmacology—increasing concentrations produce greater effects: a sufficiently high concentration will anesthetize the patient; even higher concentrations will kill. Yet, for any individual patient, only a guess can be made in advance as to the necessary concentration to produce anesthesia. If everything were known about the function of the body, it is possible that the necessary anesthetizing concentration could be predicted. Instead, one must rely on the minimum alveolar anesthetic concentration (MAC), which characterizes the response to halothane for a group of patients. It allows only an initial guess as to the amount required for any individual patient.

Probability and statistics have been formulated to solve concrete problems, such as betting on cards, understanding biologic inheritance, and improving food processing. Studies in anesthesia have even inspired new statistics; the National Halothane Study prompted new advances in the analysis of frequency tables. The development of statistical techniques is manifest in the increasing use of more sophisticated research designs and statistical tests in anesthesia research.

If a physician is to be a practitioner of scientific medicine, he or she must read the language of science in order to be able to independently assess and interpret the scientific report; and, without exception, the language of the medical report is increasingly statistical. Readers of the anesthesia literature, whether in a community hospital or a university environment, cannot and should not totally depend on the editors of journals to banish all errors of statistical analysis and interpretation. In addition there are regularly questions about simple statistics in examinations required for anesthesiologists. Finally, certain statistical methods have everyday applications in clinical medicine. This chapter briefly scans some elements of experimental design and statistical analysis; it does not provide the systematic review.

DESIGN OF RESEARCH STUDIES

The scientific investigator should view himself or herself as an experimenter and not merely as a naturalist. The naturalist goes out into the field ready to capture and report the numbers that flit into view; this is a worthy activity, typified by the case report. Case reports engender interest, suspicion, doubt, wonder, and, one hopes, the desire to experiment; however, the case report is not sufficient evidence to advance scientific medicine. The experimenter attempts to constrain and control, as much as possible, the environment in which he or she collects numbers to test a hypothesis.

In undertaking a research project, the investigator is implicitly accepting the philosophical concept that the results in a group of patients can be applied to an individual patient. Especially as applied to the therapy of disease, this idea has engendered controversy for centuries. On the one side is the contention that the individuality of each person demands that the therapy of disease be unique. Proponents would argue as follows: "The probabilities and results of a research report may not apply to an individual patient. For the individual patient, a treatment is either a failure or a success. A patient cannot be four-fifths alive, but is either alive or dead. Treatment should be individualized to each patient. Any type of therapy which might be possibly and plausibly beneficial should be allowed."

More persuasive is the argument adopted by proponents of scientific medicine: "No therapeutic agent can be employed with discrimination unless the general efficacy of the agent has been confirmed in analogous cases. Although each patient is distinct and therapy should be adapted to the circumstances, the most likely therapy to benefit a patient will be that which is supported by experimental evidence." The hope for the generalizability of medical research results impels the publication of medical journals.

Sampling

Two words of great importance to statisticians are *population* and *sample*. In statistical language, each has a specialized meaning. Instead of referring only to the count of individuals in a geographic or political region, population refers to any target group of things (animate or inanimate) in which there is interest. For anesthesia researchers, a typical target population might be mothers in the first stage of labor, for example, or head trauma victims undergoing craniotomy. A target population could also be cell cultures, isolated organ preparations, or hospital bills. A sample is a subset of the target population. Samples are taken because of the impossibility of observing the entire population; it is generally not affordable, convenient, or practical to examine more than a relatively small fraction of the population. Nevertheless, the researcher wishes to generalize from the results of the small sample group to the entire population.

Although the subjects of a population are alike in at least one way, these population members are generally quite diverse in other ways. Since the researcher can work only with a subset of the population, he or she hopes that the sample of subjects in the experiment is representative of the population's diversity. Head-injury patients can have open or closed wounds, a variety of coexisting diseases, and normal or increased intracranial pressure. These subgroups within a population are called *strata*. Often the researcher wishes to increase the sameness or homogeneity of the target population by further restricting it to just a few strata; perhaps only closed and not open head injuries will be included. Restricting the target population to eliminate too much diversity must be balanced against the desire to have the results be applicable to the broadest possible population of patients.

The best hope for a representative sample of the population would be realized if every subject in the population had the same chance of being in the experiment; this is called *random sampling*. If there are several strata of importance, random sampling from each stratum would be appropriate. Unfortunately, in most clinical anesthesia studies researchers are limited to using those patients who happen to show up at their hospitals; this is called *convenience sampling*. Convenience sampling is also subject to the nuances of the surgical schedule, the goodwill of the referring physician and attending surgeon, and the willingness of the patient to cooperate. At best, the convenience sample is representative of patients at that institution, with no assurance that these patients are similar to those elsewhere. Convenience sampling is

also the rule in studying new anesthetic drugs in volunteers; such studies are typically performed on healthy, young students.

The researcher must define the conditions to which the sample members will be exposed. Particularly in clinical research, one must decide whether these conditions should be rigidly standardized or whether the experimental circumstances should be adjusted or individualized to the patient. In anesthetic drug research, should a fixed dose be given to all members of the sample or should the dose be adjusted to produce an effect or to achieve a specific end point? Standardizing the treatment groups by fixed doses simplifies the research work. There are risks to this standardization, however: (1) A fixed dose may produce excessive numbers of side effects in some patients; (2) a fixed dose may be therapeutically insufficient in others; and (3) a treatment standardized for an experimental protocol may be so artificial that it has no broad clinical relevance, even if demonstrated to be superior.

Control Groups

Even if a researcher is studying just one experimental group, the results of the experiment are usually not interpreted solely in terms of that one group but are also contrasted and compared with other experimental groups. Examining the effects of a new drug on blood pressure during anesthetic induction is important, but what is more important is comparing those results with the effects of one or more standard drugs commonly used in the same situation. Where can the researcher obtain these comparative data? There are several possibilities: (1) Each patient could receive the standard drug under identical experimental circumstances at another time; (2) another group of patients receiving the standard drug could be studied simultaneously; (3) a group of patients could have been studied previously with the standard drug under similar circumstances; and (4) literature reports of the effects of the drug under related but not necessarily identical circumstances could be used. Under the first two possibilities the control group is contemporaneous—either *self-control* (cross-over) or *parallel control* group. The second two possibilities are examples of the use of *historical controls*.

Because historical controls already exist, they are convenient and seemingly cheap to use. Unfortunately, the history of medicine is littered with the debris of therapies enthusiastically accepted on the basis of comparison with past experience but later found to be worthless. A classic example was operative ligation of the internal mammary artery for the treatment of angina pectoris. There is now firm empirical evidence that studies using historical controls usually show a favorable outcome for a new therapy, whereas studies with concurrent controls, *i.e.*, parallel control group or self-control, less often reveal a benefit. Nothing seems to increase the enthusiasm for a new treatment as much as the omission of a concurrent control group. If the outcome with an old treatment is not studied simultaneously with the outcome of a new treatment, one cannot know if any differences in results are a consequence of the two treatments, or of unsuspected and unknowable differences between the patients, or of other changes over time in the general medical environment. One possible exception would be in studying a disease that is uniformly fatal (100% mortality) over a very short time.

Random Allocation of Treatment Groups

Having accepted the necessity of an experiment with a control group, the question arises as to the method by which each subject should be assigned to the predetermined experimental groups. Should it depend on the whim of the investigator, the day of the week, the preference of a referring physician, the wish of the patient, the assignment of the previous subject, the availability of a study drug, a hospital chart number, or some other arbitrary criterion? All such methods have been used and are still used, but all can ruin the purity and usefulness of the experiment. It is important to remember the purpose for sampling: by exposing a small number of subjects from the target population to the various experimental conditions, one hopes to make conclusions about the entire population. Thus, the experimental groups should be as similar as possible to each other in reflecting the target population; if the groups are different, this introduces a bias into the experiment. Although randomly allocating subjects of a sample to one or another of the experimental groups requires additional work, this principle prevents selection bias by the researcher, minimizes (but can not always prevent) the possibility that important differences exist among the experimental groups, and disarms the critics' complaints about research methods. Random allocation is most commonly accomplished by computer-generated random numbers.

Blinding

Blinding refers to the masking from the view of patient and experimenter the experimental group to which the subject has been or will be assigned. In clinical trials, the necessity for blinding starts even before a patient is enrolled in the research study. There is good evidence that, if the process of random allocation is accessible to view, the referring physicians, the research team members, or both are tempted to manipulate the entrance of specific patients into the study to influence their assignment to a specific treatment group; they do so having formed a personal opinion about the relative merits of the treatment groups and desiring to get the "best" for someone they favor. This creates bias in the experimental groups.

Each subject should remain, if possible, ignorant of the assigned treatment group after entrance into the research protocol. The patient's expectation of improvement, a placebo effect, is a real and useful part of clinical care. But when studying a new treatment, one must ensure that the fame or infamy of the treatments does not induce a bias in outcome by changing patient expectations. Such a study, in which the subject is unaware of the treatment given, is called *single blind*. A researcher's knowledge of the treatment assignment can bias his or her ability to administer the research protocol and to observe and record data faithfully; this is true for clinical, animal, and *in vitro* research. If the treatment group is known, those who observe data cannot trust themselves to record the data impartially and dispassionately. A *double-blind* study, in which both subject and data collector are ignorant of the treatment group, is the best way to test a new therapy.

Types of Research Design

Ultimately, research design consists of choosing what subjects to study, what experimental conditions and constraints to enforce, and which observations to collect at what intervals. A few key features in this research design largely determine the strength of scientific inference on the collected data. These key features allow the classification of research reports (Table 3-1). This classification reveals the variety of experimental approaches and indicates strengths and weaknesses of the same design applied to many research problems.

-
- I. Longitudinal studies
 - A. Prospective (cohort) studies
 - 1. Studies of deliberate intervention
 - a. Concurrent controls
 - b. Historical controls
 - 2. Observational studies
 - B. Retrospective (case-control) studies
 - II. Cross-sectional studies
-

Table 3-1. CLASSIFICATION OF BIOMEDICAL RESEARCH REPORTS

The first distinction is between *longitudinal* and *cross-sectional* studies. The former's object is the study of changes over time, whereas the latter describes a phenomenon at a certain point in time. For example, reporting the frequency with which certain drugs are used during anesthesia is a cross-sectional study, whereas investigating the hemodynamics of different drugs during anesthesia is a longitudinal one.

Longitudinal studies are next classified by the method with which the research subjects are selected. These methods for choosing research subjects can be either *prospective* or *retrospective*; these two approaches are also known as *cohort* (prospective) or *case-control* (retrospective). A prospective study assembles groups of subjects by some input characteristic that is thought to change an output characteristic; a typical input characteristic would be the primary drug used for anesthetic induction, *e.g.*, alfentanil or sufentanil. A retrospective study gathers subjects by an output characteristic; an output characteristic is the status of the subject after an event, *e.g.*, the occurrence of a myocardial infarction. A prospective (cohort) study would be one in which a group of patients undergoing heart surgery was divided in two groups, given two different anesthetic inductions (alfentanil or sufentanil), and followed for the development of a perioperative myocardial infarction. In a retrospective (case-control) study, patients who suffered a perioperative myocardial infarction would be identified from hospital records; a group of subjects of similar age, gender, and disease who did not suffer a perioperative myocardial infarction also would be chosen, and the two groups would then be compared for the relative use of the two anesthetic induction drugs (alfentanil or sufentanil). Retrospective studies are a primary tool of epidemiology. A case-control study can often identify an association between an input and output characteristic, but the causal link or relationship between the two is more difficult to specify.

Prospective studies are further divided into those in which the investigator performs a deliberate intervention and those in which the investigator merely observes. In a

study of *deliberate intervention*, the investigator would choose several anesthetic maintenance techniques and compare the incidence of postoperative nausea and vomiting. If it was performed as an *observational study*, the investigator would observe a group of patients receiving anesthetics chosen at the discretion of each patient's attending anesthesiologist and compare the incidence of postoperative nausea and vomiting among the anesthetics used. Obviously, in this example of an observational study, there has been an intervention; an anesthetic has been given. The crucial distinction is whether the investigator controlled the intervention. An observational study may reveal differences among treatment groups, but whether such differences are the consequence of the treatments or of other differences among the patients receiving the treatments will remain obscure.

Studies of deliberate intervention are further subdivided into those with concurrent controls and those with historical controls. Concurrent controls are either a simultaneous parallel control group or a self-control study; historical controls include previous studies and literature reports. A *randomized controlled trial* is thus a longitudinal, prospective study of deliberate intervention with concurrent controls.

Although most of this discussion about experimental design has focused on human experimentation, the same principles apply and should be followed in animal experimentation. The randomized, controlled clinical trial is the most potent scientific tool for evaluating medical treatment; randomization into treatment groups is relied upon to equally weight the subjects of the treatment groups for baseline attributes that might predispose or protect the subjects from the outcome of interest.

Hypothesis Formulation

Whether the research subjects are tissue preparations, animals, or people, the researcher is constantly faced with finding both similarities and differences among the diversities of a group of subjects. The researcher starts the work with some intuitive feel for the phenomenon to be studied. Whether stated explicitly or not, this is the *biologic hypothesis*; it is a statement of experimental expectations to be accomplished by the use of experimental tools, instruments, or methods accessible to the research team. An example would be the hope that isoflurane would produce less myocardial ischemia than fentanyl; the experimental method might be the electrocardiographic determination of ST segment changes. The biologic hypothesis of the researcher becomes a *statistical hypothesis* during research planning. The researcher measures quantities that can vary—variables such as heart rate or temperature or ST segment change. In a statistical hypothesis, statements are made about the relationship among parameters of one or more populations. A *parameter* is a number describing a variable of a population; Greek letters are used to denote parameters. The statistical hypothesis can be established in a somewhat rote fashion for every research project, regardless of the methods, materials, or goals.

The most frequently used method of setting up the algebraic formulation of the statistical hypothesis is to create two mutually exclusive statements about some parameters determined from the study population (Table 3-2); estimates for the values for these parameters are acquired by sampling data. In the hypothetical example comparing isoflurane and fentanyl, f_1 and f_2 would represent the ST segment changes with isoflurane and with fentanyl. The *null hypothesis* is the hypothesis of no difference of ST segment changes between isoflurane and fentanyl. The *alternative hypothesis* is usually nondirectional, *i.e.*, either $f_1 < f_2$ or $f_1 > f_2$; this is known as a two-tail alternative hypothesis. This is a more conservative alternative hypothesis than assuming that the inequality can only be either $<$ or $>$.

| | |
|---------------------------|--|
| $H_0: \phi_1 = \phi_2$ | (null hypothesis) |
| $H_1: \phi_1 \neq \phi_2$ | (alternative hypothesis) |
| ϕ_1 | = Parameter estimated from sample of first population |
| ϕ_2 | = Parameter estimated from sample of second population |

Table 3-2. ALGEBRAIC STATEMENT OF STATISTICAL HYPOTHESES

Logic of Proof

One particular decision strategy is used almost universally to choose between the null and alternative hypothesis. The decision strategy is similar to a method of indirect proof used in mathematics called *reductio ad absurdum*. If a theorem cannot be proved directly, assume that it is not true; show that the falsity of this theorem will lead to contradictions and absurdities; thus, reject the original assumption of the falseness of the theorem. For statistics, the approach is to assume that the null hypothesis is true even if the goal of the experiment is to show that there is a difference. One examines the consequences of this assumption by examining the actual sample numbers obtained for the variable(s) of interest. This is done by calculating what are called *sample test statistics*; sample test statistics are calculated from the sample numbers. Associated with a sample test statistic is a *probability*. One also chooses the *level of significance*; the level of significance is the probability level considered too low to warrant support of the null hypothesis being tested. If sample values are sufficiently unlikely to have occurred by chance (*i.e.*, the probability of the sample test statistic is less than the chosen level of significance), the null hypothesis is rejected; otherwise the null hypothesis is not rejected.

Because the statistics deal with probabilities, not certainties, there is a chance that the decision concerning the null hypothesis is erroneous. These errors are best displayed in table form (Table 3-3); Condition 1 and Condition 2 could be different drugs, two doses of the same drug, or different patient groups. Of the four possible outcomes, two are clearly undesirable. The error of wrongly rejecting the null hypothesis (false positive) is called the *Type I* or *alpha error*. The experimenter should choose a probability value for alpha before collecting data; the experimenter decides how cautious to be about falsely claiming a difference. The most common choice for the value of alpha is 0.05. What are the consequences of choosing an alpha of 0.05? Assuming that there is, in fact, no difference between the two conditions and that the experiment is to be repeated 20 times, then during one of these experimental replications (5% of 20) a mistaken conclusion that there is a difference would be made. The probability of a Type I error depends on just two factors: the chosen level of significance and the existence or nonexistence of a difference between the two experimental conditions. The smaller the chosen alpha, the smaller will be the risk of a Type I error.

| | | REALITY (POPULATION PARAMETERS) | |
|--|--------------------------------------|---|---|
| | | Conditions 1 and 2 equivalent | Conditions 1 and 2 not equivalent |
| CONCLUSION FROM OBSERVATIONS (SAMPLE STATISTICS) | Conditions 1 and 2 equivalent* | Correct conclusion | False-negative Type II error (beta error) |
| | Condition 1 and 2 not equivalent† | False-positive Type I error (alpha error) | Correct conclusion |

* Do not reject null hypothesis: Condition 1 = Condition 2.
† Reject null hypothesis: Condition 1 ≠ Condition 2.

Table 3-3. ERRORS IN HYPOTHESIS TESTING: THE TWO-WAY TRUTH TABLE

The error of failing to reject a false null hypothesis (false negative) is called a *Type II* or *beta error*. The power of a test is 1 minus beta. The probability of a Type II error depends on four factors. Unfortunately, the smaller the alpha, the greater the chance of a false-negative conclusion; this fact keeps the experimenter from automatically choosing a very small alpha. Second, the more variability there is in the populations being compared, the greater the chance of a Type II error. This is analogous to listening to a noisy radio broadcast; the more static there is, the harder it will be to discriminate between words. Next, increasing the number of subjects will lower the probability of a Type II error. The fourth and most important factor is the magnitude of the difference between the two experimental conditions. The probability of a Type II error goes from very high, when there is only a small difference, to extremely low, when the two conditions produce large differences in population parameters.

Sample Size Calculations

Discussion of hypothesis testing by statisticians has always included mention of both Type I and Type II errors, but researchers have typically ignored the latter error in experimental design. The practical importance of worrying about Type II errors reached the consciousness of the medical research community about 20 years ago. Some controlled clinical trials that claimed to find no advantage of new therapies compared with standard therapies lacked sufficient statistical power to discriminate between the experimental groups and would have missed an important therapeutic improvement. There are four options for decreasing Type II error (increasing statistical power): (1) Raise alpha, (2) reduce population variability, (3) make the sample bigger, and (4) make the difference between the conditions greater. Under most circumstances, only the sample size can be varied. Sample size planning has become an important part of research design for controlled clinical trials. Some published research still fails the test of adequate sample size planning.

Implications

The elements of good experimental design—random sampling, control groups, random allocation, blinding, and sample size planning—are not mere theoretical concerns; they have a solid empirical basis. This is illustrated by two controversies.

The best anesthetic to minimize perioperative myocardial ischemia and infarction and to lower perioperative mortality in patients undergoing coronary artery bypass grafting (CABG) remains a continuing disputation. After an assertion was made in the 1980s that isoflurane fosters myocardial ischemia, two randomized controlled trials provided conflicting reports about isoflurane's danger or lack thereof. In one study (1989) of about 1000 patients, approximately equal numbers were anesthetized with enflurane, halothane, isoflurane, or sufentanil; in-hospital mortality was low (1–2%) and roughly equivalent among the four groups. In another study (1990) of about 1200 patients, approximately equal numbers were anesthetized with enflurane or isoflurane; in-hospital mortality was significantly higher in those receiving isoflurane (2.1%) compared to those receiving enflurane (0.3%). Is isoflurane safe? Which study should be believed? Many comparisons can be made between the two studies, but one of the most pertinent concerns experimental design. While both studies claimed to use random allocation of treatment groups, the 1990 report actually alternated the anesthetic used in all operating rooms between enflurane and isoflurane every week. This is an example of pseudo random allocation. The 1989 report did indeed randomly allocate patients to their anesthetic group; in fact, to eliminate a misallocation of the four anesthetics among the patients of the four surgeons participating in the research, random allocation was stratified (performed separately) by surgeon. Greater weight should be given to the study design with true random allocation. This experimental design is less likely to be afflicted with biases in patient selection.

Pulse oximetry has helped revolutionize monitoring in the operating room and is now a standard of care in many countries. Yet it was adopted without a prior demonstration of an improvement—by its routine use—of patient outcome. Finally a multicenter, randomized controlled trial was completed and published. More than 20,000 adult patients were randomly divided into two groups: in 10,000 pulse oximetry was applied in the operating room and the post anesthesia care unit; no pulse oximetry monitoring was used for the other 10,000. There were approximately equal numbers of deaths, cardiac arrests, myocardial infarctions, strokes, and all other serious morbidity in the two groups. Editorial comment about this study has focused on the near impossibility of studying the effect of improved monitoring on anesthetic mortality and serious morbidity. Why is there such an impossibility? Anesthesia is now so safe that it may require 500,000 to millions of patients to detect improvement—that is, to have sufficient statistical power to distinguish outcome differences. There are no resources (money, personnel, interest) to perform such large studies.

STATISTICAL TESTING

Statistics is a method for working with sets of numbers, a set being a group of objects. Statistics involves the description of number sets, the comparison of number sets with theoretical models, comparison between number sets, and comparison of recently acquired number sets with those from the past. A typical scientific hypothesis asks which of two methods, X and Y, is better. A statistical hypothesis is formulated concerning the sets of numbers collected for X and Y. Statistics provides methods for deciding if the values of set X are different from the values of set Y. Statistical methods are necessary because there are sources of variation in any data set, including random biologic variation and measurement error. These errors in the data cause difficulties in avoiding bias and in being precise. Bias keeps the true value from being known and fosters incorrect decisions; precision deals with the problem of the data scatter and with quantifying the uncertainty about the value in the population from which a sample is drawn. These statistical methods are relatively independent of the particular field of study. Regardless of whether the numbers in sets X and Y are systolic pressures, body weights, or serum chlorides, the approach for comparing sets X and Y is usually the same.

Data Structure

Data collected in an experiment include the defining characteristics of the experiment and the values of events or attributes that vary over time or conditions. The former are called *explanatory variables* and the latter are called *response variables*. The researcher records his or her observations on data sheets or case record forms, which may be one to many pages in length, and assembles them together for statistical analysis. Variables such as gender, age, and doses of accompanying drugs reflect the variability of the experimental subjects. Explanatory variables, it is hoped, explain the systematic variations in the response variables. In a sense, the response variables are dependent on the explanatory variables.

Response variables are also called *dependent variables*. Response variables reflect the primary properties of experimental interest in the subjects. Research in anesthesiology is particularly likely to have repeated measurement variables, *i.e.*, a particular measurement recorded more than once for each individual. Some variables can be both explanatory and response; these are called *intermediate response variables*. Suppose an experiment is conducted comparing electrocardiographic and myocardial responses between five doses of an opioid. One might analyze how ST segments depended on the dose of opioids; here, maximum ST segment depression is a response variable. Maximum ST segment depression might also be used as an explanatory variable to address the more subtle question of the extent to which the effect of an opioid dose on postoperative myocardial infarction can be accounted for by ST segment changes.

The mathematical characteristics of the possible values of a variable fit into five classifications (Table 3-4). Properly assigning a variable to the correct data type is essential for choosing the correct statistical technique. For *interval variables*, there is equal distance between successive intervals; the difference between 15 and 10 is the same as the difference between 25 and 20. *Discrete interval data* can have only integer values, *e.g.*, ages in years, number of live children, or papers rejected by a journal. *Continuous interval data* are measured on a continuum and can be a decimal fraction; for example, blood pressure can be described as accurately as desired, *e.g.*, 136, 136.1, or 136.14 mm Hg. The same statistical techniques are used for discrete and continuous data.

| Data Types | Definition | Examples |
|--------------------|---|---------------------------------------|
| INTERVAL | | |
| Discrete | Data measured with an integer-only scale | Age, parity |
| Continuous | Data measured with a constant scale interval | Blood pressure, temperature |
| CATEGORICAL | | |
| Dichotomous | Binary data | Mortality, gender |
| Nominal | Qualitative data that cannot be ordered or ranked | Eye color, drug category |
| Ordinal | Data ordered, ranked, or measured without a constant scale interval | ASA physical status score, pain score |

Table 3-4. DATA TYPES

Categorical variables are derived by putting observations into two or more discrete categories; for statistical analysis, numeric values are assigned as labels to the categories. *Dichotomous data* allow only two possible values, *e.g.*, male versus female. *Ordinal data* have three or more categories that can logically be ranked or ordered; however, the ranking or ordering of the variable indicates only relative and not absolute differences between values; there is not necessarily the same difference between American Society of Anesthesiologists Physical Status score I and II as there is between III and IV. Although ordinal data are often treated as interval data in choosing a statistical technique, such analysis may be suspect; alternative techniques for ordinal data are available. *Nominal variables* are placed into categories that have no logical ordering. The eye colors blue, hazel, and brown might be assigned the numbers 1, 2, and 3, but it is nonsense to say that blue <1 hazel <1 brown.

Descriptive Statistics

A typical hypothetical data set could be $A = (29, 32, 27, 28, 26, 27, 28, 29, 30, 32, 35, 31)$, representing a sample of ages (the variable) of 12 residents in an anesthesia training program (the population). Although the results of a particular experiment might be presented by repeatedly showing the entire set of numbers, there are concise ways of summarizing the information content of the set A into a few numbers. These numbers are called *sample* or *summary statistics*; summary statistics are calculated using the numbers of the sample. By convention, the symbols of summary statistics are Roman letters. The two summary statistics most frequently used for interval variables are the *central location* and the *variability*, but there are other summary statistics. Other data types have analogous summary statistics.

Although the first purpose of descriptive statistics is to describe the sample of numbers obtained, there is also the desire to use the summary statistics from the sample to characterize the population from which the sample was obtained. For example, what can be said about the age of all anesthesia residents from the information in set A ? The population also has measures of central location and variability called the parameters of the population; as previously mentioned, population parameters are denoted by Greek letters. Usually, the population parameters cannot be directly calculated, because data from all population members cannot be obtained. The beauty of properly chosen summary statistics is that they are the best possible estimators of the population parameters.

These sampling statistics can be used in conjunction with a theoretical probability distribution to provide additional descriptions of the sample and its population. A theoretical probability distribution is an algebraic equation, $f(x)$, which gives a theoretical percentage distribution of x . Each value of x has a probability of occurrence given by $f(x)$. This probability may be expressed as a percentage: $100 \times f(x)$. If $f(x)$ is summed or integrated for all possible values of x , the percentage must total 100% and the probability must total 1.0. The most important probability distribution is the *normal* or *gaussian function*. There are two parameters (population mean and population variance) in the equation of the normal function which are denoted μ and σ^2 . The normal equation can be plotted and produces the familiar bell-shaped curve. Why are the mathematical properties of this curve so important to biostatistics? First, it has been empirically noted that when a biologic variable is sampled repeatedly, the pattern of the numbers plotted as a histogram resembles the normal curve; thus, most biologic data are said to follow or to obey a normal distribution. Second, if it is reasonable to assume that a sample is from a normal population, the mathematical properties of the normal equation can be used with the sampling statistic estimators of the population parameters to describe the sample and the population. Third, a mathematical theorem (the Central Limit Theorem) allows the use of the assumption of normality for certain purposes, even if the population is not normally distributed.

Central Location

The three most common summary statistics of central location for interval variables are the arithmetic *mean*, the *median*, and the *mode*. The mean is merely the average of the numbers in the data set. Statistical formulas use a summation notation that considerably reduces the ink needed to print mathematical equations. The summary notation for the arithmetic mean is given below:

$$\bar{x} = \sum x_i / n \quad (3-1)$$

Capital sigma (Σ) is the summation operator; its purpose is to add up all values of x from x_1 to x_n ; the sum is then divided by the count of individuals (n) in the sample. Being a summary statistic of the sample, the arithmetic mean is denoted by the Roman letter \bar{x} . If all values in the population could be obtained, then the population mean (μ) could be calculated similarly. Because all values of the population cannot be obtained, the sample mean is used.*

The median is the middlemost number or the number that divides the sample into two equal parts. The median is obtained by first ranking the sample values from lowest to highest and then counting up halfway. The concept of ranking is used in nonparametric statistics. A virtue of the median is that it is hardly affected by a few extremely high or low values. The mode is the most popular number of a sample, *i.e.*, the number that occurs most frequently. A sample may have ties for the most common value and be bi- or polymodal; these modes may be widely separated or adjacent. The raw data should be inspected for this unusual appearance. The mode is always mentioned in discussions of descriptive statistics but is rarely used in statistical practice.

Spread or Variability

Any set of interval data has variability unless all the numbers are identical. The range of ages from lowest to highest expresses the largest difference within set A . This spread, diversity, and variability can also be expressed in a concise manner. Variability is specified by calculating the *deviation* or *deviate* of each individual x_1 from the center (mean) of all the x_1 's. The *sum of squared deviates* is always positive unless all set values are identical. This sum is then divided by the number of individual measurements. The result is the *averaged squared deviations*; the average squared deviation is ubiquitous in statistics.

The concept of describing the spread of a set of numbers by calculating the average distance from each number to the center of the numbers applies to both a sample and a population; this average squared distance is called the *variance*. The population variance is a parameter and is represented by σ^2 . As with the population mean, the population variance is not usually known and cannot be calculated. Just as the sample mean is used in place of the population mean, the sample variance is used in place of the population variance. The sample variance, s^2 , is

$$s^2 = \sum (x_i - \bar{x})^2 / (n - 1) \quad (3-2)$$

Statistical theory demonstrates that if the divisor in the formula for s^2 is $n - 1$ rather than n , the sample variance is an unbiased estimator of the population variance. While the variance is used extensively in statistical calculations, the units of variance are squared units of the original observations. The square root of the variance has the same units as the original observations; the square roots of the sample and population variances are called the *sample* and *population standard deviations*, s and S , respectively.

It was previously mentioned that most biologic observations appear to come from populations with normal or gaussian distributions. By accepting this assumption of a normal distribution, further meaning can be given to the sample summary statistics that have been calculated. This involves the use of the expression $\bar{x} \pm k \times s$, where $k = 1, 2, 3$, etc. If the population from which the sample is taken is unimodal and roughly symmetric, then

$\bar{x} \pm 1 \times s$ encompasses roughly 68% of the sample and population members;

$\bar{x} \pm 2 \times s$ encompasses roughly 95% of the sample and population members;

$\bar{x} \pm 3 \times s$ encompasses roughly 99% of the sample and population members.

In our example of hypothetical resident age, \bar{x} and s are 29.5 and 2.6; calculating the three intervals, $29.5 \pm 2 \times 2.6$ includes 10 of 12 observations, $29.5 \pm 2 \times 2.6$ includes 11 of 12 observations, and $29.5 \pm 3 \times 2.6$ includes all 12 values. The s usually gives a fairly good approximation of the spread of the sample data.

Confidence Intervals

A confidence interval describes how likely it is that the population parameter is estimated by any particular sample statistic such as the mean.* Confidence intervals are a range of the following form: summary statistic \pm (confidence factor) \times (precision factor).

The *precision factor* is derived from the sample itself, whereas the *confidence factor* is taken from a theoretical probability distribution and also depends on the specified confidence level chosen. For a sample of interval data taken from a normally distributed population for which confidence intervals are to be chosen for μ , the precision factor is called the *standard error of the mean* (SE) and is obtained by dividing s by the square root of the sample size:

$$SE = \frac{s}{\sqrt{n}} = \sqrt{\sum (x_i - \bar{x})^2 / n(n - 1)} \quad (3-3)$$

The confidence factors are the same as those used for the dispersion or spread of the sample and are obtained from the normal distribution. The confidence interval is read as follows:

$\bar{x} \pm 1 \times \text{SE}$ has roughly a 68% chance of containing the population mean;

$\bar{x} \pm 2 \times \text{SE}$ has roughly a 95% chance of containing the population mean;

$\bar{x} \pm 3 \times \text{SE}$ has roughly a 99% chance of containing the population mean.

For Sample A the SE is -0.8 ; there is a 95% chance that 29.5 ± 1.6 years will include the mean age of the anesthesia residents in the population sampled. The coefficients given above for confidence intervals are not exact; the 95% interval should use the coefficient 1.96. But 1, 2, and 3 are easier to remember and use. These confidence intervals are also calculated, assuming that the population s is known. In actuality, s was substituted for s . Strictly speaking, when s is not known, the confidence factors should be taken from the *t distribution*, another theoretical probability distribution. These coefficients will be larger than those used above. This is usually ignored if the sample size is reasonable, for example, $n > 125$. Even when the sample size is only five or greater, the use of the coefficients 1, 2, and 3 is simple and sufficiently accurate for quick mental calculations of parameter confidence intervals.

Almost all research reports include the use of SE, regardless of the probability distribution of the populations sampled. This use is a consequence of the Central Limit Theorem—one of the most remarkable theorems in all of mathematics. The Central Limit Theorem states that the SE can always be used, if the sample size is sufficiently large, to specify confidence intervals on the population mean. These confidence intervals are calculated as described above. This is true even if the population distribution is so different from normal that s cannot be used to characterize the dispersion of the population members. Only rough guidelines can be given for the necessary size of n ; for interval data, certainly, $n = 25$ and above is large enough and $n = 4$ and below is too small.

Although the SE is discussed along with other descriptive statistics, it is really an inferential statistic. SE and s are mentioned together because of their similarities of computation and because of the confusion of their use in research reports. This use is most often of the form “mean \pm number”; some confusion results from the failure of the author to specify whether the number after the \pm sign is the one or the other. More important, the choice between using s and using SE has become controversial; because SE is always less than s , it has been argued that authors seek to deceive by using SE to make the data look better than they really are. The choice is actually simple. When describing the spread, scatter, or dispersion of the sample, use s ; when describing the precision with which the population center is known, use the SE.

Proportions

Categorical binary data, also called *enumeration data*, provide counts of subject responses. Given a sample T of n subjects of whom x have a certain characteristic (e.g., death, female sex), a ratio of responders to the number of subjects can be easily calculated as $p = x/n$; this can also be expressed as a percentage, $100 \times p$. The ratio p is a descriptive or summary statistic of the sample T . Assume that $n = 15$ subjects and $x = 10$ deaths for sample T ; then $p = 10/15 = 0.67$ and $100 \times p = 67\%$. It should be clear that p is a measure of central location of sample T in the same way that \bar{x} was a measure of central location for sample A. In the population from which the sample T is taken, the ratio of responders to total subjects is a population parameter, denoted p ; p is the measure of central location for the population. This population parameter, p , is related to the geometry constant π ($p = 3.1415 \dots$). As with other data types, p is usually not known but must be estimated from the sample. The sample ratio p is the best estimate of p .

The probability of binary data is provided by the *binomial distribution*, another theoretical probability distribution. This distribution calculates the chance of x occurrences in a sample of n subjects from a population with an occurrence rate of p :

$$f(x) = \left(\frac{n!}{(x!(n-x)!)} \right) \times \pi^x \times (1 - \pi)^{(n-x)} \quad (3-4)$$

If the p of a population is known, then the probability of the observed response rate p is easily calculated. For example, if there are 10 deaths in 15 subjects and the population death rate is 50% ($p = 0.5$), then the probability is $15!/(10! \times (15-10)!) \times (0.5^{10}) \times (1-0.5)^{(15-10)} = 0.09$. This would be expressed as follows: If the population death rate was 50%, then in a sample of 15 individuals, there would be about a 9% chance of finding 10 deaths.

Since the population p is not generally known, the experimenter usually wishes to estimate p by the sample statistic p and to specify with what confidence p is known. If the sample is sufficiently large ($n \times p > 2.5$ and $n \times (1-p) > 2.5$), advantage is taken of the Central Limit Theorem to derive a standard error analogous to that derived for interval data:

$$\text{SE} = \left(p \times \frac{(1-p)}{n} \right)^{0.5} \quad (3-5)$$

This sample standard error is exactly analogous to the sample standard error of the mean for interval data, except that it is a standard error of the proportion. Just as a 95% confidence limit of the mean was calculated, so may a confidence limit on the proportion be obtained. Using the data of 10 deaths in 15 subjects, the summary statistic $p = 10/15 = 0.67$. Since $15 \times 0.67 = 10$ and $15 \times (1 - 0.67) = 5$, then n is sufficiently large. The sample standard error is $(0.67 \times (1 - 0.67)/15)^{0.5} = 0.12$. The 95% confidence interval on p will be $p \pm 2 \times \text{SE} = 0.67 \pm 2 \times 0.12 = 0.67 \pm 0.24$.

Thus, the best guess of the population death rate is 67%, and there is a 95% certainty that in the population sampled the death rate is in the range of 43–91%. The approximate nature of this calculation is reflected by the exact 95% confidence interval (36–86%) derived for these data from the binomial equation. Larger n 's and p 's closer to 0.5 will make the approximate and exact confidence intervals closer to identical. The reader can use this simple equation when authors do not calculate confidence intervals on rates and proportions.

Inferential Statistics

There are two major areas of statistical inference: the estimation of parameters and the testing of hypotheses. The use of the SE to create confidence intervals is an example of *parameter estimation*. The testing of hypotheses or *significance testing* is the main focus of inferential statistics. Hypothesis testing allows the experimenter to use data from the sample to make inferences about the population. Statisticians have created formulas that use the values of the samples to calculate test statistics. Statisticians have also explored the properties of various theoretical probability distributions. Depending on the assumptions about how data are collected, the appropriate theoretical probability distribution is chosen as the source of critical values to accept or reject the null hypothesis; if the value of the test statistic calculated from the sample(s) is greater than the critical value, the null hypothesis is rejected. The critical value is chosen from the appropriate probability distribution after the magnitude of the Type I error is specified.

There are parameters within the equation that generate any particular theoretical probability distribution; for the normal probability distribution, the parameters are m and S^2 . For the normal distribution, each set of values for m and S^2 will generate a different shape for the bell-like normal curve. All theoretical probability equations contain one or more parameters and can also be plotted as curves; these parameters may be discrete (integer only) or continuous. Each value or combination of values for these parameters will create a different curve for the probability distribution being used. Thus, each theoretical probability distribution is actually a family of probability curves. Some additional parameters of theoretical probability distributions have been given the special name *degrees of freedom*, and are represented by the letters m , n , p , and s .

Associated with the formula for computing a test statistic is a rule for assigning integer values to the one or more parameters called degrees of freedom. The number of degrees of freedom and the value for each degree of freedom depend on (1) the number of subjects, (2) the number of experimental groups, (3) the specifics of the statistical hypothesis, and (4) the type of statistical test. The correct curve of the theoretical probability distribution from which to obtain a critical value for comparison with the value of the test statistic is obtained with the values of one or more degrees of freedom.

To accept or reject the null hypothesis, the following steps are performed: (1) Confirm that experimental data conform to the assumptions of the intended statistical test; (2) choose a significance level (α); (3) calculate the test statistic; (4) determine the degree(s) of freedom; (5) find the critical value for the chosen α and the degree(s) of freedom from the appropriate theoretical probability distribution; (6) if the test statistic exceeds the critical value, reject the null hypothesis; (7) if the test statistic does not exceed the critical value, do not reject the null hypothesis. There are general guidelines that relate the variable type and the experimental design to the choice of statistical test ([Table 3-5](#)).

| Variable Type | One-Sample Tests | Two-Sample Tests | Multiple-Sample Tests |
|------------------------|--------------------------------------|---|--|
| Discrete or ordinal | Binomial distribution | Chi-square test | Chi-square test |
| Ordinal | Chi-square test | Chi-square test, nonparametric tests | Chi-square test, nonparametric tests |
| Continuous or discrete | t distribution or F distribution | Copied t test, paired t test, nonparametric tests | Analysis of variance, nonparametric analysis of variance |

Table 3-5. WHEN TO USE WHAT

Interval Data

Parametric statistics are the usual choice in the analysis of interval data, both discrete and continuous. The purpose of such analysis is to test the hypothesis of a difference between population means. The population means are unknown and are estimated by the sample means. A typical example would be the comparison of the mean heart rates of patients receiving and not receiving atropine. Parametric test statistics have been developed by using the properties of the normal probability distribution and two related theoretical probability distributions, the t and the F distribution. In using such parametric methods, the assumption is made that the sample or samples is / are drawn from population(s) with a normal distribution. The parametric test statistics that have been created for interval data all have the form of a ratio. In general terms, the numerator of this ratio is the variability of the means of the samples; the denominator of this ratio is the variability among all the members of the samples. These variabilities are similar to the variances developed for descriptive statistics. The test statistic is thus a ratio of variabilities or variances. All parametric test statistics are used in the same fashion; if the test statistic ratio becomes large, the null hypothesis of no difference is rejected. The critical values against which to compare the test statistic are taken from tables of the three relevant probability distributions.

By definition, in hypothesis testing, at least one of the population means is unknown, but the population variance(s) may or may not be known. Parametric statistics can be divided into two groups according to whether or not the population variances are known. If the population variance is known, the test statistic used is called the z score; critical values are obtained from the normal distribution. In most biomedical applications, the population variance is rarely known and the z score is little used.

t Test

An important advance in statistical inference came early in the 20th century with the creation of *Student's t test statistic* and the *t distribution*, which allowed the testing of hypotheses when the population variance is not known. The most common use of Student's t test is to compare the mean values of two populations. This use is further subdivided by a particular aspect of experimental design. If each subject has two measurements taken, for example, one before and one after a drug, then one sample or *paired t test* procedure is used; each control measurement taken before drug administration is paired with a measurement in the same patient after drug administration. Of course, this is a self-control experiment. This pairing of measurements in the same patient reduces variability and increases statistical power. There are two target populations in such an experiment: subjects before and subjects after the study drug. The difference d_i of each pair of values is calculated and the average d is calculated. In the formula for Student's t statistic, the numerator is \bar{d} , whereas the denominator is the standard error of \bar{d} (SE_d):

$$t \text{ test statistic} = \frac{\bar{d}}{SE_d} \quad (3-6)$$

All t statistics are created in this way; the numerator is the difference of two means, whereas the denominator is the standard error of the two means. If the difference between the two means is large compared with their variability, then the null hypothesis of no difference is rejected. The critical values for the t statistic are taken from the t probability distribution. The t distribution is symmetric and bell-shaped but more spread out than the normal distribution. The t distribution has a single integer parameter; for a paired t test, the value of this single degree of freedom is the sample size minus one. There can be some confusion about the use of the letter t . It refers both to the value of the test statistic calculated by the formula and to the critical value from the theoretical probability distribution. The critical t value is determined by looking in a t table after a significance level is chosen and the degree of freedom is computed.

More commonly, measurements are taken on two separate groups of subjects. For example, one group receives blood pressure treatment, whereas no treatment is given to a control group. The number of subjects in each group might or might not be identical; regardless of this, in no sense is an individual measurement in the first group matched or paired with a specific measurement in the second group. An *unpaired* or *two-sample t test* is used to compare the means of the two groups. The numerator of the t statistic is $(\bar{X}_1 - \bar{X}_2)$. The denominator is a weighted average of the SEs of each sample. The degree of freedom for an unpaired t test is calculated as the sum of the subjects of the two groups minus two. As with the paired t test, if the t ratio becomes large, the null hypothesis is rejected.

Multiple Comparisons and Analysis of Variance

Experiments in anesthesia, whether they are with humans or with animals, may not be limited to one or two groups of data for each variable. It is very common to follow a variable longitudinally; heart rate, for example, might be measured five times before and during anesthetic induction. These are also called repeated measurement experiments; the experimenter will wish to compare changes between the initial heart rate measurement and those obtained during induction. The experimental design might also include several groups receiving different induction drugs, e.g., comparing heart rate across groups immediately after laryngoscopy. Researchers have commonly handled these analysis problems with the t test. If heart rate is collected five times, these collection times could be labeled A , B , C , D , and E . Then A could be compared with B , C , D , and E ; B could be compared with C , D , and E ; and so forth. The total of possible pairings is ten; thus, ten paired t tests could be calculated for all the possible pairings of A , B , C , D , and E . A similar approach can be used for comparing more than two groups for unpaired data.

The use of t tests in this fashion is inappropriate. In testing a statistical hypothesis, the experimenter sets the level of Type I error; this is usually chosen to be 0.05. When using many t tests, as in the example above, the chosen error rate for performing all these t tests is much higher than 0.05, even though the Type I error is set at 0.05 for each individual comparison. In fact, the Type I error rate for all t tests simultaneously, i.e., the chance of finding at least one of the multiple t test statistics significant merely by chance, is given by the formula $\alpha = 1 - 0.95^k$. If 13 t tests are performed, the real error rate is 49%. Applying t tests over and over again to all the possible pairings of a variable will misleadingly identify statistical significance when there is, in fact, none.

The most versatile approach for handling comparisons of means among more than two groups is called *analysis of variance* and is frequently cited by the acronym ANOVA. Analysis of variance consists of rules for creating test statistics on means when there are more than two groups. These test statistics are called *F ratios*, after Ronald Fisher; the critical values for the F test statistic are taken from the F theoretical probability distribution that Fisher derived.

Suppose that data for three groups are obtained. What can be said about the mean values of the three target populations? The F test is actually asking several questions simultaneously: Is group 1 different from group 2, is group 2 different from group 3, and is group 1 different from group 3? As with the t test, the F test statistic is a ratio; in general terms, the numerator expresses the variability of the mean values of the three groups, whereas the denominator expresses the average variability or difference of each sample value from the mean of all sample values. The formulas to create the test statistic are computationally elegant but are rather hard to appreciate intuitively. The F statistic has two degrees of freedom, denoted m and n ; the value of m is a function of the number of experimental groups; the value for n is a function of the number of subjects in all experimental groups. The analysis of multigroup data is not necessarily finished after the ANOVAs are calculated. If the null hypothesis is rejected and it is accepted that there are differences among the groups tested, how can it be decided where the differences are? A variety of techniques are available to make what are called multiple comparisons after the ANOVA test is performed.

Robustness and Nonparametric Tests

Most statistical tests depend on certain assumptions about the nature of the distribution of values in the underlying populations from which experimental samples are taken. For the parametric statistics, i.e., t tests and analysis of variance, it is assumed that the populations follow the normal distribution. However, for some data, experience or historical reasons suggest that these assumptions of a normal distribution do not hold; some examples include proportions, percentages, and response

times. What should the experimenter do if he or she fears that the data are not normally distributed?

The experimenter might choose to ignore the problem of non-normal data and inhomogeneity of variance, hoping that everything will work out. Such insouciance is actually a very practical and reasonable approach to the problem. Parametric statistics are called “robust” statistics; they stand up to much adversity. To a statistician, robustness implies that the magnitude of Type I errors is not seriously affected by ill-conditioned data. Parametric statistics are sufficiently robust that the accuracy of decisions reached by means of *t* tests and analysis of variance remains very credible, even for moderately severe departures from the assumptions.

Another possibility would be to use statistics that do not require any assumptions about probability distributions of the populations. Such statistics are known as *nonparametric tests*; they can be used whenever there is very serious concern about the shape of the data. Nonparametric statistics are also the tests of choice for ordinal data. The basic concept behind nonparametric statistics is the ability to rank or order the observations; nonparametric tests are also called *order statistics*.

Most nonparametric statistics still require the use of theoretical probability distributions; the critical values that must be exceeded by the test statistic are taken from the binomial, normal, and chi-square distributions, depending on the nonparametric test being used. The *nonparametric sign test*, *Mann-Whitney rank sum test*, and *Kruskal-Wallis one-way analysis of variance* are analogous to the paired *t* test, unpaired *t* test, and one-way analysis of variance, respectively. The currently available nonparametric tests are not used more commonly because they do not adapt well to complex statistical models and because they are less able than parametric tests to distinguish between the null and alternative hypotheses if the data are, in fact, normally distributed.

Contingency Tables

In a hypothetical experiment comparing performance on an examination, about 83% of the anesthesia faculty passed, whereas less than 38% of anesthesia residents passed. Is this difference real? This question is also stated as whether there is a dependency or association between the rows and the columns of the 2 × 2 (2 rows and 2 columns) contingency table. A variety of statistical techniques allow us to compare this pass/fail rate in the underlying populations of all anesthesia faculty and all anesthesia residents. The *chi-square test* offers the advantage of being computationally simpler; it can also analyze contingency tables with more than two rows and two columns. The chi-square test statistic is a sum of ratios. For each cell of the contingency table, the observed value has been recorded. Using the assumption that there is no association between the rows and the columns, the expected value for each cell is the row total multiplied by the column total divided by the total number of subjects. For each cell, the squared difference between the observed and expected value expressed the variability of the observed value away from the expected value. The test statistic is the sum of these difference ratios:

$$\chi^2_{(df)} = \sum \frac{(|\text{observed} - \text{expected}| - 0.5)^2}{\text{expected}} \quad (3-7)$$

If the difference between observed and expected cell values grows larger, it is more likely that there is an association between the rows and columns. This equation can be used to calculate a chi-square statistic for any size contingency table. The critical values used with the chi-square test statistic are from the χ^2 or chi-square continuous theoretical probability distribution with its associated degree of freedom. The value of this degree of freedom is the product of the number of rows minus 1 times the number of columns minus 1. For 2 × 2 tables, the value for the degree of freedom is always 1. The smallest expected cell value should be at least 5 or the test statistic will be biased. For 2 × 2 contingency tables, the counts within the four cells are usually labeled *a*, *b*, *c*, and *d* with *n* equaling the sum of the counts of the four cells; there is a simpler formula for the calculation of the chi-square test statistic of 2 × 2 contingency tables:

$$\chi^2_1 = \frac{(|a \times d - b \times c| - n/2)^2 \times n}{(a + b)(a + c)(b + d)(c + d)} \quad (3-8)$$

Interpretation of Results

Scientific studies do not end with the statistical test. The experimenter must submit an opinion as to the generalizability of his or her work to the rest of the world. Even if there is a statistically significant difference, the experimenter must decide if this difference is medically or physiologically important. Statistical significance does not always equate with biologic relevance. The questions an experimenter should ask about the interpretation of results are highly dependent on the specifics of the experiment. First, even small, clinically unimportant differences between groups can be detected if the sample size is sufficiently large. On the other hand, if the sample size is small, one must always worry that identified or unidentified confounding variables may explain any difference; as the sample size decreases, randomization is less successful in assuring homogenous groups. Second, if the experimental groups are given three or more doses of a drug, do the results suggest a steadily increasing or decreasing dose–response relationship? Suppose the observed effect for an intermediate dose is either much higher or much lower than that for both the highest and lowest dose; a dose–response relationship may exist, but some skepticism about the experimental methods is warranted. Third, for clinical studies comparing different drugs, devices, and operations on patient outcome, are the patients, clinical care, and studied therapies sufficiently similar to those provided at other locations to be of interest to a wide group of practitioners? This is the distinction between *efficacy*—does it work under the best (research) circumstances—and *effectiveness*—does it work under the typical circumstances of routine clinical care. Finally, in comparing alternative therapies, the confidence that a claim for a superior therapy is true depends on the study design. The strength of the evidence concerning efficacy will be least for an anecdotal case report; next in importance will be a retrospective study, then a prospective series of patients compared with historical controls, and finally a randomized, controlled clinical trial. The greatest strength for a therapeutic claim is a series of randomized, controlled clinical trials confirming the same hypothesis.

READING JOURNAL ARTICLES

Tens of hundreds of thousands of words are written each year in journal articles relevant to anesthesia. No one can read them all. How should the clinician determine which articles are useful? All that is possible is to learn to rapidly skip over most articles and concentrate on the few selected for their importance to the reader. Those few should be chosen according to their relevance and credibility. Relevance is determined by the specifics of one's anesthetic practice. Credibility is a function of the merits of the research methods, the experimental design, and the statistical analysis; the more proficient one's statistical skills, the more rapidly one can accept or reject the credibility of a research article.

Guidelines

Six easily remembered appraisal criteria for clinical studies can be fashioned from the words WHY, HOW, WHO, WHAT, HOW MANY, and SO WHAT: (1) WHY: Is the biologic hypothesis clearly stated? (2) HOW: What is the research design? (3) WHO: Is the target population clearly defined? (4) WHAT: How was the therapy administered and the data collected? (5) HOW MANY: Are the test statistics convincing? (6) SO WHAT: Is it clinically relevant to my patients? Although the statistical knowledge of most physicians is limited, these skills of critical appraisal of the literature can be learned and can tremendously increase the efficiency and benefit of journal reading.

The Evidenced-Based Medicine Working Group—a group of mainly Canadian physicians and statisticians from McMaster University, Ontario, Canada—has been organized to de-emphasize a foundation of unsystematic clinical experience, clinical intuition, and pathophysiologic rationale as the basis for medical decision and to teach the systematic evaluation of published evidence. Since 1993 members of this group have published more than 20 detailed articles—all titled “Users' Guides to the Medical Literature”—in *JAMA*, the *Journal of the American Medical Association*. Specific topics have ranged from “How to Use an Article About Therapy or Prevention” to “How to Use an Article About Disease Probability for Differential Diagnosis.” While some elements of probabilistic reasoning and statistical testing are included, a greater emphasis is on an appreciation of experimental design.

Statistical Resources

Accompanying the exponential growth of medical information since World War II has been the creation of a wealth of biostatistical knowledge. Textbooks with expositions of basic, intermediate, and advanced statistics abound; several introductory texts are listed in the Bibliography. There are new journals of biomedical statistics, including *Controlled Clinical Trials*, *Statistics in Medicine*, and *Statistical Methods in Medical Research*, whose audiences are both statisticians and biomedical researchers. Some medical journals, e.g., the *British Medical Journal*, regularly publish expositions of both basic and newer advanced statistical methods. Extensive internet resources can be linked from the home page of the long established American Statistical Association (<http://www.amstat.org>) and at the StatLib (<http://lib.stat.cmu.edu>) of Carnegie Mellon University including electronic textbooks of basic statistical methods, online statistical calculators, standard datasets, reviews of statistical software, and so on.

Examples of Statistics Applied to Journal Reading

Zero Numerators. During the last two decades anesthesiologists have become more involved with the postoperative management of analgesia using a variety of new drug delivery routes and methods. However, benefits and risks must be weighed in the balance for all therapies, new or old. The strikingly impressive analgesia of neuraxial opioids for most patients is matched by a delayed respiratory depression in a very few patients. Reviews of published reports suggest that current techniques produce an acceptably low complication rate (1 in 1000 or less). There is a continuing onslaught of new reports touting new variations of drug, dosing, route, and adjuvant therapies. How much evidence is necessary before acceptance is given? The answer will, of course, depend on practicality, efficacy, and safety.

Suppose research findings claim that the direct injection of morphine into the cisterna magna of 23 patients produced total postoperative analgesia without apneic episodes. Is this sufficient evidence concerning the safety of this difficult technique? Should this technique be immediately introduced into clinical practice?

Physicians tend to ignore the size of the denominators on which rates are based and focus on numerators. Perhaps a zero numerator carries weight in that it falsely suggests that an event is impossible. A zero numerator does not mean there is no risk. In fact, in a small sample it is not unusual to find no complications even if the actual rate of complications is clinically important. If, for example, only 1 in 50 patients suffers apnea, there is still about a 40% chance of not observing an apneic episode in 23 patients (Table 3-6). If none of n patients shows the event about which we are concerned, the upper 95% confidence limit of a $0/n$ rate is approximately $3/n$; from a sample with 23 patients having no complications, the best estimate of the population complication rate is 0%, but it might be as high as 13% (Table 3-7). Thus, anesthesiologists should not accept this hypothetical report of 23 patients as sufficient safety evidence to start cisterna magna injections.

| Sample rate of: | Rules out any long-run (population) rate higher than: |
|-----------------|---|
| 0 in 10,000 | $3/10,000 = 0.03\%$ (0.03%)* |
| 0 in 1000 | $3/1000 = 0.3\%$ (0.3%) |
| 0 in 100 | $3/100 = 3\%$ (3%) |
| 0 in 50 | $3/50 = 6\%$ (6%) |
| 0 in 25 | $3/25 = 12\%$ (12%) |
| 0 in 10 | $3/10 = 30\%$ (30%) |

*Exact results derived by solving $(1 - \text{maximum rate})^n = 0.05$.

Table 3-7. CONFIDENCE INTERVALS AND LOW-FREQUENCY EVENTS: LONG-RUN RISK RULED OUT BY $0/n$ (UPPER BOUND OF 95% CONFIDENCE INTERVAL)

| If the long-run complication rate is: | Then the probability of observing zero complications in 23 patients is: |
|---------------------------------------|---|
| 1 in 10,000 | 99.9% |
| 1 in 1000 | 97.7% |
| 1 in 100 | 89.3% |
| 1 in 10 | 79.4% |
| 1 in 50 | 62.9% |
| 1 in 25 | 56.0% |

Table 3-6. LOW-FREQUENCY EVENTS: PROBABILITY THAT A SAMPLE OF 23 WILL HAVE ZERO COMPLICATIONS

Confidence Interval on Difference of Means. Clinical anesthesia research reports often focus on extending the duration of drug effect. Consider, for example, prolongation of post-Cesarean epidural analgesia. Twenty parturients were randomly divided into two groups after surgery; 50 mg sufentanil was given to all patients, 10 with 300 mg epinephrine, 10 without epinephrine. Analgesia without epinephrine lasted 266.7 ± 80.2 minutes, but 348.7 ± 77.8 minutes with epinephrine (mean \pm s). This was statistically significant. Unfortunately, the epinephrine group had more pruritus and nausea. Is the difference in duration sufficient to accept more side effects in the epinephrine group?

One approach to this question focuses on the magnitude of benefit from epinephrine and the precision with which it is known; one calculates the confidence intervals on the differences of the means. The best estimate of the true difference between the groups is $\bar{x}_1 - \bar{x}_2$. The difference in duration of analgesia is $348.7 - 266.7 = 82$ minutes.

The 95% confidence interval for the difference of means is approximately

$$\bar{x}_1 - \bar{x}_2 - 2 \times SE_{\text{diff}} \text{ to } \bar{x}_1 - \bar{x}_2 + 2 \times SE_{\text{diff}} \quad (3-9)$$

Using the values for n_1 , n_2 , s_1 , and s_2 , then SE_{diff} and s are defined by

$$SE_{\text{diff}} = s \times \sqrt{\left(\frac{1}{n_1} + \frac{1}{n_2}\right)} \quad (3-10)$$

$$s = \sqrt{\frac{(n_1 - 1) \times s_1^2 + (n_2 - 1) \times s_2^2}{n_1 + n_2 - 2}} \quad (3.11)$$

The 95% confidence interval of the difference in means is 11 to 153 minutes. The precision of the estimate of the difference is obviously poor. Considering the increased risk of pruritus and nausea, an anesthesiologist might well decide that the benefit is not sufficiently characterized to warrant a change. Statisticians have encouraged journal authors to cite results with appropriate confidence intervals. This advice has not been widely followed. However, the mathematics is rather simple with an electronic calculator and can be reckoned by the journal reader.

CONCLUSION

One intent of this chapter is to present the scope of support that the discipline of statistics can provide to anesthesia research. Although an intuitive understanding of certain basic principles is emphasized, these basic principles are not necessarily simple and have been developed by statisticians with great mathematical rigor. Academic anesthesia needs more workers to immerse themselves in these statistical fundamentals. Having done so, these statistically knowledgeable academic anesthesiologists will be prepared to improve their own research projects, to assist their colleagues in research, to efficiently seek consultation from the professional statistician, to strengthen the editorial review of journal articles, and to expound to the clinical reader the whys and wherefores of statistics. The clinical reader also needs to expend his or her own effort to acquire some basic statistical skills. Journals are increasingly difficult to understand without some basic statistical understanding. Some clinical problems can be best understood with a perspective based on probability. Finally understanding principles of experimental design can prevent premature acceptances of new therapies from faulty studies.

*Statisticians describe the sample mean as the unbiased, consistent, minimum variance, sufficient estimator of the population mean; thus, $\bar{x} = m$, where m is the population mean.

*The technical definition of confidence interval is more rigorous. A 95% confidence interval implies that if the estimation procedure were done over and over again, then 95 of each 100 confidence intervals would be expected to contain the true value of the mean.

Anesthesia personnel spend long hours, in fact, most of their waking days, in an environment filled with many potential hazards—the operating room. This setting is unique among workplaces owing to potential exposure to chemical vapors, ionizing radiation, and infectious agents while the anesthesia team is subject to heightened levels of psychological stress engendered by the high-stakes nature of the practice. Although such physical hazards as explosions from flammable anesthetic agents are no longer a concern, occupational illnesses, such as alcohol and drug abuse, are now well recognized as significant within the anesthesia community. Some hazards, such as exposure to trace levels of waste anesthetic gases, have been extensively studied, whereas others, like suicide, have been recognized but not adequately pursued. Only within the past few decades have epidemiologic surveys been conducted to assess the health of anesthesia personnel. In general, the potential health risks to those working in the operating room may be significant, but with awareness of the problems and the use of proper precautions, they are not formidable.

PHYSICAL HAZARDS

Anesthetic Gases

Although the inhalation anesthetics diethyl ether, nitrous oxide, and chloroform were first used in the 1840s, the biologic effects of occupational exposure to anesthetic agents were not investigated until the 1960s. Reports on the effects of chronic environmental exposure to anesthetics have included epidemiologic surveys, *in vitro* studies, cellular research, and studies in laboratory animals and humans. Areas addressed include fertility and spontaneous abortion; incidence of congenital malformations; mortality rate; incidence of cancer, hematopoietic diseases, liver disease, and neurologic disease; and psychomotor and behavioral changes produced by anesthetic exposure.

Anesthetic Levels in the Operating Room

Early investigators established that significant levels of ether were present in the operating room when the open drop technique was used, but the first report of occupational exposure to modern anesthetics was by Linde and Bruce in 1969.¹ They sampled air at various distances from the pop-off valve of anesthesia machines and noted an average concentration of halothane of 10 parts per million (ppm) and of nitrous oxide of 130 ppm.* End-expired air samples taken from 24 anesthesiologists after work revealed 0 to 12 ppm of halothane. Others reported similar levels of halothane around semiclosed and nonbreathing circuits and showed that the environmental levels could be reduced significantly with the use of scavenging equipment.²

Specific anesthetic techniques such as inhalation induction in pediatric patients are associated with higher levels of waste gas exposure.³ Dosimeters worn by anesthesiologists recorded 532 ppm/hr (time-weighted average) of nitrous oxide after cases using an inhalation induction, compared with 219 ppm/hr with intravenous inductions. Although appropriate operating room ventilation and machine scavenging was used, the nitrous oxide levels in all cases were higher than expected. In spite of the characteristic odors of volatile anesthetics, smell is not a reliable method for detecting trace levels of halothane in operating room air. Only 50% of volunteers could detect 33 ppm of halothane by smell, and 75% could not detect 15 ppm.⁴

The waste anesthetic concentrations in operating rooms where routine scavenging is performed are less than those noted before the 1960s and are often less than those found in the only studies conducted to assess the effects of occupational exposure. This raises the questions of whether chronic exposure to these low levels of waste anesthetic gases actually constitutes a significant occupational hazard and whether results from studies performed in “unscavenged” operating rooms are applicable to current practice.

Epidemiologic Studies

Epidemiologic surveys were among the first studies to suggest the possibility of a hazard resulting from trace levels of anesthetics. Although epidemiologic studies may be useful in assessing problems of this type, they have the potential for errors associated with the collection of data and their interpretation. In his review of the potential of trace anesthetic gases to produce disease, Ferstandig outlined the design strategies necessary for valid epidemiologic studies.⁵ First, there should be an appropriate control group for the cohort being studied. Second, the use of questionnaires to obtain personal medical information may be misleading because individuals may knowingly or unknowingly give incorrect information. The use of medical records provides more reliable data. Third, retrospective epidemiologic studies rely on recorded or remembered data. In prospective studies, the anticipated, significant information can be collected temporally. Fourth, cause-and-effect relationships cannot be documented by epidemiologic data unless all other possible etiologies can be ruled out or other lines of evidence are used for substantiation. Fifth, most epidemiologic studies use a *p* of 0.05 for determination of statistical significance. Walts *et al*, in reviewing one epidemiologic study, argued that this level of statistical significance is too high.⁶ Because a false-positive conclusion may have profound implications, even a *p* level of 0.01 may be too large for epidemiologic data. Sixth, percentage increases in the incidence of disease are sometimes reported. Large changes in percentage may imply clinical significance, even when the findings are not statistically significant. Few epidemiologic studies on the effects of occupational exposure to waste anesthetic gases fulfill these criteria.

Reproductive Outcome. One of the largest studies to assess the effects of trace anesthetics on reproductive outcome was conducted by an Ad Hoc Committee of the American Society of Anesthesiologists (ASA).⁷ Questionnaires were sent to 49,585 operating room personnel who had potential exposure to waste anesthetic gases (members of the ASA, the American Association of Nurse Anesthetists, the Association of Operating Room Nurses, and the Association of Operating Room Technicians). A nonexposed group of 23,911 from the American Academy of Pediatrics and the American Nurses' Association served as controls. The Committee concluded that there was an increased risk of spontaneous abortion and congenital abnormalities in children of women who worked in the operating room and an increased risk of congenital abnormalities in offspring of unexposed wives of male operating room personnel. Several reviews have identified inconsistencies in the data used to compare exposed and unexposed groups and make within-group comparisons. Expected levels of anesthetic exposure did not correlate with reproductive

outcome.^{5,6}

A Swedish study clearly demonstrates the inaccuracies encountered when surveys rely on data obtained from mailed questionnaires.⁸ Women working at one hospital were surveyed to determine the relationship between anesthetic exposure and spontaneous abortion rate and the confounding effects of age, smoking habits, and work site during the first trimester of pregnancy. All spontaneous abortions in the exposed group were accurately documented in the responses to the questionnaire, but a review of hospital records revealed that one third of spontaneous abortions went unreported in the unexposed group. When verified data were analyzed, there was no statistically significant difference between reproductive outcome in the exposed and nonexposed groups.

The ASA commissioned a group of epidemiologists and biostatisticians to evaluate the many epidemiologic surveys that had been published in the literature to provide an assessment of the conflicting data.⁹ The group used the relative risk (the ratio of the rate of disease among those exposed to that found in those not exposed) as a measure of the strength of the association between exposure to the operating room environment and several disease processes. In considering studies on spontaneous abortion and congenital abnormalities in offspring of anesthesia personnel, the data from all but five studies were excluded from analysis because of errors in study design or statistical analysis.^{7,8,10,11,12} The relative risks of spontaneous abortion for female physicians and female nurses working in the operating room were 1.4 and 1.3, respectively (a relative risk of 1.3 represents a 30% increase in risk when compared with the risk of the control population). The increased relative risk for congenital abnormalities was of borderline statistical significance for exposed physicians only. In considering these findings, Mazze and Lecky¹³ noted that the epidemiologic studies assessing the association of cigarette smoking and lung cancer have established a value for relative risk of 8 to 12 for men in the United States. The high relative risks found in smoking studies contrast with the values of less than 2 in most of the well designed reproductive studies among those working in the operating room environment. Relative risks of less than 2 to 3 may occur solely from incorrect classification of subjects. Although Buring *et al*⁹ found a statistically significant relative risk of spontaneous abortion and congenital abnormalities in women working in the operating room, the relative risk was small compared with other, better documented environmental hazards. They also point out that duration and level of anesthetic exposure were not measured in any of the studies and that other factors, such as stress, infections, and radiation exposure, were not considered.

More recent studies have also suggested that there is a slightly greater risk of adverse reproductive outcomes in women occupationally exposed to anesthetics. Using a case-control study design and data obtained from a national register, Hemminki *et al* noted a small but not significant increase [odds ratio (OR) = 1.2] in spontaneous abortion in female nurses with anesthetic exposures.¹⁴ Another study, using a postal survey of female resident physicians, demonstrated that the overall rate of spontaneous abortion was not increased compared to female partners of male residents.¹⁵ When the data were assessed by specialty, women in anesthesia residencies had a higher rate than those in specialties without anesthetic exposure.

Because some personnel working in dental operatories have exposure to nitrous oxide, the dental literature has also addressed these issues. One pertinent study used data collected via telephone interviews with 418 female dental assistants to assess the effect of nitrous oxide exposure on fertility.¹⁶ Fecundability* was significantly reduced in women with 5 or more hours of exposure to unscavenged nitrous oxide per week. In another study of 7000 female dental assistants, questionnaires were used to determine rates of spontaneous abortion.¹⁷ There was an increased rate [relative risk (RR) = 2.6, adjusted for age, smoking, and number of amalgams prepared per week] of spontaneous abortion among women who worked for 3 or more hours per week in offices not using scavenging devices for nitrous oxide. These findings must be viewed with caution because the estimates of nitrous oxide exposure were based solely on respondents' reports, and measurements of nitrous oxide concentrations in the work space were not performed. Therefore, dose-effect relationships cannot be confirmed. It is important to note that in both studies of female dental assistants, use of nitrous oxide in offices with scavenging devices was not associated with an increased risk for adverse reproductive outcomes.^{16,17}

A meta-analysis of 19 epidemiologic studies, which included hospital workers, dental assistants, and veterinarians and veterinary assistants, demonstrated an increased risk of spontaneous abortion (RR = 1.48; 95% confidence interval, 1.40–1.58) in women with occupational exposure to anesthetic gases.¹⁸ Additional analysis demonstrated that the relative risk of 1.48 corresponded to an increased absolute risk of abortion of 6.2%. Stratification by job category indicated that the relative risk was greatest for veterinarians (RR = 2.45) followed by dental assistants (RR = 1.89) and hospital workers (RR = 1.30). When the meta-analysis was confined to the five studies^{17,19,20,21,22} that controlled for several nonoccupational confounding variables, had appropriate control groups, and had sufficient response rate, the relative risk for spontaneous abortion was 1.90 (95% confidence interval, 1.72–2.09). The author notes that the routine use of scavenging devices has been implemented since the time that most of the studies in this analysis were performed and that there was no risk of spontaneous abortion in studies of personnel that worked in scavenged environments.

Retrospective surveys of large numbers of women who worked during pregnancy indicate that negative reproductive outcomes may be related to job-associated conditions other than exposure to trace anesthetic gases. In a Canadian study, the ratio of observed to expected late spontaneous abortions (16 to 28 weeks) was increased in operating room nurses as well as radiology technicians and employees in agriculture and horticulture.²³ Analysis of the data from health workers demonstrated an increased risk of abortion associated with specific work requirements and conditions: lifting heavy weights more than 15 times a day, other physical effort, working 46 or more hours a week, and changing shift work.

Although many of the existing epidemiologic studies have potential flaws in design, the evidence taken as a whole suggests that there is a slight increase in the relative risk of spontaneous abortion and congenital abnormalities in offspring for female physicians working in the operating room.²⁴ Whether this is attributable to anesthetic exposure cannot be definitely determined from this type of investigation. Well designed surveys of large numbers of personnel and appropriate control groups are necessary to link trace anesthetic exposures to adverse reproductive outcomes. The routine use of scavenging techniques has generally lowered environmental anesthetic levels in the operating room and may make it more difficult to prove any adverse effects using epidemiologic data.

Mortality and Nonreproductive Diseases. One of the first surveys enumerating causes of death among anesthesiologists was reported by Bruce *et al* in 1968.²⁵ The authors compared the death rates of members of the ASA from 1947 to 1966 with those for American men and male policyholders of a large insurance company. There was a higher death rate among male anesthesiologists from malignancies of the lymphoid and reticuloendothelial tissues and from suicide, but a lower death rate from lung cancer and coronary artery disease.

In a subsequent prospective study, Bruce *et al* compared the causes of death in ASA members during the years 1967 to 1971 with those of men insured by one company.²⁶ The overall death rate for ASA members was lower than for the controls, and contrary to the previous results, there was no increase in death rates from malignancies of lymphoid and reticuloendothelial tissues. The authors concluded that their data provided no evidence to support the speculation that lymphoid malignancies were an occupational hazard for anesthesiologists.

The national study conducted by the ASA found no differences in cancer rates between men exposed and those not exposed to trace concentrations of anesthetic gases.⁷ For women who responded to the survey, there was an approximately 1.3-fold to 2-fold increase in the occurrence of cancer in the exposed group, resulting predominantly from an increase in leukemia and lymphoma. The analysis of Buring *et al* of these data confirmed an increase in relative risk of cancer in exposed women (1.4) but attributed the increase solely to cervical cancer (2.8).⁹ They also noted that the ASA study did not assess the effect of confounding variables, such as sexual history or smoking, that may have contributed to the findings. It is doubtful that the carcinogenic effect of anesthetics would be sex related, and the conflicting results for men and women, especially in light of the low statistical significance of the data, cast doubt that anesthetics were the causative agents.

The data from the ASA survey showed a statistical increase in hepatic disease for female anesthesiologists, female nurse anesthetists, and male anesthesiologists, but not for other exposed groups.⁷ Again, it is difficult to explain why male anesthetists did not experience the same consequences from exposure to trace anesthetic gases as their female nurse anesthetist counterparts. Although the investigators tried to exclude infectious hepatitis as a cause of hepatic disease, hepatitis B is asymptomatic in approximately 50% of infected people. At the time that this survey was conducted, the serum markers to identify hepatitis B had not been elucidated. From the information collected for this study, it cannot be determined whether the hepatic disease was caused by anesthetic exposure or by hepatitis B or another viral infection acquired from frequent exposure to blood.

In a survey of mortality among British physicians from 1951 to 1971, the overall mortality rate and incidence of death caused by ischemic heart disease, chronic bronchitis, and lung cancer were lower for anesthesiologists than the average for all medical specialists.²⁷ There was a slightly increased risk of other cancers (107% of expected) because of cancer of the pancreas in anesthesiologists. These mortality data were confirmed when applied to members of the ASA in a survey published in 1979.²⁸ ASA membership lists from 1954, 1959, 1967, and 1976 were obtained, so that the population studied included those exposed both to older anesthetics and to halogenated volatile agents. Mortality from all causes in anesthesiologists remained below that of the general population since 1954. Specifically, there was no evidence for an increased rate of cancer or hepatic or renal disease.

The most recent mortality study of anesthesiologists, sponsored by the ASA, was performed by Domino *et al*.²⁹ The mortality risks of a cohort of 40,242 anesthesiologists were compared to a matched cohort of internists using data on cause of death from the National Death Index covering the period from 1976 to 1996. There was no difference between the two groups in overall mortality risk or mortality due to cancer or heart disease.

Epidemiologic studies are useful tools for attempting to identify adverse effects of the operating room environment, including exposure to many substances, of which waste anesthetic gases comprise but one factor. The data from epidemiologic surveys can, at best, suggest relationships but can never prove cause-and-effect

associations between exposure to some condition or substance and a disease process. There are shortcomings in many surveys that attempt to assess the effects of waste anesthetic gases, and these have resulted in conflicting conclusions. Overall, there appears to be some evidence that the operating room environment produces a slight increase in the rate of spontaneous abortion and cancer in female anesthesiologists and nurses.⁹ There is also a statistically significant increase in liver disease in both men and women, but this is consistent with the proven risk of infectious hepatitis among operating room personnel (see section on [Infection Hazards](#), later). Overall mortality rates for anesthesiologists appear lower than for the general population and for other medical specialists.

Laboratory Studies

Concurrent with the epidemiologic studies, investigators have been active in the laboratory, assessing the effects of anesthetic agents on cell, tissue, and animal models. It is hoped that this work will provide the scientific evidence linking anesthetics to the adverse effects that have been suggested by epidemiologic surveys.

Cellular Effects. At clinically useful concentrations, volatile anesthetics interfere with cell division in a reversible manner, possibly because of a reduction in oxygen uptake by mitochondria. There have been no cellular studies to indicate that trace levels of volatile anesthetics have a similar effect.

Nitrous oxide administered in clinically useful concentrations affects hematopoietic and neural cells. After exposure to 0.8 atmospheres (atm) of nitrous oxide for 30 minutes, liver methionine synthetase activity decreased by more than 50% in mice.³⁰ Although 0.05 atm of nitrous oxide did not affect methionine synthetase activity after 4 hours, exposure to 1100 ppm for 8 to 22 days produced a significant reduction in enzyme activity. Nitrous oxide oxidizes the cobalt atom of vitamin B₁₂ from an active to inactive state, which inhibits methionine synthetase. This prevents the conversion of methyltetrahydrofolate to tetrahydrofolate, which is required for DNA synthesis.³⁰ Inhibition of methionine synthetase in people exposed to high concentrations of nitrous oxide may result in anemia and polyneuropathy, but chronic exposure to trace levels does not appear to produce these effects.^{31,32}

Many studies have been performed in animals to assess the carcinogenicity of anesthetics. A preliminary study suggested that isoflurane produced hepatic neoplasia when administered to mice during gestation and early life,³³ but a subsequent, well controlled study failed to reproduce these results.³⁴ Other studies in mice and rats found no carcinogenic effect of halothane, nitrous oxide, or enflurane.^{35,36} In an attempt to simulate environmental exposure to waste anesthetics, rats were exposed to low levels of halothane and nitrous oxide for 7 hours per day, 5 days per week, for 104 weeks.³⁵ This degree of exposure produced no effect on body weight, behavior, survival, or incidence of tumors.

Several investigators have used the popular Ames bacterial assay system for studying the mutagenicity of anesthetics. This assay is rapid, inexpensive, and has a high true-positive rate when compared with *in vivo* tests. Halothane, enflurane, methoxyflurane, isoflurane, and urine from patients anesthetized with these agents were not mutagenic using this assay.^{37,38} Urine from people working in scavenged or unscavenged operating rooms was also negative for mutagens.³⁹

There have been reports of structural changes in cells brought about by prolonged exposure of animals to subclinical levels of anesthetics. Chang and Katz reviewed a series of relevant studies from their laboratory.⁴⁰ Exposure to halothane, 10 to 500 ppm, for 4 to 8 weeks produced ultrastructural changes in hepatic, renal, and neuronal tissue. Changes included degeneration of the mitochondria, endoplasmic reticulum, and bile canaliculi in hepatocytes. The extent of the changes cannot be ascertained from these reports, and because control animals were not used, the effects of tissue preparation and other factors are unknown. It is also possible that the ultrastructural changes were reversible and resulted from the administration of the xenobiotic. There is no proof that there is a relationship between anesthetic exposure, cellular ultrastructural changes, and functional abnormalities.

Reproductive Outcome. Because of the suggestion from epidemiologic data that occupational exposure to waste anesthetic gases resulted in an increase in spontaneous abortion and congenital abnormalities, numerous studies have been performed in laboratory animals to assess reproductive outcome. One study exposed male and female rats, for 60 days before mating, to concentrations of halothane and nitrous oxide similar to those found in unscavenged operating rooms.⁴¹ Exposed females had decreased ovulation and implantation efficiency, especially in the groups receiving higher concentrations of anesthetics. There were no major teratologic effects. Chromosomal aberrations were observed in both bone marrow and spermatogonial cells in the male rats.

Prolonged exposure of pregnant rats to 1000 ppm nitrous oxide resulted in smaller litter size, increased frequency of fetal resorption, and reduced fetal crown-rump measurements.⁴² Lower concentrations of nitrous oxide had no effect on reproductive outcome. Similarly, daily exposure of mice to 4000 ppm isoflurane before and during pregnancy produced no adverse effect on their litters.⁴³

Most animal experiments fail to demonstrate alterations in female or male fertility or reproduction with exposure to subanesthetic concentrations of the currently used anesthetic agents. It is important to realize that data from laboratory investigations in animals may not be directly applicable to humans. Although it is easy to measure and quantify the levels of anesthetic in the operating room air, it is harder to measure and assess the effect of other possible factors, such as stress, alterations in working schedule, and fatigue.

Effects of Trace Anesthetic Levels on Psychomotor Skills

Several studies have been conducted to attempt to clarify whether low concentrations of anesthetics alter the psychomotor skills required for providing high-quality care. Student volunteers were exposed to 500 ppm nitrous oxide with or without 15 ppm halothane in air for 4 hours and were then given tests of perceptual, cognitive, and motor skills.⁴⁴ After exposure to halothane and nitrous oxide, their performance was impaired on 4 of 12 tests; exposure to nitrous oxide alone produced decreased performance on only 1 test. A subsequent study by the same investigators assessed the effect of nitrous oxide (500, 50, or 25 ppm) alone or with halothane (10, 1.0, or 0.5 ppm) by using psychomotor tests.⁴⁵ After exposure to the highest concentrations of nitrous oxide and halothane, subjects' performance declined on 4 of the 7 tests. Interestingly, there was a decrease in ability in 6 of 7 tests after exposure to the same level of nitrous oxide alone. Exposure to the lowest concentrations studied, 25 ppm nitrous oxide and 0.5 ppm halothane, produced no effects as measured by this battery of tests.

Other investigators, using similar protocols, have found no effect on psychomotor test performance after exposure to trace concentrations of halothane or nitrous oxide.⁴⁶ The reason for differences in outcome between studies is unclear, but Bruce, one of the original investigators, has attributed the psychological effects of low levels of anesthetics to unusual sensitivity in the group of paid volunteers used in the study.⁴⁷

Recommendations of the National Institute for Occupational Safety and Health

In 1970, Congress created the National Institute for Occupational Safety and Health (NIOSH), the federal agency responsible for ensuring that workers have a safe and healthful working environment. The agency was to meet these goals through the conduct and funding of research, through education of employers and employees about occupational illnesses, and through establishing occupational health standards. A second federal agency, the Occupational Safety and Health Administration (OSHA), was responsible for enacting job health standards, investigating work sites to detect violation of standards, and enforcing the standards by citing violators.^{48,49} In 1977, NIOSH published a criteria document that recommended that waste anesthetic exposure should not exceed 2 ppm (1-hour ceiling) of halogenated anesthetic agents when used alone, or 0.5 ppm of a halogenated agent and 25 ppm of nitrous oxide (time-weighted average during use).⁵⁰ In addition, it stated that operating room employees should be advised of the potential harmful effects of anesthetics. The guidelines proposed that annual medical and occupational histories be obtained from all personnel and that any abnormal outcomes of pregnancies should be documented. The publication also included information on scavenging procedures and equipment and methods for monitoring concentrations of waste anesthetic gases in the air. The 1977 NIOSH criteria document⁵⁰ has not been adopted by OSHA, which currently does not have a standard for nitrous oxide. Some states, however, have instituted regulations calling for routine measurement of ambient nitrous oxide in operating rooms and have mandated that levels not exceed an arbitrary maximum.

It is interesting to examine the rationale given for the selection of NIOSH's standards for waste anesthetic gases. According to the criteria document, "Based on the available health information a safe level of exposure to the halogenated agents cannot be defined. Since a safe level of occupational exposure to halogenated anesthetic agents cannot be established by either animal or human investigations, NIOSH recommends that exposure be controlled to levels no greater than the lowest level detectable using the sampling and analysis techniques recommended by NIOSH in this document."⁵⁰ Based on this, the recommendations for halogenated agents were set for 2 ppm. The recommendations for nitrous oxide were based on the studies of Bruce *et al*, who noted that after exposure to levels of 25 ppm nitrous oxide with 0.5 ppm halothane, there was no impairment of subjects' performance on psychomotor tests.⁴⁵

In 1994, NIOSH published an alert to warn health care personnel that exposure to nitrous oxide may produce "harmful effects."⁵¹ In this document, NIOSH recommends the following to reduce nitrous oxide exposure: (1) monitoring the air in operating rooms; (2) implementation of appropriate engineering controls, work practices, and equipment maintenance procedures; and (3) institution of a worker education program.

In view of the conflicting scientific data, it is reasonable to ask what is an acceptable exposure level for waste anesthetic gases. Although it may be difficult to be certain of a threshold concentration below which chronic exposure is "safe," it is prudent to institute measures that reduce waste anesthetic levels in the operating room

environment without compromising patient safety. Methods for reducing and monitoring waste gases in the operating room have been suggested.⁵² Through the use of scavenging equipment, equipment maintenance procedures, altered anesthetic work practices, and efficient operating room ventilation systems, the environmental anesthetic concentration can be reduced to minimal levels. Monitors to detect leaks in the high- and low-pressure systems of anesthetic machines, contamination due to faulty anesthetic technique, and scavenging system malfunction should be incorporated in programs to ensure reduced occupational exposure. Environmental levels of anesthetics can be measured using instantaneously collected samples, continuous air monitoring, or time-weighted averages.⁵²

With appropriate care, environmental levels of anesthetics in the operating room can be reduced to comply with those suggested by NIOSH. In a survey conducted in Ontario hospitals, the level of exposure to halogenated anesthetics was within the published standard, but nitrous oxide concentrations exceeded 25 ppm in many operating rooms.⁵³ When improved scavenging devices and routine equipment maintenance were instituted, nitrous oxide levels were reduced. A similar situation was documented through a survey of operating rooms in four Glasgow hospitals.⁵⁴

Anesthetic Levels in the Postanesthesia Care Unit

As patients awaken from general anesthesia, waste anesthetic gases are released into the postanesthesia care unit (PACU). Early investigators reported less than 0.6 ppm halothane⁵⁵ and 10–34 ppm nitrous oxide⁵⁶ in grab samples taken from the area of the patients' breathing zone in the PACU. In a 1998 study, the time-weighted average concentrations for isoflurane, desflurane, and nitrous oxide were 1.1 ppm, 2.1 ppm, and 29 ppm, respectively, in the breathing zone of PACU nurses.⁵⁷ Half of the patients were intubated on arrival in the PACU, suggesting that they were still partially anesthetized and hence exhaling a greater concentration of anesthetic gases than were awake patients. In contrast, other investigators reported time-weighted nitrous oxide levels less than 2.0 ppm from two PACUs.⁵⁸ In these institutions, nitrous oxide was routinely discontinued at the end of surgery, approximately 5 minutes before the patient left the operating room, and there was adequate ventilation in the PACUs. This suggests that turning off anesthetics in the operating room can minimize levels of waste anesthetic gases in the PACU, particularly if the PACU is well ventilated.⁵⁹

Chemicals

Methylmethacrylate

Methylmethacrylate is commonly used to cement prostheses to bone or to repair bone defects. The cardiovascular effects of methylmethacrylate in patients have been thoroughly studied and reviewed, but there are fewer data on the effects of occupational exposure. Factory workers exposed to methylmethacrylate complained of respiratory, cutaneous, and genitourinary problems after exposure to levels lower than the 8-hour, time-weighted average allowable exposure of 100 ppm established by OSHA.⁶⁰ When the Ames test was used to assess the mutagenic potential of methylmethacrylate, it was found that the compound was toxic; and when it was incubated with a rat liver enzyme metabolizing system, mutagenesis was induced.

When methylmethacrylate is prepared for use in the operating room, concentrations up to 90 ppm have been measured during the period required for polymerization. Use of commercially available scavenging devices for venting methylmethacrylate vapor decreased peak concentrations of the vapor by 75%.

Allergic Reactions

In addition to concerns about toxic effects of methylmethacrylate vapor and waste anesthetic gases, allergic reactions to these substances have been reported. Occupational asthma after exposure to methylmethacrylate in orthopedic operating rooms has been described.⁶¹ One anesthesiologist experienced asthma 8 to 12 hours after administering enflurane to his patients.⁶²

Halothane. A thoroughly documented case report of an anesthesiologist in whom recurrent hepatitis developed after exposure to and challenge with halothane was interpreted to indicate that halothane was a sensitizing agent in some individuals.⁶³ Repeated bouts of hepatitis in this anesthesiologist were attributed to hypersensitivity reactions rather than to a direct toxic effect of halothane.

Latex Sensitivity. Latex in surgical and examination gloves has become a common source of allergic reactions among operating room personnel.^{64,65} Approximately 70% of adverse reactions to latex reported to the Food and Drug Administration's (FDA) MedWatch database involve health care workers.⁶⁶ The prevalence of latex sensitivity among anesthesiologists is estimated to be 12.5%⁶⁷ to 15.8%.⁶⁸

Latex is a complex substance composed of polyisoprenes, lipids, phospholipids, and proteins. A number of additional substances, including preservatives, accelerators, antioxidants, vulcanizing compounds, and lubricating agents (such as cornstarch), are added in the manufacture of the final product. The protein content of latex is responsible for the vast majority of generalized allergic reactions to latex-containing surgical gloves. These reactions are exacerbated by the presence of glove powder such as cornstarch or talc. Latex particles adhere to glove powder and when aerosolized during the donning or removal of gloves, can be spread to room surfaces and to the mucosa and respiratory system of personnel.

Irritant or contact dermatitis accounts for approximately 80% of reactions from latex-containing gloves (Table 4-1). In the study reported by Brown *et al*, 24% of anesthesia personnel were found to manifest evidence of contact dermatitis.⁶⁷ True allergic reactions present clinically as T-cell-mediated contact dermatitis (Type IV) or as an IgE-mediated anaphylactic reaction.

| Reaction | Signs/Symptoms | Cause | Management |
|--|--|--|--|
| Instant contact dermatitis | Itching, drying, cracking of skin | Direct skin contact by gloves, powder, soap | Identify reaction, avoid irritant, possible use of glove liner, use of alternative product |
| Type IV—Delayed hypersensitivity | Itching, blistering, swelling (delayed > 24 hours) | Chemical additives used in manufacturing, such as accelerators | Identify offending chemical, possible use of alternative product without chemical additive, possible use of glove liner, identify reaction |
| Type I—Immediate hypersensitivity (A) Localized contact dermatitis | Itching, hives in area of contact with latex (immediate) | Proteins found in latex | Avoid latex-containing products, use of barrier or powder-free low-protein gloves for co-workers |
| (B) Generalized reaction | Hives, rash, swollen eyes, generalized hives or hives, bronchospasm, anaphylaxis | | Anaphylaxis protocol |

Table 4-1. TYPES OF REACTIONS TO LATEX GLOVES

Anesthesiologists who believe that they are allergic to latex should take immediate steps to assess this possibility.⁶⁴ To help make the diagnosis, a careful clinical history should be obtained to try to correlate latex exposure with allergic symptoms. The laboratory evaluation for latex allergy, involving both *in vitro* and *in vivo* tests, has been outlined by Warshaw.⁶⁹ Once the diagnosis of latex allergy has been established, the affected anesthesiologist must avoid all direct contact with latex-containing products. It is also important that co-workers wear powderless, low latex-allergen gloves to limit the levels of ambient latex allergens. Prevention of exposure to latex protein is the best strategy for avoiding latex allergy because sensitivity cannot be reversed.⁶⁴

Radiation

Oncogenesis, teratogenesis, and long-term genetic effects can occur with sufficiently high exposure to radiation. Regulatory agencies consider two classes medical personnel: those who are only occasionally exposed to radiation (*i.e.*, anesthesia personnel) and radiation workers whose normal duties require them to be in areas with large potential exposure.⁷⁰ The nonoccupational limit of exposure is set at less than 500 mrem per year.

There exist numerous situations in which anesthesia personnel may experience radiation exposure. Diagnostic radiographs are taken in the operating room, PACU, and intensive care units. Fluoroscopy is utilized during many surgical procedures. Frequently, patients undergoing diagnostic or therapeutic procedures such as angiography, angioplasty, biliary dilation, extracorporeal shock wave lithotripsy, or radiation therapy require care by anesthesiologists. Anesthesia personnel may also be exposed to radionuclides given to patients for diagnostic procedures or for therapy. Strategies that can be used to reduce exposure to radiation include use of

personal protective equipment, such as lead aprons and shields, and maintaining a position as far as possible from the source of radiation.

Technologic advances in imaging equipment and radiation handling have reduced the risk of exposure to significant doses of radiation. McGowan *et al* assessed radiation exposure of anesthesia personnel working in an orthopedic operating room where image intensifiers were commonly used.⁷¹ Since all dosimeter readings were below detectable limits, the authors concluded that anesthesia personnel are at minimal risk for radiation exposure.

Radiation exposure should be monitored with film badges or pocket dosimeters in anesthesia personnel at risk. Educational programs on the effects of radiation and techniques for preventing exposure are important parts of radiation safety programs.

Noise Pollution

A potential health hazard that is virtually uncontrolled in the modern hospital and specifically in the operating room is noise pollution.⁷² Noise pollution is quantified by determining both the intensity of the sound in decibels (dB) and the duration of the exposure. The National Institute for Occupational Safety and Health has established a maximum level for safe noise exposure of 90 dB for 8 hours.⁷³ Furthermore, each increase in noise of 5 dB halves the permissible exposure time, so that 100 dB is acceptable for just 2 hours per day. The maximum allowable exposure in an industrial setting is 115 dB.

The noise level in many operating rooms is surprisingly close to what constitutes a health hazard.⁷⁴ In one study it was 77.3 dB.⁷⁵ Ventilators, suction equipment, music, and conversation produce background noise at a level of 75 to 90 dB. Superimposed on this are such sporadic and unexpected noises as dropped equipment, surgical saws and drills, and monitor alarms. Resultant noise levels frequently exceed those of a freeway and even of a rock-and-roll band.

Excessive levels of noise can have an adverse influence on the anesthesiologist's capacity to perform his or her chores. Noise can interfere with an anesthesiologist's ability to discern conversational speech⁷⁴ and even to hear auditory alarms.⁷⁶ Mental efficiency and short-term memory are diminished by exposure to excess noise.⁷⁵ The complex psychomotor tasks associated with anesthesiology, such as monitoring and vigilance, are particularly sensitive to the adverse influences of noise pollution.⁷⁷

There also are chronic ramifications of long-term exposure to excessive noise in the workplace. At the very least, noise pollution is an important factor in decreased worker productivity. At higher noise levels, workers are likely to show signs of irritability and demonstrate evidence of stress, such as elevated blood pressure. Ultimately, hearing loss ensues. In a sample of anesthesiologists less than 55 years of age, median hearing threshold was worse than for the general population, and the hearing deficits in the higher frequencies were significant enough to interfere with detection of some equipment alarms.⁷⁶ The specific cause of the anesthesiologists' hearing loss could not be determined from the study data.

Conversely, music can provide beneficial effects as a different kind of "background noise." Music proved advantageous as a supplement to sedation for awake patients during surgery.⁷⁸ Self-selected background music contributed to reduced autonomic responses in a group of surgeons and improved performance during a stressful nonsurgical laboratory task.⁷⁹ The beneficial effects were less pronounced when the music was chosen by a third party. Unfortunately, the latter situation more frequently exists for the anesthesiologist.⁸⁰

Human Factors

The work performed by an anesthesiologist is intricate and includes a number of complex tasks. A large body of research has evolved with the goal of applying high-technology solutions to assist the anesthesiologist in managing this demanding workload. Less attention has been given to using human factor technology to improve our workplace and ensure patient safety. The greatest source of patient morbidity and mortality remains human error.⁸¹

A number of human factor problems potentially exist in the operating room. These include issues specific to the nature of our workload, as well as team and organizational difficulties. The design and positioning of our equipment can serve as a deterrent to the successful completion of all of our obligatory tasks. Most modern anesthesia machines are direct descendants of Boyle's original apparatus—an apparatus that has undergone progressive embellishment with additional monitors and alarms. Unfortunately, this evolutionary development has not resulted in an optimal product by ergonomic standards. For example, the placement of anesthesia monitors in many operating rooms redirects the anesthesiologist's attention away from the patient. Indeed, nearly half of the anesthesiologist's time is spent performing tasks that are away from the patient–surgeon field and not directly related to patient care.^{82,83} This was illustrated in a study by Weinger *et al*, who demonstrated that insertion and monitoring of a transesophageal echocardiograph added significantly to the anesthesiologist's workload while diverting attention away from other patient-specific tasks.⁸⁴ Conversely, automated record keeping devices permit an increase in direct patient care activities by reducing time spent on record keeping.

Many tasks that are routinely performed by anesthesiologists involve the ability to respond to critical incidents and to sustain complex monitoring tasks, such as maintaining vigilance; these tasks are vulnerable to the distractions created by poor equipment design or placement. *Vigilance* is "the ability to detect changes in a stimulus during prolonged monitoring tasks when the subject has no prior knowledge of whether or when any changes might occur."⁸⁵ According to Gaba *et al*, "Vigilance is thus a necessary, but not sufficient condition for averting [anesthetic] accidents."⁸⁶ The seal of the American Society of Anesthesiologists bears as its only motto, "Vigilance" (Fig. 4-1), and the official motto of the Australian Society of Anaesthetists is "*Vigila et Ventila*." These mottoes serve as formal recognition of the critical importance of this function.

Figure 4-1. Official Seal of the American Society of Anesthesiologists. "VIGILANCE" has always been recognized as the most critical of the anesthesiologist's tasks.

Several components of the vigilance task deserve attention. First, it is important to recognize that this particular function may be repetitive and monotonous. The task does not fully occupy the anesthesiologist's mental activity, but neither does it leave him or her free to perform other mental functions. Finally, the task is complex, requiring visual attention as well as manual dexterity.

Vigilance tasks are generally performed at the level of 90% accuracy.⁸⁷ In a setting where the stakes are as high as that of anesthesia, this leaves an unacceptable margin of error. In fact, human error, in part resulting from lapses in attention, accounts for a large proportion of the estimated 2000 preventable deaths and serious injuries resulting from anesthetic mishaps in the United States annually.⁸⁸

In addition to poor equipment design, a number of other factors at work in the operating room environment serve to diminish the ability of the anesthesiologist to perform multiple tasks that demand cognitive skills.⁸⁵ Obvious factors are sleep loss and fatigue. Several studies have documented the deleterious effect of sleep loss and fatigue on work efficiency.⁸⁹ In addition, sleep deprivation has detrimental effects on cognitive tasks such as monitoring and accurate clinical decision making.^{90,91} Subsequent to a period of sleep deprivation, performance does not return to normal levels until a 24-hour period of rest and recovery has occurred. An interesting phenomenon is the "end-spurt," in which previously deteriorated performance shows improvement when the subject realizes that the task is 90% completed. The converse undoubtedly also occurs, a "let-down" with additional deterioration in performance when the procedure is unexpectedly prolonged.

Any factor that entails the expenditure of excessive energy to perform a given task contributes to fatigue and produces a predictable decrement in performance. Even the most trivial aspect of an operator's performance plays a significant role over the course of time. For example, if the anesthesiologist must make frequent, rapid changes in observation from a dim, distant screen to a bright, nearby one, the continuous muscular activity required for pupil dilation and constriction and lens

accommodation promotes fatigue.

Excessive energy expenditure need not be entirely physical. As more functions are monitored in the operating room and more data are processed during the course of a surgical procedure, increasingly larger amounts of mental work are expended. The mental work varies directly with the difficulty encountered in extracting the information from the monitors and displays competing for the anesthesiologist's attention.

Poor design in the monitor displays and the various other sources of information input can adversely affect the anesthesiologist's ability to perform necessary tasks. Engineering details, such as signal frequency and strength, as well as the mode of presentation of the input, significantly influence the operator's performance. For example, if the signal rate is slow, observers tend to produce more false-positive alarms. On the other hand, when confronted with a fast event rate, especially when the signal is of low intensity, the observer tends toward more frequent false-negative findings. Interestingly, monitoring complex displays and the need to "time-share" attention among several vigilance tasks are not associated with a performance decrement.

Even the alarms that have been developed with the specific goal of supplementing the task of vigilance have considerable drawbacks.⁹² In a report by Wallace *et al*, 7% of anesthesiologists worked with monitors whose alarm intensities were lower than their detectable threshold.⁷⁶ In general, alarms are nonspecific (the same alarm being triggered by as many as 12 different faults) and can be a source of frustration and confusion. They are also susceptible to artifacts and transients (true readings of no significance), and frequent false-positive alarms can distract the observer from more clinically significant information. One depiction of a commercial airline accident, with more than 150 fatalities, describes all three officers in the cockpit completely immersed in concern over a flashing light that indicated the landing gear was still down, a trivial concern at the time. In contrast, the altimeter, which indicated that the aircraft was losing altitude, went unnoticed until too late. Analogous situations occur in the operating room; therefore, it is not unusual for frequently distractive alarms to be deactivated.

Noise may have a detrimental influence on the anesthesiologist working at multiple tasks. The average noise level of 77 dB found in operating rooms has been shown to reduce mental efficiency and short-term memory in anesthesia residents.⁷⁵ In general, intrusive noises, such as loud talking, excessive clanging of instruments, and "broadband" noise, are associated with decrements in performance. On the other hand, certain types of background music produce the least effect on vigilance.⁹³

Some studies suggest that exposure to low concentrations of waste anesthetic gases may adversely affect the performance of anesthesiologists;⁹⁴ however, others have failed to corroborate these findings.⁹⁵

There are team and organizational issues that can adversely affect the ability of the anesthesiologist to perform well. "Production pressure," as a result of increased competition in the health care industry, can engender an environment in which issues of safety are superseded by those of productivity.⁹⁶ Production pressure has been associated with the commission of errors resulting from haste and/or deliberate deviations from known safe practices.

Problems with communication among team members can ultimately play a significant role in patient safety. The potential for disaster as a result of poor communication has been well illustrated in a number of airline catastrophes. The possibility for miscommunication and resultant accident is heightened in the operating room where, in contrast to the structure inherent in an airline crew, there is an absence of a well-defined hierarchical structure and borders of expertise and responsibility overlap.⁹⁷

The application of simulation technology has proved very useful in the study of human performance issues in anesthesiology.^{98,99} Much, however, remains to be done in bringing human factor research to the anesthesiologist's work environment.¹⁰⁰

Work Hours and Night Call

Sleep deprivation and accompanying fatigue are ubiquitous components of many anesthesiologists' life style. For practicing anesthesiologists, 10- to 12-hour workdays are not unusual. Emergency and on-call coverage is usually tacked onto the end of one of these days, resulting in a 24- to 32-hour shift. The average work week was 56 hours in Gravenstein's study of the work patterns of anesthesia providers.¹⁰¹ Seventy-four percent of the study respondents reported that they had worked without a break for longer periods than they thought was safe. An error in anesthetic management was attributed to fatigue by 64% of the study participants.

The duration of the work week for anesthesiology residents is in general 10 hours longer than that reported among fully trained practitioners.^{101,102} However, the work week of a typical anesthesiology resident is shorter than that of residents in other medical specialties (74 hours) and is within current recommendations.¹⁰³

Long hours of work and night call are especially challenging for the aging anesthesiologist. Older individuals are particularly sensitive to disturbances of the sleep-wake cycle and are in general better suited to phase advances (morning work) than phase delays (nocturnal work).¹⁰⁴ Demands associated with night call have been identified as the most stressful aspect of practice,¹⁰⁵ and are most frequently cited as an impetus toward retirement.¹⁰⁶

Several studies have substantiated the claim that fatigue or continuous wakefulness has a deleterious effect on many physical and cognitive functions. Even simple tasks, such as driving a car, are demonstrably impaired as a result of sleep deprivation among residents in anesthesiology.¹⁰⁷ The performance of more complex cognitive tasks such as monitoring and vigilance are disturbed to a greater extent.¹⁰⁸ What is particularly troubling is the suggestion that this deterioration in psychomotor functioning may contribute directly to anesthetic mishaps. A survey conducted by Gaba *et al* revealed that 54% of respondents felt that fatigue was a contributing factor in errors they had committed in clinical management.⁹⁶ In another survey of serious anesthetic-related accidents, fatigue was one of the two major sources of human error (confusion involving anesthetic equipment was the other).¹⁰⁹ Together, these two sources of error accounted for more than 96% of the lethal or near-lethal human errors reported. Similarly, in an analysis of critical incidents by Cooper *et al*, fatigue was among the most frequently reported factors associated with anesthetic mishaps and was a contributing factor in 70% of potentially serious anesthetic events.¹¹⁰

An additional area of concern is the potential effect of sleep deprivation and chronic fatigue on health and psychosocial adjustment.¹¹¹ Work schedules that disrupt circadian rhythms are associated with impaired health, emotional problems, and a decline in performance. The sleep loss pattern experienced by anesthesiologists who take night call is complex and includes elements of each of the three general classes of sleep deprivation: total, partial, and selective sleep deprivation. Selective sleep deprivation resulting from frequent interruptions is most disruptive to the important components of sleep, including slow wave sleep (associated with "body repair") and rapid eye movement sleep ("mind repair"). Indicators of psychosocial distress, including irritability, displaced anger, depression, and anxiety have all been identified in house officers suffering from sleep deprivation.¹¹²

National attention was focused on the problem of fatigue by the well-publicized Libby Zion case.¹¹³ A large portion of this claim hinged on the allegation that fatal, avoidable mistakes were made by exhausted, unsupervised house officers. A number of medical organizations and state legislatures have identified the problem of sleep deprivation among physicians. Several medical specialty boards have ratified policies that limit the number of work hours for their resident physicians, and some state legislatures have instituted regulations that prohibit resident physicians from working more than 24 consecutive hours. However, the medical community remains significantly behind other industries, most notably the transportation and airline industries, in identifying and regulating work practices that condone excessively long shifts.¹¹⁴

INFECTION HAZARDS

Anesthesia personnel are at risk for acquiring infections both from patients and from other personnel.⁶⁵ Viral infections reflecting their prevalence in the community are the most significant threat to health care workers. Most commonly, these are spread through the respiratory route—a mechanism that is, unfortunately, the most difficult to control effectively with environmental alterations (Table 4-2). Immunity against some viral pathogens can be provided through vaccination.¹¹⁵ Bloodborne pathogens such as hepatitis and human immunodeficiency virus cause serious infections, but transmission can be prevented with mechanical barriers blocking portals of entry or, in the case of hepatitis B, by producing immunity by vaccination. Current recommendations from the Centers for Disease Control (CDC) for pre-employment screening, infection control practices, vaccination, postexposure treatment, and work restrictions for infected personnel should be consulted for specific information related to each pathogen.^{65,116}

-
1. A source of infectious particles, usually from patients or personnel who are carriers
 2. The stability of the pathogen in the physical environment
 3. The number of infectious particles in the vehicle of transmission
 4. The infectivity of the agent
 5. The appropriate vector or medium for transmission
 6. A portal of entry in a susceptible host
-

Table 4-2. FACTORS INVOLVED IN THE SUCCESSFUL TRANSMISSION OF INFECTIOUS AGENTS, BACTERIA, AND VIRUSES

Respiratory Viruses

Respiratory viruses, which are responsible for many community-acquired infections, are usually transmitted by two routes. Small-particle aerosols produced by coughing, sneezing, or talking may propel viruses over large distances. The influenza and measles viruses are spread in this way. The second mechanism requires close person-to-person contact. Transmission can occur when large droplets produced by coughing or sneezing contaminate the donor's hands or an inanimate surface, whereupon the virus is transferred to the oral, nasal, or conjunctival mucous membranes of a susceptible person by self-inoculation. Rhino-virus and respiratory syncytial virus (RSV) are spread by this process.

Influenza Viruses

Since influenza viruses are easily transmitted, community epidemics of influenza are common, with large outbreaks occurring annually. Acutely ill patients shed virus through small-particle aerosols by coughing or sneezing for as long as 5 days after the onset of symptoms. Respiratory isolation precautions can be used for the duration of the clinical illness in an attempt to prevent spread to susceptible individuals. Because of their contact with nasopharyngeal secretions, anesthesiologists may play a role in the spread of influenza virus in hospitals.

Influenza rarely produces significant morbidity in healthy health care workers, but may result in high rates of absenteeism. Hospital staff, especially those who care for patients in high-risk groups, should be immunized annually with the inactivated (killed virus) influenza virus vaccine.^{116,117} Antigenic variation of influenza viruses occurs over time, so that new viral strains (usually two Type A and one Type B) are selected for inclusion in each year's vaccine. Vaccination programs for personnel should be conducted in October or November, because the number of cases of influenza in the community begins to increase in December. During hospital outbreaks of influenza A, the antiviral agents amantadine and rimantadine are reasonably effective in preventing influenza A infection in unvaccinated hospital personnel and, if administered within 48 hours of the onset of illness, can reduce the duration and severity of illness. Another class of drugs, neuraminidase inhibitors, has been shown to be effective in preventing and treating both influenza A and B in clinical trials.¹¹⁸

Because of possible morbidity to hospitalized patients and to hospital personnel, it is recommended that during community influenza epidemics, hospitals should consider limiting elective admissions and surgery. If surgery is necessary in a patient with influenza, data from an animal model suggest that general anesthesia results in no increase in respiratory morbidity.¹¹⁹

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is the most important cause of serious lower respiratory tract disease in infants and young children worldwide.¹²⁰ During periods when RSV is prevalent in the community (usually late November through May in the United States), many hospitalized infants and children may carry the virus. Large numbers of virus are present in respiratory secretions of infected children, and viable virus can be recovered for up to 6 hours on contaminated environmental surfaces. Infection of susceptible people occurs by self-inoculation when RSV in secretions is transferred to the hands, which then contact the mucous membranes of the eyes or nose. Although most children have been exposed to respiratory syncytial virus early in life, immunity is not permanent and reinfection is common.

Respiratory syncytial virus is shed for approximately 7 days after infection. Hospitalized patients with the virus should be isolated in a single room or in a unit with other infected patients (contact isolation procedures¹²¹), but during seasonal outbreaks large numbers of patients may make isolation impractical. Careful hand washing between contacts with patients and the use of gowns, gloves, masks, and goggles have all been shown to reduce RSV infection in hospital personnel.¹²²

Herpes Viruses

Varicella-zoster virus (VZV), herpes simplex virus Types 1 and 2, and cytomegalovirus (CMV) are members of the Herpesviridae family. Close personal contact is required for transmission of all the herpes viruses except for VZV, which is spread by direct contact or small-particle aerosols. After primary infection with herpes viruses, the organism becomes latent and may reactivate at a later time. Most people in the United States have been infected with all of the herpes viruses by middle age. Therefore, nosocomial transmission is uncommon except in the pediatric population and in immunosuppressed patients.

Varicella-Zoster Virus

Varicella-zoster virus produces both chickenpox and herpes zoster (shingles). Although the primary infection (chickenpox) is usually uncomplicated in healthy children, VZV infection in adults may be associated with major morbidity or death. Infection during pregnancy may result in fetal death or, rarely, in congenital defects. Health care workers with active VZV infection may transmit the virus to other personnel or to immunocompromised patients.

After the primary infection, VZV remains latent in dorsal root or extramedullary cranial ganglia. Herpes zoster results from reactivation of the VZV infection and produces a painful vesicular rash in the innervated dermatome. Anesthesiologists working in pain clinics may be exposed to VZV when caring for patients who have discomfort from herpes zoster.

Varicella-zoster virus is highly contagious, especially from patients with chickenpox or disseminated zoster. The CDC estimates that the period of communicability begins 1 to 2 days before the onset of the rash and ends when all the lesions are crusted, usually 4 to 6 days after the rash appears.¹²³ Since VZV may be spread through airborne transmission, respiratory isolation should be used for patients with chickenpox or disseminated herpes zoster.¹²¹ Use of gloves to avoid contact with vesicular fluid is adequate to prevent VZV spread from patients with localized herpes zoster.

Most adults in the United States have protective antibodies to VZV and are immune to new infection. One survey of hospital health care workers found that all of those aged 36 years and older had VZV antibodies, whereas 7.5% of those younger were susceptible.¹²⁴ Anesthesia personnel should be questioned about prior VZV infection, and those with a negative or unknown history of such infection should be serologically tested.⁶⁵ All employees with negative titers should be restricted from caring for patients with active VZV infection and should consider immunization with live, attenuated varicella vaccine. Susceptible personnel with a significant exposure to people with VZV infection are candidates for varicella zoster immune globulin (VZIG), which is most effective when administered within 96 hours after exposure. Because VZIG can prolong the incubation period of the virus, susceptible hospital personnel with significant VZV exposure should not have direct patient contact from the 10th to the 21st day after exposure.¹²³ Personnel without VZV immunity should be reassigned to alternative locations so that they do not care for patients who have active VZV infections.

Herpes Simplex

Herpes simplex infection is quite common in adults. After viral entry through the mucous membranes of the mouth, the primary infection with herpes simplex virus Type 1 is usually clinically inapparent but may involve severe oral lesions, fever, and adenopathy. In healthy people, the primary infection subsides and the virus persists in a latent state within the sensory nerve ganglion innervating the site of infection. Any of several mechanisms can reactivate the virus to produce recurrent infection, which manifests in the vicinity of the primary lesion.

A second herpes simplex virus, Type 2, is usually associated with infections below the waist and is spread by sexual contact. Newborns may become infected with

herpes simplex virus Type 2 during vaginal delivery from the mother's genital infection.

Herpes simplex virus Type 1 is probably spread by self-inoculation after contact with contaminated oral secretions. Asymptomatic individuals can unknowingly transmit herpes simplex virus Type 1, because the virus has been isolated from oral secretions of 5% of some populations. The fingers of health care personnel may be inoculated by direct contact with body fluids carrying either herpes simplex virus Type 1 or 2.

Herpetic Whitlow. Herpetic infection of the finger, herpetic paronychia or herpetic whitlow, is an occupational hazard for anesthesia personnel.¹²⁵ The infection usually begins at the portal of viral entry, a site on the distal finger where the integrity of the skin has been broken. Initially, there is itching and pain at the site of infection, followed by the appearance of a vesicle surrounded by erythema. There may be associated constitutional symptoms such as fever, malaise, and lymphadenopathy. Satellite vesicles appear near the primary lesion over several days. Within 3 weeks, the throbbing pain lessens, and the lesions begin to heal. A diagnosis of herpes simplex infection can be made by demonstrating multinucleated giant epithelial cells or nuclear inclusion bodies in smears (Tzanck's technique) taken from a vesicle. Although the process may resemble a bacterial paronychia, treatment should be conservative and surgical drainage is not indicated.

To prevent herpes simplex virus infections of the hands, anesthesia personnel should wear gloves when in contact with patients' oral secretions such as during endotracheal intubation and extubation, pharyngeal suctioning, and insertion of naso-gastric tubes.¹²⁶ Personnel with herpes simplex infections of the fingers or hands should not contact patients until their lesions are healed.⁶⁵ Treatment with acyclovir, an antiviral drug that inhibits replication of herpes simplex virus Types 1 and 2, may shorten the course of primary cutaneous viral infection.

Cytomegalovirus

Cytomegalovirus (CMV) infection commonly occurs during childhood, and antibodies to CMV develop in most individuals after the initial infection, which may be clinically inapparent. After this, there are intermittent periods of virus excretion even in the presence of high levels of circulating antibody. Transmission of CMV probably occurs through close contact with an individual excreting the virus or through contact with contaminated saliva or urine. It is unlikely that aerosols or small droplets play a role in CMV transmission.

Primary or recurrent CMV infection during pregnancy results in fetal infection in up to 2.5% of occurrences. Congenital CMV syndrome may be found in up to 10% of infected infants. Thus, although CMV infection usually does not result in morbidity in healthy adults, it may have significant sequelae in pregnant women. CMV infection can also be deadly in immunocompromised patients, such as those undergoing bone marrow transplantation.

The two major reservoirs of CMV infection within the hospital include infected infants and immunocompromised patients, such as those who have undergone organ transplants or those on oncology units. Studies of employees at a pediatric hospital indicate that personnel with patient care responsibilities have no greater risk of CMV infection than do personnel who have no patient contact.¹²⁷ It appears that routine infection control procedures, such as hand washing after patient contact and use of gloves to avoid touching body fluids, are sufficient to prevent CMV infection in health care workers (Table 4-3 and Table 4-4).⁶⁵ Pregnant personnel should be made aware of the risks associated with CMV infection during pregnancy and of appropriate infection control precautions to be used when caring for high-risk patients. There is no evidence to indicate that it is necessary to reassign pregnant women from patient care areas in which they may have contact with CMV-positive patients.

| Infectious Agent | Preventive Measures* |
|------------------------------|--|
| Cytomegalovirus | Standard precautions |
| Hepatitis B | Vaccine; hepatitis B immune globulin, standard precautions |
| Hepatitis C | Standard precautions |
| Herpes simplex | Standard precautions; contact precautions if disseminated disease |
| Human immunodeficiency virus | Postexposure prophylactic antiretrovirals; standard precautions |
| Influenza | Vaccine; prophylactic antiretrovirals; droplet precautions |
| Measles | Vaccine; airborne precautions |
| Rubella | Vaccine; droplet precautions |
| Tuberculosis | Airborne precautions; isoniazid ± ethambutol for PPD conversion |
| Varicella-zoster | Vaccine; varicella-zoster immune globulin; airborne and contact precautions; standard precautions if localized disease |

* Isolation Precautions outlined in Table 4-4.

Table 4-3. PREVENTION OF OCCUPATIONALLY ACQUIRED INFECTIONS^{65,121}

Table 4-4. HOSPITAL ISOLATION PRECAUTIONS¹²¹

Rubella

Outbreaks of rubella, or German measles, in hospital personnel have resulted in significant loss in employee working time, employee morbidity, and cost to the hospital. Although most adults in the United States are immune to rubella, up to 20% of women of child-bearing age are still susceptible. Rubella infection during the first trimester of pregnancy is associated with congenital malformations or fetal death.

Rubella is transmitted by contact with nasopharyngeal droplets from infected individuals. Patients are most contagious while the rash is erupting but can transmit the virus from 1 week before to 5 to 7 days after the onset of the rash. Droplet precautions should be used to prevent transmission (Table 4-4).⁶⁵

Ensuring immunity at the time of employment should prevent nosocomial transmission of rubella to personnel. Immunity can be documented by evidence of prior vaccination with live rubella vaccine or serologic confirmation. It has been shown that history is a poor indicator of immunity. A live, attenuated rubella virus vaccine is available to produce immunity in susceptible personnel.^{115,128} For individuals without confirmed immunity, routine serologic testing for antibody prior to vaccination is usually not cost-effective. Many state or local health departments mandate rubella immunity for all health care personnel, and local regulations should be consulted.

Measles (Rubeola)

Measles virus is highly transmissible both by large droplets and by the airborne route. Since the introduction of the measles vaccine in the United States in 1963, the incidence of the disease has decreased significantly. After a resurgence in the disease from 1989 to 1991, vaccination programs in preschool-aged children and implementation of programs for a second vaccine dose have successfully eliminated indigenous cases of measles in the United States. Importation of measles from other countries continues to occur.

Health care workers are at increased risk for acquiring measles (13 times that of the general population) and transmitting the virus to co-workers and patients. The CDC recommends that medical personnel have adequate immunity to measles, as documented by one of the following: evidence of two doses of live measles vaccine, a record of physician-diagnosed measles, or serologic evidence of measles immunity (Table 4-3).⁶⁵ Susceptible personnel born in or after 1957 should receive two

doses of the live measles vaccine at the time of employment.¹²⁸

Viral Hepatitis

Although many viruses may produce hepatitis, the most common are Type A or infectious hepatitis, Type B (HBV) or serum hepatitis, and Type C (HCV), which is responsible for most cases of parenterally transmitted non-A, non-B hepatitis (NANBH) in the United States. Delta hepatitis, caused by an incomplete virus, occurs only in people infected with HBV. Outbreaks of an enterically transmitted NANBH (hepatitis E) have been reported from outside the United States and are usually caused by contaminated water. The greatest risks of occupational transmission to anesthesia personnel are associated with HBV and HCV.

Hepatitis A

About 20–40% of viral hepatitis in adults in the United States is caused by the Type A virus, a picornavirus containing RNA. Hepatitis A is usually a self-limited illness, and no chronic carrier state exists. Spread is predominantly by the fecal–oral route, either by person-to-person contact or by ingestion of contaminated food or water. Outbreaks are usually found in institutions or other closed groups where there has been a breakdown in normal sanitary conditions. Hospital personnel do not appear to be at increased risk for hepatitis A.

Occasional hospital outbreaks of hepatitis A have occurred when patients were admitted during the prodromal stage of the infection. The use of gloves and meticulous hand washing during contact with feces or contaminated linens or clothing should be adequate to prevent viral spread to hospital personnel. Personnel exposed to patients with hepatitis A should receive immune globulin within 2 weeks of the exposure to reduce the likelihood of infection.^{129,130} Immune globulin provides protection against hepatitis A through passive transfer of antibodies and is used for postexposure prophylaxis. Hepatitis A vaccine is prepared from inactivated virus and is not routinely recommended for health care personnel except for those that may be working in countries with high hepatitis A endemicity.^{115,130}

Hepatitis B

Hepatitis B is a significant occupational hazard for nonimmune anesthesiologists and other medical personnel who have frequent contact with blood and blood products. The prevalence* of hepatitis B in the general population of the United States is 3–5%, and the carrier rate is 0.2–0.9% based on serologic screening. Serosurveys including more than 2400 anesthesia personnel conducted in the United States and several other countries demonstrated a mean prevalence of HBV serologic markers of 17.8% (range, 3.2–48.6%).¹³¹ The range of seropositive findings in anesthesia personnel in various locations probably reflects the prevalence of HBV carriers in the referral population for the area. Within the United States, the prevalence of hepatitis B markers in anesthesia personnel varied from 19% in one multicenter study¹³² to 49% in the anesthesia department of an inner-city hospital.¹³³

Acute HBV infection usually resolves without significant hepatic damage. Less than 1% of acutely infected patients will have fulminant hepatitis. The remaining 10% of infected people become chronic carriers of HBV (*i.e.*, serologic evidence demonstrated for more than 6 months). Within 2 years, half of the chronic carriers resolve their infection without significant hepatic impairment. Chronic active hepatitis, which may progress to cirrhosis, is found most commonly in those individuals with chronic viral infection for more than 2 years. Although prior estimates suggested that occupationally acquired HBV resulted in the death of 250 medical personnel each year, the implementation of routine vaccination and use of universal precautions have significantly reduced the risk of HBV infection (90% decline from 1985 to 1994) and its sequelae.⁶⁵

The diagnosis and classification of the stage of HBV infection can be made on the basis of serologic testing. Antibody to the surface antigen (anti-HBs) appears with resolution of the acute infection and confers lasting immunity against subsequent HBV infections. Chronic HBV carriers are likely to have hepatitis B surface antigen (HBsAg) and antibody to the core antigen (anti-HBc) present in serum samples.

Hepatitis B virus transmission in the community takes place through sexual contact, close personal contact (as occurs in institutions), shared use of needles and syringes for intravenous drug use, and perinatally from infected mother to newborn. Anesthesia personnel are at risk for occupationally acquired HBV infection as a result of accidental percutaneous or mucosal contact with blood or body fluids from infected patients. Patient groups with a high prevalence of HBV carriers include immigrants from endemic areas, users of illicit parenteral drugs, homosexual men, and patients on hemodialysis.¹²⁹ Carriers are frequently not identified during hospitalization because the clinical history and routine preoperative laboratory tests may be insufficient for diagnosis. Percutaneous exposure (usually an accidental needle stick) to blood carrying HBV (e-antigen–positive individuals) may result in infection in up to 30% of occurrences. HBV can be found in saliva, but the rate of transmission is less after mucosal contact with infected oral secretions than after percutaneous exposures to blood. HBV is a hardy virus that may be infectious for at least 1 week in dried blood on environmental surfaces.¹³⁴

Hepatitis B Vaccines. Use of hepatitis B vaccine is the primary strategy to prevent occupational transmission of HBV to anesthesia personnel and other health care workers at increased risk.¹²⁹ Administration of three doses of vaccine in the deltoid muscle results in the production of protective antibodies (anti-HBs) in more than 90% of healthy hospital workers. Hepatitis B vaccines now available in the United States are composed of HBsAg that has been produced by recombinant technology. Hospitals or anesthesia departments should have policies for educating, screening, and counseling personnel about their risk of acquiring HBV infection and should make vaccination available for susceptible personnel.^{129,135}

To ensure adequate postvaccination immunity, serologic testing of vaccinees for anti-HBs should take place within 6 months after the last dose of vaccine. Protective antibodies may develop in nonresponders with additional vaccine doses.¹³⁶ Vaccine-induced antibodies decline over time, with maximum titers after vaccination correlating directly with duration of antibody persistence.¹³⁶ The CDC states that for vaccinated adults with normal immune status, routine booster doses are not necessary for at least 7 years after vaccination.¹²⁹ Surveillance programs are continuing to assess the need for booster doses after longer intervals.

When susceptible, nonvaccinated anesthesia personnel have documented exposure to a contaminated needle or to blood from an HBsAg-positive patient, postexposure prophylaxis with HBV hyperimmune globulin and initiation of HBV vaccine series is recommended.^{129,137} HBV hyperimmune globulin (HBIG) is prepared from human plasma that contains a high anti-HBs titer and provides temporary, passive immunity.

Hepatitis C

The hepatitis C virus (HCV) is the etiology of most cases of parenterally transmitted NANBH and is a leading cause of chronic liver disease in the United States.¹³⁸ Antibodies to HCV (anti-HCV) can be detected in most patients with hepatitis C, but its presence does not correlate with resolution of the infection or progression of the hepatitis.¹³⁹ Immunity against HCV infection is not conferred by anti-HCV. Seropositivity for hepatitis C RNA using polymerase chain reaction is a marker of chronic HCV infection and can be used to identify individuals with potential to transmit the infection.¹⁴⁰

Sporadic parenteral transmission of NANBH accounts for 20–40% of all reported cases of acute viral hepatitis in the United States. CDC surveillance demonstrates that only about 6% of cases of NANBH are attributed to blood transfusions, whereas 42% are associated with intravenous drug use. Only 2% occur in health care workers from occupational exposure.¹⁴¹ The prevalence of anti-HCV in the United States is estimated to be 1.8% (3.9 million persons) with 74% (2.7 million persons) positive for HCV RNA.¹⁴²

People infected with HCV have a high rate of chronic hepatitis. Up to 60% of HCV-infected patients will have biopsy-proven chronic hepatitis, with many progressing to cirrhosis. HCV RNA can still be detected in more than 75% of patients after resolution of hepatitis C.¹³⁹ Interferon- α 1b has been an effective treatment for chronic hepatitis C, but unfortunately many patients relapse on discontinuation of the therapy. Combination therapy with interferon and ribavirin is more effective than treatment with interferon alone.^{143,144}

Like HBV, HCV is transmitted through blood and sexual contact, but the rate of HCV infection through routine personal contact is not high. The risk of hepatitis C after a HCV-infected needle stick exposure appears to be about 2–4%.^{145,146} This rate of transmission is significantly less than that for HBV, possibly owing to a lower viral titer in the blood of carriers. There is no effective postexposure prophylaxis available to prevent HCV infection, and use of immune globulin is no longer recommended.^{145,147} Interferon treatment begun during the early course of HCV infection is more effective than during chronic infection,¹⁴⁸ but the drug has not been tested for efficacy for postexposure prophylaxis. Personnel who have had a percutaneous or mucosal exposure to anti-HCV-positive blood should have serologic testing and counseling at the time of the exposure and at 6 months.¹⁴⁵

Pathogenic Human Retroviruses

The agent that produces acquired immunodeficiency syndrome (AIDS) is the Type 1 human immunodeficiency virus (HIV-1), one of several pathogenic human

retroviruses.¹⁴⁹ HIV-1 (HIV) is a member of the human T-cell lymphotropic viruses (HTLV) and was initially designated as HTLV-III. HTLV-I was the first human retrovirus to be discovered and has been documented as a cause of adult T-cell leukemia/lymphoma and a chronic degenerative neurologic disease, tropical spastic paraparesis. HTLV-I has been found in intravenous drug users and female prostitutes in the United States and has been identified and is tested for in the U.S. blood supply. Serologic studies indicate that the virus is endemic in parts of Japan, the Caribbean, and Africa.

Human T-cell lymphotropic virus II (HTLV-II) is similar to HTLV-I, and initial serologic testing often failed to differentiate the two viruses. HTLV-II is prevalent in intravenous drug users in the United States and Europe. HTLV-II has not been specifically linked with any disease, but the virus has been isolated from some patients with hairy cell leukemia. Transmission of HTLV-I/II appears to be through blood or during sexual intercourse. Occupational transmission to health care workers has not been studied, but because it is a bloodborne infection, this cannot be ruled out.

A second virus, HIV-2, produces an AIDS-like syndrome in parts of western Africa. The epidemiologic pattern of HIV-2 spread is predominantly through heterosexual activity, with almost equal numbers of infected men and women. The only reported cases of HIV-2 infection in the United States have been in patients who came from, or had contact with residents of Africa.

HIV Infection and AIDS

Current estimates suggest that 600,000 to 900,000 people in the United States are infected with HIV. The initial infection presents clinically as a mononucleosis-like syndrome with lymphadenopathy and rash. Although the patient then enters an asymptomatic period, monocyte-macrophage cells serve as a reservoir for the virus throughout the body, and CD4+T cells harbor the virus in the blood. Infection results in a serum antibody that may be detected by the enzyme-linked immunosorbent assay (ELISA) and is confirmed using the more specific Western blot test. Based on studies of homosexual men, AIDS develops in half of infected persons within 8 years of infection. During this phase of the disease, there is an increase in viral titer and impaired host immunity, resulting in opportunistic infections and malignancies.¹⁵⁰ According to CDC data, from 1981 through June 1999 there have been 711,344 cases of AIDS in the United States.¹⁵¹ The recent decline in the annual number of new cases of AIDS has been attributed to the effect of new antiretroviral treatments for HIV infection.

Human immunodeficiency virus is spread by sexual contact, perinatally from infected mother to neonate, and through infected blood (transfusion or shared needles) and blood products.¹⁵² Investigation of AIDS patients with no recognized risk factors indicates no evidence for additional modes of transmission. Although the virus can be found in saliva, tears, and urine, these body fluids have not been implicated in viral transmission.¹⁵² Groups of adults that account for the highest percentage of AIDS cases include homosexual/bisexual males, intravenous drug users, heterosexuals with a history of contact with an HIV-infected person, or individuals receiving an infected blood transfusion, blood component, or tissue.

All HIV-infected patients may not be identified as such by their initial or presenting diagnosis. Six percent of patients cared for in one urban hospital emergency department had HIV infection, with 63% of those being unrecognized.¹⁵³ Serologic testing of patients at 20 acute care hospitals in 15 U.S. cities indicated an overall rate of HIV seroprevalence of 4.7% and a range of 0.2–14.2%.¹⁵⁴

Risk of Occupational Human Immunodeficiency Virus Infection. Although there are several modes of transmission for HIV infection in the community, the most important source for occupational transmission of HIV to health care workers is blood contact.¹⁵⁵ Prospective studies by the CDC^{156,157} and the National Institutes of Health¹⁵⁸ demonstrated that the rate of seroconversion in prospectively followed health care workers sustaining a percutaneous exposure (needle stick injury) to HIV-infected blood was 0.3%.^{157,158,159} Although no infections occurred after cutaneous or mucous membrane exposures in these studies, the rate of transmission of HIV after mucous membrane exposure is estimated to be 0.09%.¹⁶⁰ Through June 1999, the CDC had documented HIV seroconversion in 55 health care workers after occupational exposure.¹⁵¹ Forty-nine of the infected health care workers had percutaneous exposure. A search of the worldwide literature provided reports of 94 health care workers with occupationally acquired HIV infection through September 1997.¹⁶¹

A case-control study has demonstrated that specific factors are associated with an increased rate of HIV transmission after a percutaneous injury.¹⁶² Increased risk was associated with a deep injury, visible blood on the device producing the injury, a procedure in which the needle was placed in an artery or vein, and terminal illness (death from AIDS within 2 months) in the source patient. Therefore, the risk of occupational HIV transmission is greatest after a deep injury with a blood-filled, large-gauge, hollow-bore needle used on a patient in the terminal phase of AIDS.

The occupational risk of HIV infection is a function of the annual number of blood exposures, the rate of HIV transmission with each exposure to infected blood, and the prevalence of HIV infection in the specific patient population. Based on values for these variables taken from the literature, Buergler *et al* calculated a 1-year risk of HIV infection for anesthesiologists to be between 0.001 and 0.129%.¹⁶³ Greene *et al* prospectively collected data on 138 contaminated percutaneous injuries to anesthesia personnel.¹⁶⁴ The rate of contaminated percutaneous injuries per year per full time equivalent anesthesia worker was 0.42, and the average annual risk of HIV and HCV infection was estimated to be 0.0016% and 0.015%, respectively. Based on these infection rates, it was estimated that occupational exposures would result in 0.56 HIV infections and 5.18 HCV infections per year in anesthesia personnel.

Anesthesia personnel are frequently exposed to blood and body fluids during invasive procedures such as insertion of vascular catheters, arterial punctures, and endotracheal intubation.^{164,165} Although many exposures are mucocutaneous and can be prevented by the use of gloves and protective clothing, these barriers do not prevent percutaneous exposures such as needle stick injuries, which carry a greater risk for pathogen transmission. Thirty-two percent of a sample of anesthesiologists reported a contaminated needle stick injury during the prior year.¹⁶⁶ Because of the tasks they perform, anesthesia personnel are likely to use and be injured by large-bore, hollow needles such as IV catheter stylets and needles on syringes.^{164,167} Because these needles carry a larger volume of blood and possibly a greater viral inoculum when contaminated, they are associated with a higher risk of pathogen transmission.¹⁶⁸ Needleless or protected needled safety devices are becoming available and should be considered to replace standard devices to reduce the risk of needle stick injuries.^{135,169} Although safety devices usually are more expensive than a comparable needled item, they may be more cost-effective when the cost of needle stick injury investigation and medical care for infected personnel is considered. Percutaneous injuries have now been accepted as a significant occupational risk for health care workers and several states have passed legislation requiring the use of available needleless or safety needled devices. OSHA has issued a revised directive (CPL 2-2.44D) to its compliance officers that updates enforcement procedures for its Bloodborne Pathogen Standard.¹³⁵ The new directive emphasizes the use of safety devices to help reduce the risk of needlesticks and other sharps injuries.

Postexposure Treatment and Prophylactic Antiretroviral Therapy. When personnel have been exposed to patients' blood or body fluids, the incident should immediately be reported to the employee health service or the appropriate individual within the institution. Based on the nature of the injury, the exposed worker and the source individual may be tested for serologic evidence of HIV, HBV, and HCV infection.¹⁷⁰ Current local laws must be consulted to determine policies for testing the source patient. Confidentiality should be maintained at all times. When the source patient is found to be HIV-positive, the employee should be retested periodically for HIV antibodies for a minimum of 6 months after exposure, although most infected people are expected to undergo seroconversion within the first 6 to 12 weeks after exposure. During this period, the exposed employee should follow CDC recommendations for preventing transmission of HIV to family members and patients.¹⁷⁰

Zidovudine is effective in reducing the rate of transmission of HIV from infected mother to newborn¹⁷¹ and after a percutaneous occupational exposure to HIV-infected blood.¹⁶² The CDC has published an algorithm for postexposure prophylaxis for health care workers who have incurred a percutaneous injury.¹⁷⁰ The use of specific antiretroviral agents is based on the type of exposure and source patient. Since protocols for chemoprophylaxis are likely to change with additional research and the introduction of new antiretroviral drugs, the most current recommendations should be consulted prior to instituting postexposure prophylactic therapy.

Occupational Safety and Health Administration Standards, Universal Precautions, and Isolation Precautions

The CDC formulated recommendations, or Universal Precautions, for preventing transmission of bloodborne infections (including HIV, HBV, and HCV) to health care workers.¹⁷² The guidelines are based on the epidemiology of HBV as a worst-case model for transmission of bloodborne infections and current knowledge of the epidemiology of HIV and HCV. Because some carriers of bloodborne viruses are not identified, Universal Precautions were recommended for use during all patient contact. Although exposure to blood carries the greatest risk of occupationally related transmission of HIV, HBV, and HCV, it was recognized that universal precautions should also be applied to semen, vaginal secretions, human tissues, and the following body fluids: cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic. Subsequently, the CDC synthesized the major features of Universal Precautions into Standard Precautions, a single set of precautions that should be applied to all patients (Table 4-4).¹²¹ Standard Precautions were included in a set of Isolation Precautions which contain guidelines (Airborne Precautions, Droplet Precautions, and Contact Precautions) to reduce the risk of transmission of bloodborne and other pathogens in hospitals.¹²¹

Standard Precautions recommends use of gloves when a health care worker contacts mucous membranes and oral fluids, such as during endotracheal intubation and pharyngeal suctioning. The selection of specific barriers or personal protective equipment should be commensurate with the task being performed. Gloves may be all that is necessary during insertion of a peripheral intravenous catheter, whereas gloves, gown, mask, and face shield may be required during endotracheal intubation in a patient with hematemesis. Gloves should be removed after they become contaminated to prevent dissemination of blood or body fluids to equipment or personal

items. Waterless antiseptics should be available to permit anesthesia personnel to wash their hands after glove removal without leaving the operating room.

Because needlestick injuries are a frequent cause of blood exposure,¹⁶⁴ recommendations for safe needle handling are included in Standard Precautions. Many injuries occur during recapping of contaminated needles; therefore, if recapping is necessary, a one-handed technique should be used.

There is now direct evidence that implementation of Universal Precautions decreases the number of exposure incidents that result in worker contact with patient blood and body fluids.¹⁷³ Observational and postal surveys indicate that in many instances Universal Precautions are not being followed.¹⁶⁶ Anesthesiologists were more likely to comply with Universal Precautions if they thought they were caring for an HIV-infected patient. Because all infected patients cannot be identified by the routine preoperative information, the selective application of Universal Precautions is inappropriate.

The Occupational Safety and Health Administration has promulgated standards to protect employees from occupational exposure to bloodborne pathogens.¹³⁵ Employers subject to OSHA must comply with these federal regulations. The Standard requires that there must be an Exposure Control Plan specifically detailing the methods that the employer is providing to reduce employees' risk of exposure. The employer must evaluate engineering controls such as needleless devices to eliminate hazards. Work practice controls are encouraged to reduce blood exposures by altering the manner in which personnel perform tasks (e.g., an instrument rather than fingers should be used to handle needles). The employer must furnish appropriate personal protective equipment (e.g., gloves, gowns) in various sizes to permit employees to comply with Universal Precautions. The HBV vaccine must be offered at no charge to personnel. A mechanism for postexposure treatment and follow-up must be provided. An annual educational program should inform employees of their risk for bloodborne infection and the resources available to prevent blood exposures.

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease, caused by a proteinaceous infectious agent, or prion, may be unsuspected in patients presenting with dementia.¹⁷⁴ The disease has been transmitted to patients by contaminated biologic products. The risk of transmission to hospital personnel is unknown because surveillance is complicated by the long period from the time of infection until the onset of symptoms. Universal precautions should be used to prevent contact with spinal fluid, blood, or tissue specimens.¹⁷⁵ Careful hand washing is essential. The prion is difficult to eradicate from equipment, but the use of steam sterilization with or without sodium hydroxide is effective.¹⁷⁵

Tuberculosis

The incidence of tuberculosis in the United States has declined since 1992, reversing the increase in reported cases that had begun in 1986.¹⁷⁶ Although most individuals infected with tuberculosis are treated on an outpatient basis, undiagnosed patients may be hospitalized for the work-up of pulmonary pathology. Hospital personnel are especially at risk for infection from unrecognized cases.^{177,178,179} Groups with a higher prevalence of tuberculosis include (1) personal contacts of people with active tuberculosis; (2) people from countries with a high prevalence of tuberculosis; and (3) alcoholics, homeless people, and intravenous drug users.¹⁷⁷

Mycobacterium tuberculosis is transmitted through viable bacilli carried on airborne particles, 1–5 µm in size, by coughing, speaking, or sneezing. Respiratory isolation should be used for hospitalized patients suspected of having tuberculosis until they are confirmed as nontransmitters by sputum examination that demonstrates no bacilli.^{177,180} Appropriate chemotherapy is the most effective means to prevent spread of tuberculous infection. Elective surgery should be postponed until infected patients have had an adequate course of chemotherapy. If surgery is required, filters should be used on the anesthetic breathing circuit for patients with tuberculosis.^{177,181}

Several hospital outbreaks of multidrug-resistant *M. tuberculosis* infection have been reported.^{179,182} Mortality associated with these outbreaks is high. Factors responsible for nosocomial transmission include delayed diagnosis of tuberculosis so that multiple patients and personnel were exposed, and delayed recognition of drug resistance resulting in inadequate initial drug therapy.

Effective prevention of spread to health care workers requires early identification of infected patients and immediate initiation of respiratory isolation (negative-pressure rooms with air vented outside; see Table 4-4).^{177,181} Patients must remain in isolation until adequate treatment is documented. If patients with tuberculosis must leave their rooms, they should wear face masks to prevent spread of organisms into the air. Health care workers should wear respiratory protective devices when they enter an isolation room or when performing procedures that may induce coughing, such as endotracheal intubation or tracheal suctioning.¹⁷⁷ The CDC recommends that respiratory protective devices worn to protect against *M. tuberculosis* should be able to filter 95% of particles 1 mm in size at flow rates of 50 liters per minute and should fit the face with a leakage rate around the seal of less than 10% documented by fit-testing.¹⁷⁷ High-efficiency particulate air respirators (classified as N95) are NIOSH-approved devices that meet the CDC criteria for respiratory protective devices against *M. tuberculosis*.¹⁸³

Routine periodic screening of employees for tuberculosis should be included as part of a hospital's employee health policy with the frequency of screening dependent on the prevalence of infected patients in the hospitalized population. When a new conversion is detected by skin testing, a history of exposure should be sought to determine the source patient. Treatment or preventive therapy is based on the drug-susceptibility pattern of the *M. tuberculosis* in the source patient, if known. Personnel who have been exposed to a patient with active tuberculosis should be followed by skin testing.

Viruses in Laser Plumes

The laser is commonly being used for vaporizing carcinomatous and viral tumors. Use of lasers is associated with several hazards, both to patients and to operating room personnel. Risks include thermal burns, eye injuries, electrical hazards, and fires and explosions. In addition, there is now evidence that the laser plumes resulting from tissue vaporization contain toxic chemicals such as formaldehyde. Clinical and laboratory studies have demonstrated that when the carbon dioxide laser is used to treat verrucae (papilloma and warts), intact viral DNA could be recovered from the plume.¹⁸⁴ Scientists at the Center for Devices and Radiological Health used an *in vitro* model to demonstrate that viable viruses can be found in plumes produced by both carbon dioxide and argon laser vaporization of a virus-loaded culture plate.¹⁸⁵ Another model indicated that viable viruses were carried on larger particles that traveled less than 100 mm from the site being vaporized.¹⁸⁶

A case report describes laryngeal papillomatosis in a surgeon who had used a laser to remove anogenital condylomas from several patients.¹⁸⁷ Although DNA analysis of the surgeon's papillomas revealed a viral type similar to that of the condylomas, proof of transmission is lacking.

To protect operating room personnel from exposure to the viral and chemical content of the laser plume, it is recommended that the nozzle from a smoke evacuator be held as close as possible to the tissue being vaporized. This will effectively remove the particulate material in the plume by trapping it in the filter of the evacuator. In addition, operating room personnel working in the vicinity of the laser plume should wear gloves, goggles, and high-efficiency filter masks.¹⁶⁵

EMOTIONAL CONSIDERATIONS

Stress

Among the potential health hazards of working in the operating room, stress is well recognized.¹⁸⁸ However, there is very little objective information specifically directed toward understanding the nature of job-related stress among anesthesiologists. Stress is a nonspecific response to any change, demand, pressure, challenge, threat, or trauma.¹⁸⁹ There are three distinct components of the stress process: the initiating stressors, the psychological filters that process and evaluate the stressors, and the coping mechanisms that are employed in an attempt to control the stressful situation.

Stress on the job is unavoidable and, to a certain degree, desirable. A moderate, manageable level of stress is the fuel necessary for individual achievement. What distresses individual A may be pleasurable to individual B, or even to individual A in a different circumstance. Hans Selye, one of the pioneering scientists in the modern study of stress, described a beneficial effect resulting from mild, brief, and controllable episodes of stress: "The absence of stress is death."¹⁹⁰ On the other hand, extreme degrees of stress can be associated with disorders of the psychological homeostatic mechanism and consequently may lead to physical or mental disease. Exactly how an individual responds to a particular stressor is the product of a series of factors, including age, gender, experience, pre-existing personality style, available defense and coping mechanisms, support systems, and concomitant events (such as sleep deprivation).¹⁹⁰

A number of circumstances that classically define a stressful workplace are characteristic of the practice of anesthesiology. There is a background of chronic, low-level stress punctuated by intermittent episodes of extreme stress. The demands are externally paced, usually out of the anesthesiologist's control. Habituation to the demands is difficult, and perturbations are intermittently but continuously inserted into the system. Finally, failure to meet the demands imposed by the workplace produces grave consequences.

Certain stressors are specific to the practice of anesthesiology. Night call is consistently reported as one of the most stressful elements, especially among older anesthesiologists.¹⁰⁶ Concerns about liability, production pressure, economic uncertainty, and interpersonal relations are other frequently cited stressors.¹⁰⁵

It is not surprising that the process of inducing anesthesia engenders a great deal of stress in the practitioner. Although this observation is self-evident to any anesthesiologist, documentation is limited to demonstrations of changes in heart rate and blood pressure in the anesthesiologist during induction.¹⁹¹ Individual observations included cardiac dysrhythmias (premature ventricular contractions), ischemic changes on the electrocardiogram, and elevation of the blood pressure to a maximum of 193/137 mm Hg. The level of training and degree of experience play a role in determining the amount of stress perceived by an anesthesiologist. It has been shown that an inverse relationship exists between the duration of clinical experience and the level of anxiety and hemodynamic changes occurring in the anesthesiologist during the induction of anesthesia.¹⁹²

Interpersonal relationships impose a unique set of demands that may serve as stressors to the anesthesiologist. In most locations within a hospital or clinic setting (e.g., radiology department), direct responsibility for a patient is temporarily transferred to the consulting physician. In contrast, the operating room is an arena where two coequal physicians simultaneously share ultimate responsibility for the well-being of a patient. To many anesthesiologists and surgeons, the overlapping of realms of responsibility produce the highest degree of stress in their clinical practices.

Several studies have focused on personality characteristics, some identifiable before entrance to medical school, that are predictive of subsequent behavior and performance as clinicians.^{193,194,195} Prominent among traits predictive of maladaptive responses to stress is the obsessive-compulsive, dependent character structure. These individuals typically manifest pessimism, passivity, self-doubt, and feelings of insecurity. Commonly they respond to stress by internalizing anger and becoming hypochondriacal and depressed. In work reported by Vaillant *et al*, undergraduate students who demonstrated these characteristics were more likely to have their medical careers disrupted by alcoholism or drug abuse, psychiatric illness, and marital disturbances.¹⁹³ McDonald *et al* have applied some of these considerations in an attempt to identify psychological attributes that may be of value in the selection process for anesthesiology residents.¹⁹⁵ They found a modest correlation of performance on the California Psychological Inventory with some measures of success in an anesthesiology residency.

Stress on the job may produce either an improvement or a decrement in job performance. Only when the magnitude of the stress exceeds the individual's threshold do his or her defenses become exaggerated and inappropriate. It is this situation that gives rise to maladaptive behavior and the personal and professional deterioration that can lead to disorders such as drug addiction, professional burnout, and suicide.

Substance Use, Abuse, and Dependence

Illicit drug use remains one of our society's major afflictions. It is estimated that 20 million Americans are drug users, with some 5 million addicted.

Epidemiology

The abuse of drugs by physicians continues to attract considerable media attention and notoriety.¹⁹⁶ However, recognition of the problem of substance dependence among physicians is not new. In the first edition of *The Principles and Practice of Medicine*, edited by Sir William Osler and published in 1892, it is stated: "The habit [morphia] is particularly prevalent among women and physicians who use the hypodermic syringe for the alleviation of pain, as in neuralgia or sciatica."¹⁹⁷ Two years later, Mattison commented: "It is a fact striking though sad that more cases of morphinism are met with among medical men than in all other professions combined."¹⁹⁸

Whether substance abuse is more prevalent among physicians than the general population is a subject worthy of debate. There is a large body of literature that attempts to support the notion that drug problems are more frequent among physicians.¹⁹⁹ The data from which this conclusion has been drawn are notoriously difficult to accurately collect and to interpret. In her extensive review of the English-language literature, Brewster finally concluded, "No one really knows how many practicing physicians are having problems with alcohol and other drugs."²⁰⁰ More recently, Hughes *et al* did identify alcohol, minor opiates, and benzodiazepine tranquilizers as substances of more frequent abuse among physicians than in the general population.²⁰¹ In many cases the drugs were self-prescribed and were considered by the physician to be "self-treatment." On the other hand, physicians were less likely to be current users of illicit substances than their age and gender peers.

Reliable documentation suggests that substance abuse is a significant problem among anesthesiologists.^{202,203} In Domino's report, "drug-related deaths" was one category in which the risk of death among anesthesiologists was significantly greater than among the control group of internists.²⁹ In the view of many observers, addiction represents the primary occupational hazard for the specialty of anesthesiology. This conclusion is supported by a number of studies that examine the problem from various vantage points. One of the most easily accessed and frequently quoted sources of information on drug abuse comes from statistics on the number of individuals who are in drug treatment programs. However, there are major flaws inherent in this system of data collection. Before a physician is entered into any treatment program, he or she must first recognize that he or she has a drug problem. Unfortunately, denial is typically the first and most tenaciously maintained defense mechanism for the physician-substance abuser.

Even after recognizing that a drug-related problem exists, physicians are less likely than the population in general to seek professional assistance.²⁰⁴ Again, denial plays a major role in this reluctance to undergo counseling or therapy. Medical students learn early in their education to use denial mechanisms to enable them to endure long, sleepless nights and the personal shortcomings that inevitably must be faced in clinical medicine. These well-developed denial mechanisms encourage the physician-addict to conclude that his or her problem is minor and that self-treatment is possible. Physicians typically enter programs for treatment only after they have reached the end stages of their illness.

With these caveats in mind, it is still informative to look at the statistics pertaining to the number of anesthesiologists who are involved in treatment programs for drug-related illness. Probably the most extensive experience comes from the Medical Association of Georgia Disabled Doctors' Program.²⁰⁵ Their study population includes 1000 disabled physicians, 920 of whom were treated for chemical dependency. One hundred and twenty-one of these patients were anesthesiologists (12%), although anesthesia accounts for just 3.9% of the American physician population. Even more troubling is the fact that anesthesia residents constitute 33.7% of the resident population in their treatment group, despite their representation as only 4.6% of the American resident population. Anesthesia residents have a 7.4-fold excess representation in this treatment population.

Another approach to uncovering the prevalence of substance abuse among anesthesiologists is the directed survey. As with the statistics drawn from the drug treatment programs, there are major weaknesses inherent in this form of data collection. Most obvious is the willingness of the respondent to detail honestly and completely his or her experience in an area as sensitive as drug abuse.

One of the most extensive surveys was conducted by Ward *et al*.²⁰⁶ They reported on the results of a questionnaire completed by 247 American anesthesia training programs. Sixty-four percent of the respondents identified at least one of their personnel as an abuser of drugs. In 10 programs (4%), there were 5 or more such individuals identified during the 10-year study period (1970–1980). The overall incidence of suspected abuse was 1.3%, and confirmed abuse was 1.1%. The two most favored substances for abuse were reported to be meperidine and fentanyl, with a definite tendency toward the latter in the most recent half-decade of the study. This preference had previously been observed by Talbott *et al*, who had treated 105 fentanyl addicts among the 125 anesthesiologists admitted to their facility at the time.²⁰⁵

Similar results have been obtained by Menk *et al*²⁰⁷ and Gravenstein *et al*²⁰⁸ in American training programs and by Weeks *et al* in Australia.²⁰⁹ In the study by Gravenstein *et al*, 76% of the academic department chairs who responded to a survey reported that one or more of their staff had been affected by substance abuse during the period of study (1974–1979). Because of the significance of this problem in anesthesia training programs, the Accreditation Council for Graduate Medical Education's Special Requirements for Anesthesiology require that each residency program "must have a written policy and an educational program regarding substance abuse."¹⁰³

Substance Dependence as a Disease

What accounts for this disproportionately high incidence of substance dependence among anesthesiologists? To answer this, it is best to view substance dependence as a psychosocial, biogenetic disease.²¹⁰ As such, the addiction (1) is a primary condition (not a symptom), (2) is associated with specific anatomic and physiologic changes, (3) has a set of recognizable signs and symptoms, (4) has a predictable, progressive course (if left untreated), and (5) has established etiologies (Table 4-5).

Table 4-5. DSM-IV CRITERIA FOR SUBSTANCE-RELATED DISORDERS

It is important to recognize that the causative factors in this disease process involve genetics as well as the environment. The disease results from a dynamic interplay between a susceptible host and a “favorable” environment. Vulnerability in the host is an important factor. What constitutes an instigating exposure to a drug in one person may have absolutely no effect on another. Unfortunately, there is no good predictive tool to identify the susceptible individual until he or she gets the disease.

There are causative factors specific to the specialty of anesthesiology. These include job stress, an orientation toward self-medication, lack of external recognition and self-respect, the availability of addicting drugs, and a susceptible premorbid personality.²¹¹

Self-prescription is commonly seen as a prelude to more extensive substance abuse and dependence.²⁰¹ Similarly, recreational use of drugs may proceed to drug dependence, with the drug used for recreation usually becoming the primary drug of dependence. Of concern is the recreational use of drugs among younger physicians and medical students and the choice of more potent drugs with enhanced potential for addiction, such as cocaine and the synthetic opioids, fentanyl and sufentanil.²¹²

The general public's image of the anesthesiologist frequently falls short of that of other physicians. In a report from Australia, only 66% of the patients knew that anesthesiologists needed medical qualifications, and fewer than 10% could remember their anesthesiologist's name.²¹³ It is even more distressing when co-workers in the medical field fail to recognize the special skills and contributions of anesthesiologists. In another study from Australia, only 83% of hospital nurses knew that anesthesiologists had to be medically qualified.²¹⁴

Positive reinforcement and a sense of “a job well done” are important components of job satisfaction. It is more difficult for the anesthesiologist than the surgeon to achieve recognition from patients and medical colleagues for a successful outcome. The Rodney Dangerfield syndrome, “I don't get no respect,” has been cited by several authors as an instigating factor in drug experimentation.²¹¹

Anesthesiologists work in a climate in which large quantities of powerful psychoactive drugs are freely available. From the experience of the U.S. Army in Vietnam, it is apparent that when there is easy access to narcotics, alcohol use declines in favor of use of opiates.²¹⁵ As each new synthetic opioid becomes available for clinical use, it also becomes the drug of choice of abusing anesthesiologists. Currently, fentanyl and sufentanil are seen most frequently as the abused drug.

Because availability of drugs does play a role in the onset of this disease, it is logical that programs that better audit the distribution of drugs within the operating room setting should be a valuable preventive measure. Detailed protocols have been published for better controlling the distribution of these medications.²¹⁶ Talbott *et al* acknowledge that the strategies advocated within the anesthesia community are better than those of our colleagues in other medical specialties.²⁰⁵ However, these are mostly limited to academic centers and require wider dissemination to be effective.

There is an apparent link between behavior before entering medical school and subsequent development of substance abuse.²¹⁷ At least one study examining personality profiles of anesthesiologists revealed a disturbingly high proportion with a predisposition toward maladaptive behavior.²¹⁸ Talbott *et al* have observed that many of the anesthesia residents in their treatment program specifically chose the specialty of anesthesiology because of the known availability of powerful drugs.²⁰⁵ Residency selection committees should consider screening for personality disorders as an important part of the admissions process.

The consequences of substance abuse are ultimately devastating to the practicing anesthesiologist. If left untreated, substance dependence is a fatal illness. There are 100 deaths per year among U.S. physicians that are the direct result of chemical dependency.²¹⁹ Domino reported relative risks of 2.75 for drug-related deaths and 1.78 for HIV-related deaths among anesthesiologists compared to internists.²⁹ In the study reported by Ward *et al*, among the 334 confirmed drug abusers, 27 died of “drug overdose,” and in another 3, “abuse was discovered at death.”²⁰⁶ Gravenstein *et al* reported 7 deaths among 44 confirmed drug abusers.²⁰⁸ Menk *et al* reported 14 drug-related deaths (18%) among the 79 drug abusers who had been re-enrolled in their anesthesiology residencies after treatment.²⁰⁷

Intentional or inadvertent drug-related death is, of course, only one of the potential consequences of substance abuse (Table 4-6). More common is a gradual and inexorable deterioration in professional, family, and social relationships. The substance abuser becomes increasingly withdrawn and isolated, first in his or her personal life, and ultimately in his or her professional life. Every attempt is made to maintain a facade of normality at work, because discovery means isolation from the source of the abused drug. When professional conduct is finally impaired such that it is apparent to the physician's colleagues, the disease is approaching its end stage.

Table 4-6. SIGNS OF SUBSTANCE ABUSE AND DEPENDENCE

In addition to the health hazards of substance dependence, there are significant legal considerations.²⁰² Each state has laws that detail the necessary steps for handling the drug-abusing physician. Most states have established Impaired Professionals Programs and require reporting such physicians to the licensing board, so-called “snitch laws.” In many cases disciplinary action and even criminal penalties can be imposed on people who knowingly fail to report an impaired physician. Disciplinary action taken against an impaired physician must also be reported to the National Practitioner Data Bank to be in compliance with federal law.

An interesting debate exists regarding the issue of compulsory drug testing of physicians.²²⁰ Random drug testing protocols have already been established in various high-risk industries (nuclear, aviation) and the military. Although many agree that this is a step in the right direction, questions remain about the legality and effectiveness of this approach. Institution of such programs in hospitals is limited.

A very aggressive program of detection and intervention is critical if careers and lives are to be saved.²²¹ If left untreated, less than 30% of addicted physicians will be practicing in 10 years and some 10% will have died from their disease. On the other hand, physicians are usually highly motivated, and high rehabilitation rates can be expected. Anesthesiologists appear to have a recovery rate approximating that of other physicians.²²² In the report of Ward *et al*, approximately 55% of the confirmed substance abusers underwent rehabilitation, and half of these were offered re-employment in their original departments.²⁰⁶

Controversy remains about the most appropriate career path for the recovering addicted anesthesiologist. Before the reports by Talbott *et al*,²⁰⁵ and Ward *et al*,²⁰⁶ recovering addicts were discouraged from continuing their careers in anesthesiology. However, these and other encouraging reports during the 1980s provided optimism that these individuals could be successfully rehabilitated and safely returned to their practice of anesthesiology. In contrast, a subsequent report by Menk and colleagues casts doubt on the advisability of addicted anesthesiologists' re-entering the field.²⁰⁷ Among 79 opioid-dependent anesthesiology residents, there was a 66% (52 of 79) failure rate for successful rehabilitation and return to practice. Even more discouraging, there were 14 suicide or overdose deaths among those 79 returning trainees. Their conclusion is that redirection into another specialty is the safer course after rehabilitation. Others have questioned these conclusions based on concerns regarding the study design.²²³

Because of the contradictory data, no firm recommendations can be made about re-entry into the practice of anesthesia after treatment. Each state has laws or regulations that dictate the circumstances under which a physician recovering from substance abuse can return to practice. Federal laws, such as the Americans with Disabilities Act, impose additional considerations for this difficult decision. The ASA has published a sample chemical dependency policy for departments of anesthesiology.²²¹ This document describes the process of re-entry and provides a model for a re-entry contract that can be used when a recovering anesthesiologist is considered ready to come back into practice. The American Board of Anesthesiology has established a policy for candidates with a history of alcoholism or illegal use of drugs (Table 4-7).²²⁴

The American Board of Anesthesiology (ABA) screens individuals with a history of alcoholism or substance abuse who are not currently abusing alcohol or using drugs illegally. The ABA supports the intent of the ASA. The ABA will admit qualified applicants and candidates with a history of alcoholism or substance abuse to its examination system and to examination (i.e., in response to its inquiries, the ABA receives acceptable documentation that they do not currently pose a direct threat to the health and safety of others). The ABA will admit qualified applicants and candidates with a history of illegal use of drugs to its examination system and to examination (i.e., in response to its inquiries, the ABA receives acceptable documentation that they are not currently engaged in the illegal use of drugs). After a candidate with a history of alcoholism or illegal use of drugs satisfies the examination requirements for certification, the ABA will determine whether it should defer issuing its certification to the candidate for a period of time to avoid certifying a candidate who poses a direct threat to the health and safety of others. If the ABA determines that issuance of the candidate's certification is appropriate because the candidate does not currently pose a threat to the health and safety of others, the ABA will issue the specific circumstances of the candidate's history of alcoholism or illegal use of drugs to determine when the candidate should write the Board to request issuance of its certification.

Table 4-7. POLICY STATEMENT OF THE AMERICAN BOARD OF ANESTHESIOLOGY (ABA)

Impairment

Substance abuse probably accounts for some 85% of the cases of impairment* among physicians.²²⁵ Other factors that may lead to impairment include physical or mental illness and deterioration owing to the aging process. Some authorities include unwillingness or inability to keep up with current literature and techniques as a form of disability.

Data regarding the prevalence of these disabling disorders are more difficult to obtain than are those on drug abuse. Statistics derived from the admitting diagnoses to various psychiatric facilities indicate that close to 1% of those admitted are physicians. In the order of increasing frequency, admission is required for organic psychoses, personality disorders, schizophrenia, neuroses, and affective disorders, particularly depression.²²⁶

It is not surprising that depression should figure prominently among the personality characteristics of emotionally impaired physicians. Indeed, many of the personality traits that are adaptive and ensure success in the physician's world may also serve as risk factors for depression when exaggerated. These character traits include self-sacrifice, competitiveness, achievement orientation, denial of feelings, and intellectualization of emotions. Two studies on alcoholic physicians provide some insight into this link between achievement orientation and emotional disturbance. Bissell and Jones reported that more than half of their group of alcoholic physicians graduated in the upper third of their medical school class, 23% were in the upper tenth, and only 5% were in the lower third of their class.²²⁷ Similarly, a report on alcohol use in medical school demonstrated better than average academic performance among those students identified as alcohol abusers.²²⁸ Alcohol abuse clearly does not enhance the learning process. Rather, alcohol abuse is a manifestation of psychological disturbance resulting from excessive degrees of stress among some students who are determined to have flawless records.

It is difficult to identify and appropriately respond to the dilemma of the impaired or unsafe anesthesiologist.²²⁹ Fortunately, in recent years, most state legislatures and medical societies have formally recognized this problem and have formed committees and enacted laws that address the impaired physician. These programs are usually therapeutic and nonpunitive in nature. Ideally, the committees provide a nonthreatening environment for identification and intervention for the impaired physician. Only in cases in which a real risk to the public welfare exists and the involved physician is unwilling voluntarily to suspend practice and accept assistance is the license suspension power of the State Board of Medical Examiners exercised.²³⁰

Suicide

Perhaps one of the most alarming of the occupationally associated hazards for anesthesiologists is the high rate of suicide.^{25,26,28,29,231} The incidence is 3 to 4 times the suicide rate expected among a contemporary, otherwise comparable socioeconomic group and exceeds that of all but one or two other medical specialties.²³² A report from England identified five deaths from suicide over a 5-year period in anesthesiology training programs.²³³ Their ratio of 1 suicide per 500 residents compares unfavorably with the approximately 1 suicide per 12,000 in the general U.S. population and 1 suicide in 4000 for physicians per year.²³⁴

Why should there be such a high rate of suicide among anesthesiologists? A partial explanation lies with the high degree of stress that is an integral part of the job. The relationship between generalized stress and suicide is not direct. But, clearly, in susceptible people, feelings of inability to cope resulting from overwhelming stress may give way to despair and suicide ideation.

Extensive personality profiles have been collected from suicide-susceptible individuals; these indicate characteristics such as high anxiety, insecurity, low self-esteem, impulsiveness, and poor self-control. It is disturbing to note that in Reeve's study of personality traits of a sample of anesthesiologists, some 20% manifested psychological profiles that reflected a predisposition to behavioral disintegration and attempted suicide when placed under extremes of stress.¹⁹⁴ His study raises the discomfiting notion that "premorbid" personality characteristics that exist before entering specialty training are not being identified in the admissions process.²³⁵

One specific type of stress—that resulting from a malpractice lawsuit—may have a direct causative association with suicide among physicians in general and anesthesiologists in particular. An anecdotal report described, in tragic detail, the emotional deterioration and ultimate suicide of an experienced and previously healthy physician involved in a malpractice suit.²³⁶ One study specifically identified the anesthesiologist involved in a lawsuit as being at particularly high risk for suicide.²³⁷ In this report, 4 of 185 anesthesiologists being sued attempted or committed suicide.

Another potential etiologic basis for the observed high suicide rate is the high incidence of drug abuse found among anesthesia personnel. Physicians who are impaired and whose privileges to practice medicine are removed by the licensing authority are at heightened risk for attempting suicide. Crawshaw *et al* reported 8 successful and 2 near-miss suicide attempts among 43 physicians placed on probation for drug-related disability.²³⁸ Other occupational factors that may contribute to the high incidence of suicide include isolation and lack of colleagues' support at work, and the ready access to various means of carrying out the act of suicide.

The Aging Anesthesiologist

Little research has been directed toward the challenges faced by older anesthesiologists. This is in contrast to the situation in most other industries where strict attention is paid to the competence and well-being of older workers. For example, commercial pilots are required to take regular medical examinations and conform to policies regarding hours of work. Frequently, they are subject to contractual age limitations.

There are no age-specific conditions placed on state medical licensure or on the practice of anesthesiology. The American Board of Anesthesiologists has only recently established a recertification examination for those out of residency more than 10 years. In most cases, the decision to limit practice or retire remains at the discretion of

the individual anesthesiologist based upon his or her self-evaluation.

As a result of the smaller residency class sizes observed in recent years, the mean age of the anesthesiology workforce is increasing. Approximately one-half of U.S. anesthesiologists were trained before 1980,²³⁹ and 49% of anesthesiologists are aged 45 and older.²⁴⁰ Several physiologic changes frequently associated with aging have the potential of affecting an individual's ability to practice anesthesiology, including decrements in hearing, vision, short-term memory, strength, and endurance. These potential sources of impairment are often compensated by other advantages conferred by advancing age, including the experience acquired by a lifelong practice of the specialty.

One area of particular difficulty for anesthesiologists is maintaining the stamina required for long work shifts and night call. Older workers have been shown to have a reduced amplitude and a tendency toward morningness in their circadian cycles.¹⁰⁴ Superimposed upon this propensity to sleep disturbance, the demands of night call and associated sleep deprivation are particularly difficult for older anesthesiologists. Night call is considered one of the most stressful aspects of practice and the most frequently cited reason for retirement among older anesthesiologists.²⁴¹

Aging among anesthesiologists raises interesting legal issues. A number of federal laws potentially impact the decision of the aging anesthesiologist and his or her colleagues to continue to work and at what pace. These include the Age Discrimination Act, Title VII of the Civil Rights Act ("Equal Pay Act"), the Medical and Family Leave Act, the Fair Labor Standards Act, and the Employee Retirement Income Security Act (ERISA). An anesthesiologist's decision to retire must fit within the complex framework of federal and state laws and regulations. Anesthesiologists tend to retire at a younger age than do many other specialists.^{106,242} Future research should address issues regarding older anesthesiologists.

* Parts per million is a volume-per-volume unit of measurement; 10,000 ppm equals 1%.

* The ability to conceive, which is measured by the time to pregnancy during periods of unprotected sexual intercourse.

* The prevalence is the proportion of people who have or have had the condition at the time of the survey.

* An impaired physician is defined as one "whose performance as a professional person and as a practitioner of the healing arts is impaired because of alcoholism, drug abuse, mental illness, senility, or disabling disease."

In anesthesia, as in other areas of life, everything does not always go as planned. Undesirable outcomes occur regardless of the quality of care provided. The legal aspects of medical practice have become increasingly important as the American public has turned to the courts for economic redress when their expectations of medical treatment are not met. Payers such as Medicare are increasingly depending on accreditation through bodies such as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to ensure that mechanisms are in place to deliver quality care to all patients. An anesthesia risk management program can work in conjunction with a program for quality improvement to minimize the liability risk of practice while assuring the highest quality of care for patients.

This chapter provides background for the practitioner about how the legal system handles malpractice claims and the role of risk management activity in minimizing and managing liability exposure. An introduction to the concepts of quality improvement (formerly called quality assurance) extends the discussion to the broader arena of quality of care in anesthesia practice.

PROFESSIONAL LIABILITY

This section addresses the basic concepts of medical liability. A more detailed discussion of the steps of the lawsuit process and appropriate actions for physicians to take when sued is available from the American Society of Anesthesiologists (ASA).¹

Tort System

Although physicians may become involved in the criminal law system in a professional capacity, they more commonly become involved in the legal system of civil laws. Civil law is broadly divided into *contract law* and *tort law*. A tort may be loosely defined as a civil wrongdoing, and negligence is one type of tort. The majority of medical malpractice lawsuits are pursued on the basis of negligence theories, but there are occasional cases in which contract law theories are used. *Malpractice* actually refers to any professional misconduct, but its use in legal terms typically refers to professional negligence.

To be successful in a malpractice suit, the patient-plaintiff must prove four things:

1. Duty: that the anesthesiologist owed the patient a duty;
2. Breach of duty: that the anesthesiologist failed to fulfill his or her duty;
3. Causation: that a reasonably close causal relation exists between the anesthesiologist's acts and the resultant injury; and
4. Damages: that actual damage resulted because of a breach of the standard of care.

Failure to prove any one of these four elements will result in a decision for the defendant-anesthesiologist.

Duty

As a physician, the anesthesiologist establishes a duty to the patient when a doctor-patient relationship exists. When the patient is seen preoperatively, and the anesthesiologist agrees to provide anesthesia care for the patient, a duty to the patient has been established. In the most general terms, the duty the anesthesiologist owes to the patient is to adhere to the *standard of care* for the treatment of the patient. Because it is virtually impossible to delineate specific standards for all aspects of medical practice and all eventualities, the courts have created the concept of the *reasonable and prudent* physician. For all specialties, there is a national standard, which has displaced the local standard.

There are certain general duties that all physicians have to their patients, and breaching these duties may also serve as the basis for a lawsuit. One of these general duties is that of obtaining informed consent for a procedure. Consent may be written, verbal, or implied. Oral consent is just as valid, albeit harder to prove years after the fact, as written consent. Implied consent for anesthesia care may be present in circumstances in which the patient is unconscious or unable, for any reason, to give his or her consent, but where it is presumed that any reasonable and prudent patient would give consent if able.

Although there are exceptions to the requirement that consent be obtained, as a general rule, anesthesiologists should be sure to obtain consent whenever possible. Failure to do so could, in theory, expose the anesthesiologist to possible prosecution for battery.

The requirement that the consent be *informed* is somewhat more opaque. The guideline is determining whether the patient received a fair and reasonable account of the proposed procedures and the risks inherent in these procedures. The duty to disclose risks is not limitless, but it does extend to those risks that are reasonably likely in any patient under the circumstances and to those that are reasonably likely in particular patients because of their condition. For example, it would be prudent to inform the patient of possible sore throat or dental damage associated with tracheal intubation, but not about an unlikely complication such as vocal cord paralysis.

Breach of Duty

In a malpractice action, expert witnesses will review the medical records of the case and determine whether the anesthesiologist acted in a reasonable and prudent manner in the specific situation and fulfilled his or her duty to the patient. If they find that the anesthesiologist either did something that should not have been done or failed to do something that should have been done, then the duty to adhere to the standard of care has been breached. Therefore, the second requirement for a successful suit will have been met.

Causation

Judges and juries are interested in determining whether the breach of duty was the *proximate cause* of the injury. If the odds are better than even that the breach of

duty led, however circuitously, to the injury, then this requirement is met.

There are two common tests employed to establish causation. The first is the “*but for*” test, and the second is the *substantial factor* test. If the injury would not have occurred “but for” the action of the defendant-anesthesiologist, or if the act of the anesthesiologist was a substantial factor in the injury despite other causes, then proximate cause is established.

Although the burden of proof of causation ordinarily falls on the patient-plaintiff, it may, under special circumstances, be shifted to the physician-defendant under the doctrine of *res ipsa loquitur* (literally, “the thing speaks for itself”). Applying this doctrine requires proving that:

1. The injury is of a kind that typically would not occur in the absence of negligence.
2. The injury must be caused by something under the exclusive control of the anesthesiologist.
3. The injury must not be attributable to any contribution on the part of the patient.
4. The evidence for the explanation of events must be more accessible to the anesthesiologist than to the patient.

Because anesthesiologists render patients insensible to their surroundings and unable to protect themselves from injury, this doctrine may be invoked in anesthesia malpractice cases. All that needs to be proved is that the injury typically would not occur in the absence of negligence; the anesthesiologist is then put in the position of having to prove that he or she was not negligent.

Damages

The law allows for three different types of damages. *General damages* are those such as pain and suffering that directly result from the injury. *Special damages* are those actual damages that are a consequence of the injury, such as medical expenses, lost income, and funeral expenses. *Punitive damages* are intended to punish the physician for negligence that was reckless, wanton, fraudulent, or willful. Punitive damages are exceedingly rare in medical malpractice cases. More likely in the case of gross negligence is a loss of the license to practice, or in extreme cases, criminal charges may be brought against the physician. Determining the dollar amount of damages is the job of the jury, and the determination is usually based on some assessment of the plaintiff's condition versus the condition he or she would have been in had there been no negligence. Plaintiffs' attorneys generally charge a percentage of the damages, and will, therefore, seek to maximize the award given.

Standard of Care

Because medical malpractice usually involves issues beyond the comprehension of lay jurors and judges, the court establishes the standard of care in a particular case by the testimony of *expert witnesses*. These witnesses differ from factual witnesses mainly in that they may give opinions. The trial court judge has sole discretion in determining whether a witness may be qualified as an expert. Although any licensed physician may be an expert, information will be sought regarding the witness's education and training, the nature and scope of the person's practice, memberships and affiliations, and publications. The purpose in gathering this information is not only to establish the qualifications of the witness to provide expert testimony, but also to determine the weight to be given to that testimony by the jury. In many cases the success of a suit depends primarily on the stature and believability of the expert witnesses.

In certain circumstances, the standard of care may also be determined from published societal guidelines, written policies of a hospital or department, or textbooks and monographs. Some medical specialty societies have carefully avoided applying the term “standards” to their guidelines, in the hope that no binding behavior or mandatory practices have been created. In 1986 the ASA, for the first time, published “Standards for Basic Intra-operative Monitoring” (now entitled “Standards for Basic Anesthetic Monitoring”). These standards have been updated several times since their initial adoption and are more binding than guidelines. The essential difference between standards and guidelines is that guidelines *should* be adhered to and standards *must* be adhered to. Currently, the ASA also publishes standards on preanesthesia care and postanesthesia care, as well as guidelines for a variety of anesthesia-related activities.²

Causes of Suits

The principal cause of suits against anesthesiologists is patient injury. In a nationwide analysis of 1002 lawsuits against anesthesiologists conducted by the ASA Committee on Professional Liability, the leading injuries for which suits were filed were death (37%), nerve damage (15%), and brain damage (12%).³ The causes of death and brain damage were predominantly problems in airway management, such as inadequate ventilation, difficult intubation, and esophageal intubation. Nerve damage, especially to the ulnar nerve, often occurs despite apparently adequate positioning.^{4,5} Spinal cord injury was the most common cause of nerve damage claims against anesthesiologists in the 1990s.⁴

Because death and brain damage are high-cost injuries, anesthesia practice is clearly a high-risk endeavor. Anesthesiologists use complex equipment, which can fail or be used incorrectly,⁶ and potent drugs, with which mistakes in dose or labeling can have disastrous consequences. Vigilance, which is the highest priority in anesthesia practice, is often difficult to maintain at all times of the day and night through long, tedious surgical procedures. The anesthesiologist is more likely to be the target of a suit if an untoward outcome occurs because the physician-patient relationship is usually tenuous at best. The patient rarely chooses the anesthesiologist, the preoperative visit is brief, and the anesthesiologist who sees the patient preoperatively may not actually anesthetize the patient. Communication between anesthesiologists and surgeons about complications is often lacking and the tendency is for the surgeon to “blame anesthesia.”

Supervision of nurse anesthetists is another endeavor that puts the anesthesiologist in a high-risk category. The more nurse anesthetists supervised by any one anesthesiologist, the greater the exposure to the possibility of patient injury. Some professional liability insurance companies specify a staffing ratio of 1:2 or 1:3 and charge higher rates for supervision of more than this number. Anesthesiologists are liable not only for the nurse anesthetists they employ but also for those they supervise who are employed by the hospital.

Because anesthesiologists are involved in the care of patients undergoing high-risk surgical procedures, they are often sued along with the surgeon in the case of an adverse outcome. This may occur even if the outcome was in no way related to the anesthetic care.

What to Do When Sued

A lawsuit begins when the patient-plaintiff's attorney files a complaint and demand for jury trial with the court. The anesthesiologist is then served with the complaint and a summons requiring an answer to the complaint. Until this happens, no lawsuit has been filed. Insurance carriers must be notified immediately after the receipt of the complaint. The anesthesiologist will need assistance in answering the complaint, and there is a time limit placed on the response.

Specific actions at this point include the following:

1. Do not discuss the case with anyone, including colleagues who may have been involved, operating room personnel, or friends.
2. Never alter any records.
3. Gather together all pertinent records, including a copy of the anesthetic record, billing statements, and correspondence concerning the case.
4. Make notes recording all events recalled about the case.
5. Cooperate fully with the attorney provided by the insurer.

The first task the anesthesiologist must perform with an attorney is to prepare an answer to the complaint. The complaint contains certain facts and allegations with which the defense may either agree or disagree. Defense attorneys rely on the frank and totally candid observations of the physician in preparing an answer to the complaint. Physicians should be willing to educate their attorneys about the medical facts of the case, although most medical malpractice attorneys will be knowledgeable and medically sophisticated.

The next phase of the malpractice suit is called *discovery*. The purpose of discovery is the gathering of facts and clarification of issues in advance of the trial. Another purpose of discovery is to assess or harass the defendant to determine how good a witness he or she will make. This occurs at several points in the discovery process, and by several mechanisms.

The anesthesiologist will, in all likelihood, receive a written interrogatory, which will request factual information. The interrogatory should be answered in writing, in consultation with the defense attorney, because carelessly or inadvertently misstated facts can become troublesome later.

Depositions are a second mechanism of discovery. The defendant-anesthesiologist will be deposed as a fact witness, and depositions will be obtained from other anesthesiologists who will act as expert witnesses. The defendant-anesthesiologist may be asked to suggest other anesthesiologists who will review the medical

records. A nationally recognized expert in the area in question who is not a personal friend but agrees with the defense position may be very valuable.

The plaintiff's attorney, not the defense attorney, will depose the anesthesiologist. Most often, the arrangements for the deposition will be made amicably by both sides, and the deposition will occur at a place and time convenient for the anesthesiologist, typically in the defense attorney's office. As a general rule, it is best that physicians avoid having the deposition taken in their own offices, because the plaintiff's attorney will carefully note such things as the medical books on the shelves, the diplomas on the walls, and the general state of disarray of the office. Information may thus be provided that the plaintiff's attorney may use against the anesthesiologist. A second reason to avoid pleasant and familiar surroundings is that the physician will tend to lower his or her guard if comfortable and fall prey to certain common traps in deposition. *Despite the apparent informality of the deposition, the anesthesiologist must be constantly aware that what is said during the deposition carries as much weight as what would be said in court.*

It is important to be factually prepared for the deposition. A review of notes, the anesthetic record, and the medical record is necessary. The physician should dress conservatively and professionally because appearance and image are very important. The opposition is assessing the physician to see how he or she will appear to a jury. Answers to questions should be brief and concise. Being evasive or hostile is not helpful. Answer only the question asked, and do not volunteer information. Occasionally, physicians will be asked leading questions that are impossible to answer without qualifications. In this case, the physician may qualify his or her answer but should avoid giving lengthy opinion answers. The defendant-anesthesiologist is being deposed as a witness of facts, not opinions. Experts may give opinions, but the defendant should try to avoid doing so. Physicians should not admit that there are any "definitive" or "authoritative" textbooks on which they rely in their practice, as doing so may make them responsible for everything that is said in the book, whether they agree with it or not. Do not try to be humorous or make a joke, as these efforts do not translate well on paper. Court reporters will record exactly what is said, so it is important to speak clearly.

There will be depositions from expert witnesses, both for the plaintiff and for the defense. The anesthesiologist should work with his or her attorney to suggest questions and rebuttals. The better educated the attorney is about the medical facts, the reasons the anesthesiologist did what was done, and the alternative approaches, the better able he or she will be to conduct these expert depositions.

If there is some merit in the case but the damages are minimal, or if proof will be difficult, there will probably be a settlement offer. There is a high cost incurred by both plaintiffs and defendants in pursuing a malpractice claim up through a jury trial. Unless there is a strong probability of a large dollar award, reputable plaintiffs' attorneys are not likely to pursue the claim. Thus, even if physicians believe that they are totally innocent of any wrongdoing, they should not be offended or angered about settling of the case: this is solely a matter of money, not medicine.

If a settlement is not reached during the discovery phase, a trial will occur. Only about 1 in 20 malpractice cases ever reaches the point of a jury trial, because both plaintiffs' and defendants' attorneys are aware of the strengths of the case, and it usually becomes clear during discovery whether the suit will be successful. Only those cases in which both sides feel they can win, and which are likely to have significant financial impact, will proceed to trial.

The discussion of deposition testimony also applies to testimony in court, but there are a few additional points to consider during the trial. The members of the jury will not be as sophisticated medically as the attorneys who deposed the anesthesiologist during discovery. A tendency to overuse specific medical terms should be corrected by learning to explain answers in lay terms for the benefit of the jury. Do not underestimate the intelligence of the jury, however, because talking down to them will create an unfavorable impression. If the answer to a question is not known, avoid guessing. If specific facts cannot be remembered, say so. Nobody expects total recall of events that may have occurred years before.

The defendant-physician should be present during the trial, even when not testifying, and should dress conservatively, neatly, and professionally. Displays of anger, remorse, relief, or hostility will hurt the physician in court. When giving testimony, the anesthesiologist must give clear answers to all questions asked. The physician should be able to give his or her testimony without using notes or documents. When it is necessary to refer to the medical record, it will be admitted into evidence. The anesthesiologist's goal is to convince the jury that he or she behaved in this case as any other competent and prudent anesthesiologist would have behaved.

It is important to keep in mind that *proof* in a malpractice case means only "more likely than not." The patient-plaintiff must "prove" the four elements of negligence, not to absolute certainty, but only to a probability greater than 50%. On the positive side, this means that the defendant-anesthesiologist must only show that his or her actions were, more likely than not, within an acceptable standard of care.

RISK MANAGEMENT AND QUALITY IMPROVEMENT

Risk management and quality improvement programs work hand-in-hand in minimizing liability exposure while maximizing quality of patient care. Although the functions of these programs vary from one institution to another, they overlap in their focus on patient safety. They can generally be distinguished by their basic difference in orientation. A hospital risk management program is broadly oriented toward reducing the liability exposure of the organization. This includes not only professional liability (and therefore patient safety) but also contracts, employee safety, public safety, and any other liability exposure of the institution. Quality improvement programs have as their main goal the continuous maintenance and improvement of the quality of patient care and may be broader in their patient safety focus than strictly risk management.

Risk Management

Those aspects of risk management that are most directly relevant to the liability exposure of the anesthesiologist include prevention of patient injury, adherence to standards of care, documentation, and patient relations.

The key factors in the prevention of patient injury are vigilance, up-to-date knowledge, and adequate monitoring.⁷ Physiologic monitoring of cardiopulmonary function, combined with monitoring of equipment function, might be expected to reduce anesthetic injury to a minimum. This was the rationale for the adoption of the ASA Standards for Basic Anesthetic Monitoring (see [Table 2-1](#) on page 30).²

These standards call for measurement of arterial blood pressure, pulse, electrocardiogram, and pulse oximeter for all anesthetics. For all general anesthetics an oxygen analyzer with a low-limit alarm system is mandated. When a tracheal tube or laryngeal mask airway is placed, correct positioning in the trachea must be verified by detection of expired carbon dioxide. Continual monitoring for the presence of expired CO₂ is required unless invalidated by the nature of the patient, procedure, or equipment. When a mechanical ventilator is in use during general anesthesia, a disconnect alarm must be utilized.

The ASA Directory of Members should be reviewed yearly for any changes in ASA Standards of Practice. It would also be reasonable to review the ASA Guidelines and Statements published in the same directory. It should be noted that, although membership in the ASA is not required for the practice of anesthesiology, expert witnesses will, with virtual certainty, hold any practitioner to the ASA standards. It is also possible that, as a risk management strategy, a professional liability insurer or hospital may hold an individual anesthesiologist to standards higher than those promulgated by the ASA.

Another risk management tool is the use of checklists prior to each case, or at least daily, in an attempt to reduce equipment-related mishaps.^{6,8,9} and ¹⁰ A 1994 Food and Drug Administration (FDA) checklist,¹⁰ while overly complex, contains the basic elements of what needs to be checked.

A regular schedule of equipment maintenance and procedures to follow whenever equipment malfunction is suspected of contributing to patient injury should be established. If equipment malfunction is suspected to have contributed to a complication, the device should be impounded and examined concurrently by the representatives of the hospital, the anesthesiologist, and the manufacturer.

Although it may seem obvious, qualified anesthesia personnel should be in continuous attendance during the conduct of all anesthetics. The only exceptions should be those that lay people (*i.e.*, judge and jury) can understand, such as radiation hazards or an unexpected life-threatening emergency elsewhere. Even then, provisions should be made for monitoring the patient adequately. Adequate supervision of nurse anesthetists and residents is also important, as is good communication with surgeons when adverse anesthetic outcomes occur.

Informed consent should be documented with a general consent, which should include a statement to the effect that, "I understand that all anesthetics involve risks of complications, serious injury, or, rarely, death from both known and unknown causes." In addition, there should be a note in the patient's record that the risks of anesthesia and alternatives were discussed, and that the patient accepted the proposed anesthetic plan. A brief documentation in the record that the common complications of the proposed technique were discussed is helpful. If it is necessary to change the agreed-on anesthesia plan significantly after the patient is premedicated or anesthetized, the reasons for the change should be documented in the record.

Good records can form a strong defense if they are adequate and can be disastrous if inadequate. The anesthesia record itself should be as accurate, complete, and neat as possible. The use of automated anesthesia records may be helpful in the defense of malpractice cases.¹¹ In addition to vital signs every 5 minutes, special

attention should be paid to ensure that the patient's ASA classification, the monitors utilized, fluids administered, and doses and times of all administered drugs are accurately charted. Because the principal causes of hypoxic brain damage and death during anesthesia are related to ventilation and/or oxygenation, all respiratory variables that are monitored should be documented accurately. It is important to note when there is a change of anesthesia personnel during the conduct of a case. Sloppy, inaccurate anesthesia records, enlarged and placed before a jury, can be damaging to the defense.

If a critical incident occurs during the conduct of an anesthetic, the anesthesiologist should document, in narrative form, in the patient's progress notes, what happened, which drugs were used, the time sequence, and who was present. A catastrophic intra-anesthetic event cannot be summarized adequately in a small amount of space on the usual anesthesia record. The critical incident note should be written as soon as possible. The report should be as consistent as possible with concurrent records, such as the anesthesia, operating room, recovery room, and cardiac arrest records. If significant inconsistencies exist, they should be explained. Records should never be altered after the fact. If an error is made in recordkeeping, a line should be drawn through the error, leaving it legible, and the correction should be initialed and timed. Litigation is a lengthy process, and a court appearance to explain the incident to a jury may be years away, when memories have faded.

In the event of a sudden, unexpected intra-anesthetic cardiac arrest for which there is no readily apparent explanation, blood and urine should be obtained and screened for drugs that may interact adversely with drugs used for anesthesia.

If anesthetic complications occur, the anesthesiologist should be honest with both the patient and family about the cause. Whenever an anesthetic complication becomes apparent postoperatively, appropriate consultation should be obtained quickly, and the departmental or institutional risk management group should be notified. If the complication is apt to lead to prolonged hospitalization or permanent injury, the liability insurance carrier should be notified. The patient should be followed closely while in the hospital, with telephone follow-up, if indicated, after discharge. Also, the anesthesiologist and surgeon should be consistent in their explanations to the patient or the patient's family as to the cause of any complication.

Jehovah's Witnesses and Other Treatment Obligations

It is important to recognize that patients have well-established rights, and that among these is the right to refuse specific treatments because of religious beliefs. In the case of Jehovah's Witnesses, the treatment refused is the administration of blood or blood products. This is a central part of their religious beliefs, which hold that the faithful will be forbidden the pleasures of the afterlife if they receive blood or blood products. Thus, for them to receive a transfusion is a mortal sin, and many Jehovah's Witnesses would actually rather die in grace, as they see it, than live with no possibility of salvation. Anesthesiologists recognize and respect these beliefs but are also cognizant that these convictions may conflict with the physicians' personal, religious, or ethical codes.

Minor children of Jehovah's Witness parents represent a special group for consideration. Although the U.S. Supreme Court has upheld the right of an adult to become a martyr by refusing treatments based on religious convictions, no court has extended to parents the right to martyr their children.¹² Obtaining a proper court order is of critical importance in the care of a minor child of Jehovah's Witness parents when the parents refuse to authorize a blood transfusion.

As a general rule, physicians are not obligated to treat all patients who apply for treatment in elective situations. It is well within the rights of a physician to decline to care for any patient who wishes to place burdensome constraints on the physician or unacceptably to limit the physician's ability to provide optimal care. When presented with the opportunity to provide elective care for a Jehovah's Witness, the physician may decline to provide any care or may limit, by mutual consent with the patient, his or her obligation to adhere to the patient's religious beliefs. If such an agreement is reached, it must be documented clearly in the medical record, and it is desirable to have the patient co-sign the note. Not all Jehovah's Witnesses have identical beliefs regarding blood transfusions or which methods of blood preservation or sequestration will be allowed. Some patients will not allow any blood that has left the body to be reinfused. Yet others will accept autotransfusion if their blood remains in constant contact with the body (*via* tubing). Therefore, it is important to reach a clear understanding of which techniques for blood preservation are to be used and to document this plan in the record.

Emergency medical care imposes greater constraints on the treating physician, as there is no opportunity to decline the care of a patient with an immediately life-threatening condition. If the patient is an adult and is conscious and mentally competent, then he or she has the right to refuse blood transfusion. The exceptions to patients' rights in this regard include pregnant women and adults who are the sole support of minor children. In these circumstances, the interests of the fetus in surviving may supersede the rights of the mother, as may the interests of the state in not being obligated to provide for the welfare of dependent children.¹² In either case, obtaining a court order is the best plan if time permits. If the problem concerns blood products and there is insufficient time to obtain a court order, pregnant women should be given a transfusion to save the life of the fetus, but parents of minor children should not receive transfusions against their wishes unless the dependency of the children is obvious.

When the patient is a minor, it is important to ascertain the true wishes of the parents. Some parents know that a court order can be obtained and view this as a relief from the onerous burden of having to decide whether they are willing to let their child die. However, some parents are adamant that blood not be given, and there have been cases in which children have been ostracized by their parents and religious community for having received a court-ordered transfusion. Reaching an understanding about the consequences for the child who receives a court-ordered transfusion is therefore vital for the determination of what risks will be taken before ordering a transfusion.

The procedure for obtaining a court order may vary, depending on the specific state laws. Typically, an order may be obtained over the telephone. This call initiates the issue of a written order, which will arrive several days later. Although not a totally automatic procedure, it would be very rare for a judge to deny this order for a minor.

National Practitioner Data Bank

It is usually the obligation of the hospital risk management department to make reports to the National Practitioner Data Bank (NPDB), a nationwide information system that theoretically would allow licensing boards and hospitals a means of detecting adverse information about physicians.¹³ Simply moving into another state would no longer provide safe haven for incompetent physicians.

The NPDB requires input from four sources: medical malpractice payments, license actions by medical boards, clinical privilege actions taken by hospitals, and membership actions taken by societies if the society has formal peer review mechanisms. There has been a great deal of effort to establish a minimum reporting dollar value below which no report is necessary, but to date, any payment made on behalf of a physician in response to a written complaint or claim must be reported. Settlements made by cancellation of bills or settlements made on verbal complaints are not considered a reportable payment.

Once a report has been submitted, the physician is notified and has 60 days from the date the data bank processed the report to dispute the input. At this time, the reporting entity may correct the form or void it. Failing that, the physician has the option of putting a brief statement in the file or appealing to the U.S. Secretary of Health and Human Services, who may also either correct or void the form. Once it is entered, there is no means of purging the form.

Requiring legitimate inquirers to have an identification number protects the security of the data bank. Hospitals are required to query the data bank at the time a physician initially requests staff privileges and at 2-year intervals, but they may query at any time. State licensing boards also may make a query, and any health care entity that provides patient care may query as long as the entity has a formal peer review process. A plaintiff's attorney may query the data bank only when there is evidence that a hospital failed to make a mandatory query and the claim is made against the hospital. A practitioner may make a query about his or her file at any time. The existence of the NPDB reporting requirements has made physicians reluctant to allow settlement of nuisance suits because it will cause their names to be added to the data bank.

QUALITY IMPROVEMENT IN ANESTHESIA PRACTICE

Quality is a concept that has continued to elude precise definition in medical practice. However, it is generally accepted that attention to quality will improve patient safety and satisfaction with anesthesia care. The field of quality assurance or quality improvement is continually evolving, as is the terminology used to describe such efforts. The term "quality assurance" is rapidly going out of fashion, being replaced by "quality improvement" in an effort to emphasize a change in underlying philosophy. Although quality improvement programs in anesthesia are generally guided by requirements of the JCAHO, they are basically oriented toward improvement of the structure, process, and outcome of health care delivery programs.

The JCAHO annually updates its quality improvement requirements. Recent years have seen major changes in the type of quality improvement activities required by the JCAHO, with a shift in orientation (and underlying philosophy) from quality assurance to quality improvement.¹⁴ As this focus undergoes transition, further changes in JCAHO requirements may be expected. This can prove to be frustrating to the practitioner and hospital. It may seem that as soon as a quality improvement program meets JCAHO requirements, these requirements change.

An understanding of the fundamental principles of quality improvement may clarify the relationship between the continually evolving JCAHO requirements and mandated quality improvement activities. This section provides an introduction to the basic concepts of quality improvement in anesthesia and some issues to be

considered in the implementation of quality improvement programs.

Structure, Process, and Outcome: The Building Blocks of Quality

Although quality of care is difficult to define, it is generally accepted that it is composed of three components: structure, process, and outcome.¹⁵ *Structure* refers to the setting in which care was provided, e.g., personnel and facilities used to provide health care services and the manner in which they are organized. This includes the qualifications and licensing of personnel, ratio of practitioners to patients, standards for the facilities and equipment used to provide care, and the organizational structure within which care is delivered. The *process* of care includes the sequence and coordination of patient care activities, i.e., what was actually done. Was a preanesthetic evaluation performed and documented? Was the patient continuously attended and monitored throughout the anesthetic? *Outcome* of care refers to changes in health status of the patient following the delivery of medical care. A quality improvement program focuses on measuring and improving these basic components of care.

From Quality Assurance to Quality Improvement

Continuous quality improvement (CQI) differs from traditional quality assurance (QA) programs in its basic orientation.^{16,17} QA programs typically set as their goal the identification of outliers, known euphemistically as “bad apples.” Problems, often assumed to stem from operator error, were addressed at the operator level. However, QA programs lacked a method to resolve problems beyond documentation and assignment of blame and an insistence on eliminating errors. CQI, however, takes a systems approach. The operator is just one part of a complex system. An important underlying premise is that poor results may be due to either random or systematic error. Random errors are inherently difficult to prevent and programs focused in this direction are misguided. System errors, however, should be controllable and strategies to minimize them should be within reach. CQI is basically the process of continually evaluating anesthesia practice to identify systematic problems (opportunities for improvement) and implementing strategies to prevent their occurrence.

A CQI program may focus on undesirable outcomes as a way to identify opportunities for improvement in the structure and process of care. The focus is not on blame but rather on identification of the causes of undesirable outcomes. Instead of asking which practitioners have the highest patient mortality rates, a CQI program may focus on the relationship between the process of care and patient mortality. What proportion of deaths was related to the patient's disease process or debilitated condition? Are these patients being appropriately evaluated for anesthesia and surgery? Were there any controllable causes, such as a lack of hands during resuscitation? The latter may lead to a modification of personnel resources (structure) or assignments (process) to be sure that adequate personnel are available at all times.

Formally, the process of CQI involves the identification of opportunities for improvement through the continual assessment of important aspects of care. Peer review and input are critical to this process. It is a process that is instituted from the bottom up, by those who are actually involved in the process to be improved, rather from the top down by administrators. Identification of opportunities for improvement may be carried out by various means, from brainstorming sessions focusing on a systematic evaluation of care activities to the careful measurement of indicators of quality (such as morbidity and mortality). In any event, once areas are identified for improvement, their current status is measured and documented. This may involve measurement of outcomes, such as delayed recovery from anesthesia or peripheral nerve injury. Then the process of care leading to these problems is analyzed. If a change is identified that should lead to improvement, it is implemented. After an appropriate time period, the status is then measured again to determine whether improvement actually resulted. Attention may then be directed to continuing to improve this process or turning to a different process to target for improvement.

An extension of the CQI method is total quality management (TQM). A TQM program would extend beyond patient care to apply CQI methods to all aspects of the patient care delivery system. This would include such things as billing and housekeeping, for example. With expectation of continuing changes in the structure and financing of health care in the United States, CQI programs in anesthesia can be incorporated into TQM of the entire hospital system to maintain the quality of patient care as practice changes are implemented in response to a changing environment.

Difficulty of Outcome Measurement in Anesthesia

Improvement in quality of care is often measured by a reduction in the rate of adverse outcomes. However, adverse outcomes are relatively rare in anesthesia, making measurement of improvement difficult. For example, if an institution lowers its mortality rate of surgery patients from 1 in 1000 to 0.5 in 1000, this difference may not be statistically significant. Many adverse outcomes in anesthesia are even more rare.

To complement outcome measurement, anesthesia CQI programs can focus on critical incidents and sentinel events. *Critical incidents* are events that cause, or had the potential to cause, patient injury if not noticed and corrected in a timely manner. For example, a partial disconnect of the breathing circuit may be corrected before patient injury occurs, but yet has the potential for causing hypoxic brain injury or death. Critical incidents are more common than adverse outcomes. Measurement of the occurrence rate of important critical incidents may serve as a proxy measure for rare outcomes in anesthesia in a CQI program designed to improve patient safety and prevent injury.

Sentinel events are single, isolated events that may indicate a systemic problem. A sentinel event may be a significant or alarming critical incident that did not result in patient injury, such as a syringe swap and administration of a potentially lethal dose of medication that was noted and treated promptly, avoiding catastrophe. Or a sentinel event may be an unexpected significant patient injury such as intraoperative death. In either case, a CQI program may investigate sentinel events in an attempt to uncover systemic problems in the delivery of care that can be corrected. For example, a syringe swap may be analyzed for confusing or unclear labeling of medications or unnecessary medications routinely stocked on the anesthesia cart, setting the scene for unintended mix-up. In the case of death, all aspects of the patient's hospital course from selection for surgery to anesthetic management may be analyzed to determine if similar deaths can be prevented by a change in the care delivery system.

JCAHO Requirements for Quality Improvement

JCAHO requirements for quality improvement activities are updated on an annual basis. These requirements are described in detail in the JCAHO Comprehensive Accreditation Manual for Hospitals.¹⁴ A current copy of this manual should be available in every hospital.

In general, a hospital must adopt a method for systematically assessing and improving important functions and processes of care and their outcomes in a cyclical fashion. The general outline for this CQI cycle is the design of a process or function, measurement of performance, assessment of performance measures through statistical analysis or comparison with other data sources, and improvement of the process or function. Then the cycle repeats. The JCAHO accreditation manual provides specific standards that must be met, with examples of appropriate measures of performance. The goal of this cycle of design, measurement, assessment, and improvement of performance of important functions and processes is to improve patient outcomes.

Anesthesia care is one important function of the care of patients and is defined as follows: “The administration to an individual in any setting, for any purpose, by any route (general, spinal, or other) of major regional anesthesia or sedation (with or without analgesia) for which there is a reasonable expectation that, in the manner used, the analgesia or sedation will result in the loss of protective reflexes.”¹⁴ It is important that policies and procedures for administration of anesthesia be consistent in all locations within the organization. Specific JCAHO standards address preanesthetic assessment and planning, informed consent, intraoperative monitoring, and postanesthesia recovery.

The current JCAHO performance measurement requirement calls for hospitals to choose specific indicators from approved measurement systems. An indicator is “a tool used to measure, over time, the performance of functions, processes, and outcomes of an organization.”¹⁴ An example of an anesthesia indicator is in-hospital mortality of patients within two days following a procedure involving anesthesia administration, measured as a proportion of all patients receiving surgical anesthesia. Hospitals must collect data on the selected indicators for comparison with other similar hospitals. It is anticipated that by the year 2001, JCAHO will require hospitals to select measures that monitor 35% of patients (or 12 indicators, whichever is less). Exceptions will be made for small hospitals.

Measuring Quality: Approaches to Data Collection

There are various methods in use for collection of CQI data in anesthesia. These include retrospective records review as well as self-reporting by providers of care. Checklists are sometimes used. Important considerations include compliance with reporting requirements, standardization of definitions, and appropriate sampling.

Retrospective records review usually involves a random sample of anesthesia records. The actual review may be done by an anesthesia provider or by a trained medical records specialist. Explicit definitions of quality indicators would be provided, such as “hypotension = blood pressure <80% of baseline for 5 minutes or more.” Such “indicators” of possible quality problems and opportunities for improvement are restricted to data that are normally included in the anesthesia record for every

patient. Records review is an especially appropriate technique for gathering data on adequacy of documentation.

For collection of data on events or outcomes that may not normally be charted, a self-reporting system may be used. This is an especially good mechanism for tracking critical incidents and sentinel events. For example, a syringe swap that was noted and corrected before drug administration is a critical incident that would not normally be included in an anesthetic record but could be reported by an anesthesia provider in a self-report system. Many self-report systems provide a checklist of events and outcomes that is completed by the provider for each anesthetic. Other systems provide general guidelines of critical incident reporting without specific check-off items.^{18,19} The relevant clinical information is then obtained from the practitioner by quality improvement personnel.

Whatever system is used, it is important that it be in compliance with current JCAHO standards. Standardized definitions must be provided. For example, hypotension may be defined as an absolute measurement (systolic blood pressure <70 mm Hg) or relative (<80% baseline). The latter approach may detect fewer false positives and thereby enhance the relevance of data collection to quality improvement. In general, definitions that take into account the context of care (patient status, type of anesthetic) while maintaining explicit criteria for inclusion in the CQI system will most clearly reflect quality issues (rather than, for example, complications related purely to patient physical condition). For example, blood loss and replacement of 8 units would be considered excessive and indicative of a problem during a knee arthroscopy but would be considered minimal during a liver transplant. A strict definition of "excessive blood loss = >15 units" would identify both cases as quality issues where it would only be appropriate for the arthroscopy. Contextualization of definitions will help avoid the frustration of providers when presented with data that otherwise may be irrelevant to improving the process of anesthesia care.

Peer Review

Peer review, which refers to the review of cases by members of one's specialty, is an integral part of quality improvement programs. Peer review is commonly integrated into a quality improvement program in the context of the morbidity and mortality conference. This provides a forum for review of case management by all members of the department, integrating an educational component into the quality improvement process as differing knowledge bases and clinical experiences are shared. Peer review can provide a mechanism to analyze the structure and process of care and opportunities for improvement.

Peer review can also be incorporated into the analysis of critical incidents, sentinel events, and trends in measured outcomes of care. Peer review has the distinct advantage of credibility and an aura of fairness in a democratic system. Although personal bias in clinical care may be recognized, adherence to the "reasonable man" principle provides a basis for analysis that reflects generally accepted principles of care. It provides a basis for analysis of trends and incidents, suggesting hypotheses for their causes and changes in the system that might improve the structure, process, and outcome of care.

However, peer review is subject to bias that may not be recognized by the participants. This is a tendency of anesthesiologists to judge care as less than appropriate if severe patient injury occurs.²⁰ In a study of anesthesiologists presented with identical case scenarios with differing outcomes, they were more likely to judge the care as appropriate if the injury was temporary and to judge care as less than appropriate if the injury was permanent. In conducting peer review for a CQI system, this tendency toward assessments biased by case outcome should be recognized and resisted. Careful attention to the process of care and opportunities for improvement should be made regardless of the extent of patient injury. Critical incidents resulting in no injury should be as carefully analyzed for opportunities for improvement in the structure and process of care as incidents with adverse outcomes.

Even though anesthesiologists may be biased in their assessment of case management by outcome, they exhibit only moderate levels of general agreement in their assessments.^{21,22} When reviewing identical case histories, different anesthesiologists may not always agree on whether the care was appropriate. Although this disagreement may be due to differences in individually held standards and practices, it must be recognized in any analysis of case management for a CQI program. Incorporation of multiple anesthesiologists into the process of case review will compensate for this lack of agreement. Although a consensus may not be reached, decisions will not be subject to the variability of individual judgments. Incorporation of multiple peer reviewers will compensate for differences in assessments and strengthen the process by improving reliability.²²

The Future of Quality Improvement: A Multidisciplinary Focus

JCAHO is moving toward a focus on the patient's hospital course in a multidisciplinary emphasis rather than departmental quality improvement programs. The shift in emphasis is toward an analysis of the entirety of each patient's care as the process to be improved. Each department's role is just one part of this process, and the care provided by various departments is often not the relevant unit of analysis. This shift in focus may require movement from departmental peer reliance on standing committees to increased use of *ad hoc* study groups. Comparison of outcomes of care across institutions with adjustments for case mix has long been the goal but has proven to difficult to implement.

INTRODUCTION

Value-based anesthesia management defines the relationship between the costs of anesthetic management strategies and the value of this care as reflected by perioperative outcomes. Implicit in this concept of appraising costs and outcomes is identification of those anesthetic management paradigms associated with the best achievable outcome at a reasonable cost, acknowledging that economic resources are limited.¹ Although the relationships between patient outcome and health care costs are complex, it is generally accepted that most cost–benefit relationships have a diminishing slope, with additional investment of resources generally resulting in only marginal increments of improvement and perhaps even declines in outcome when overinvestment of resources results in more harmful (iatrogenic) than beneficial effects.² The slope of this relationship depends on the efficiency with which anesthesia services are provided (Fig. 6-1). Efficiency can be defined either as operational efficiency or allocative efficiency, both of which are concerned with improving the use of available resources. Operational efficiency addresses the question of how to meet some predefined objective at the least cost. Allocative efficiency considers the higher level question of maximizing the benefit to society, given that resources are finite and that not all desirable objectives can be met. The latter issue is often a central feature of the argument between providing “adequate and acceptable care” and the “best possible” care. Indeed, efficiency ultimately defines value in anesthesia management and involves assessment of the relationship between all costs (direct and indirect) and outcomes for all potential alternative utilizations of resources.¹ This chapter identifies considerations involved in the decision-making processes that define cost-effective, quality anesthetic care and efficient management of expensive resources, especially in the OR environment.

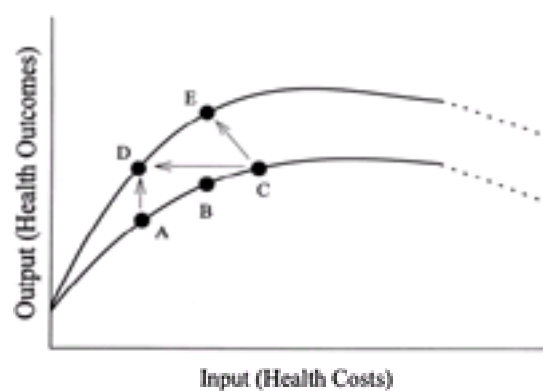

Figure 6-1. additional resources in a health system yields progressively smaller incremental gains in benefits (health outcomes), especially as the system operates along the flatter portion of the curve (A@B@C). A more efficient relationship between costs and health outcomes allows greater benefits for a given cost input (A@D) or similar (C@D) aggregate benefits as well as possibly improved outcome (C@E) at a lower overall cost. When overinvestment of resources occurs, no additional benefits may occur and complications related to additional interventions may actually reduce overall benefit (dashed portion of curve).

IMPETUS FOR ASSESSING COST-EFFECTIVENESS OF ANESTHESIA MANAGEMENT

One of the greatest dilemmas in modern medicine is how to continue to improve or maintain the quality of health care while maintaining a reasonable expenditure of resources. A generation ago, the U.S. spent less than 5% of its Gross Domestic Product (GDP) on health care. Health care costs currently account for more than 14% of the GDP³ and, as a result of five consecutive double-digit annual increases, more than \$1 trillion was spent in the U.S. on health care in 1998. Factors affecting the increase in health care expenditures include an increase in population number with a shift in population age and severity of illness, medical inflation in excess of the economy-wide inflation, and advanced (expensive) technologic innovation. In addition, the greatest contributor to the rising costs of health care may be the administration of health care delivery, estimated to account for upwards of 30–40% of recent increases in health care costs.⁴ Such staggering statistics have shifted the focus of health care delivery away from solely considering clinical risk versus clinical benefit. As a result, all physicians, including anesthesiologists, are mandated to make cost-conscious decisions that balance the needs and priorities of patients (risks and benefits) with limited available resources.⁵

Outcomes data are exceedingly important but usually limited or unavailable, and cost, patient satisfaction, and provider access are often key measures in the evaluation of health care providers. Costs, however, must be considered without losing sight of quality. It is unavoidable that physicians must include economic considerations in clinical decision-making, and when presented with more than one option for patient assessment or therapeutic intervention, they should not choose the more expensive alternative unless there is compelling evidence that it is associated with greater value. In other words, quality that increases cost should be pursued only to the extent that the benefit exceeds that obtainable from other established medical practices. This is most difficult for interventions that differ little in benefit but significantly in cost.⁶

Anesthesiologists are not immune to the overall directive to conserve health care dollars, especially since it is recognized that expenditures influenced (directly and indirectly) by anesthesia providers represent 3–5% of the total health care costs of the U.S.⁷ More and more frequently, anesthesiologists are confronted with difficult decisions about which patients are appropriate for outpatient surgical procedures, what preanesthetic evaluations are actually requisite, what anesthetic drugs or techniques are most cost-effective, what advances in (usually high-cost) monitoring technology are really necessary to equip operating rooms (ORs), and what is the most efficient method of matching personnel resources with elective surgical caseload. To deliver value-based anesthesia services, anesthesiologists must consider not only the goals of the planned intervention, but also the expectations of all customers of their services (patients, surgeons, facility administrators) as well as the costs associated with the anticipated care, because cost awareness is necessary for cost containment, especially in the low-cost provider contracted care scenario. The diversity of factors contributing to costs of anesthesia mandates the need for an organized approach to accurately assess total costs and benefits.^{7,8}

The assessment of the value basis of anesthesia management includes not only the technology and procedures utilized by anesthesiologists, but also their important role in administrative and organizational support for health care delivery. In the current market, in which insurers increasingly identify and contract for services with a provider unit that receives a single, prospectively determined, and often discounted payment covering all costs (and professional fees), anesthesiologists are compelled to define the value of their services. In this regard, the value basis of anesthesia services includes assessment of the functions of the anesthesiologist as a perioperative physician and a manager in the OR. Anesthesiologists provide value-based services by defining appropriate preoperative testing and evaluation;

optimizing intraoperative management with selection of drugs, techniques, and monitors to balance outcome, patient satisfaction, and facility efficiency with costs; and by participating in postoperative recovery processes and other services outside the OR. Value-based anesthesia management also includes facilitating the efficient use of ORs, recovery areas, and other institutionally based resources. Anesthesiologists are probably the most knowledgeable physicians for provision of administrative and organizational support of these various perioperative activities.

LINKING COST CONTAINMENT AND OUTCOMES

Modeling delivery of health care as a system is a useful approach to understanding the concepts involved in balancing cost containment and outcome preservation. The attributes of such a system include the input (*i.e.*, the patient with a surgical problem requiring perioperative anesthetic and analgesic management), resources used to manage patients, processes employed in the diagnostic and therapeutic care of patients (including hospital support systems), outcomes that allow measurement of effectiveness and costs of the resources and processes utilized, the environment (including providers and government legislation that create the operating boundaries), and a feedback/evaluation loop for analyzing, troubleshooting, and correcting the identified problems (Fig. 6-2). The amount of input to the system (patients), as well as their acuity and case mix, are important effectors because of the influence on the intensity of services provided to meet the current high expectations of health care. In such a system, the resources include physicians, nurses, laboratory and support personnel, and administrators, as well as diagnostic and therapeutic devices, including drugs, devices, equipment, maintenance procedures, and information systems. Processes include not only the process of diagnostics and therapy, but also the process of access to a health facility. All pertinent outcomes (*e.g.*, morbidity, mortality, costs, length of postoperative stay, duration of recuperative period) must be considered in concert with patient characteristics and practice setting.

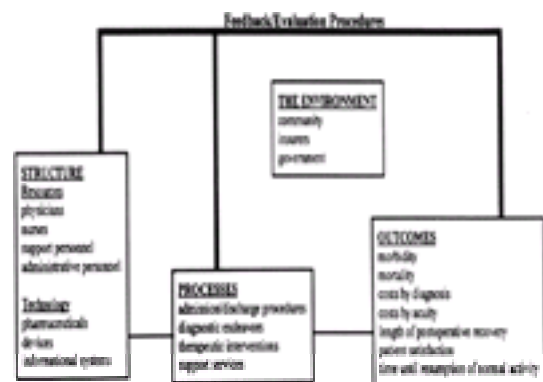

Figure 6-2. Key elements for assessing quality and value in health care.

The Science of Outcomes Assessment

The capacity to evaluate outcomes and costs, and strategically employ these measures, is integral to maintenance and improvement of cost-effectiveness and ultimately to the determination of value in health care. In the context of anesthetic care, *outcome* refers to the end result of the patient encounter and is considered an essential component of the classic triad (structure, process, outcome) used to evaluate quality of care (see Fig. 6-2). *Process* refers to the ways in which medical resources (structure) are utilized. The assumption behind structure and process evaluation to ensure quality and value is that if these variables are satisfactory, good patient care will follow. This assumption is not always valid: a pulse oximeter may be present and properly used in the OR, yet brain damage may still occur if there is inability to intubate and ventilate. Poor correlation can occasionally exist between processes and outcome so that properly conducted studies to validate and evaluate the effects of process variables on outcome variables are crucial to define value in anesthesia services. In this context, inferences about the benefits of a specific choice of anesthetic management based on differences in intermediate “process” variables are generally not as important as those based on differences in real outcome measures. For example, when seeking to identify patterns of care triggered by cost containment that may adversely affect quality of care, evaluation of anesthetic management paradigms using a surrogate endpoint such as hemodynamic stability is much less useful than the assessment of rates and etiologies for unscheduled admissions to treat (or rule out) complications such as myocardial infarction, prolonged postanesthesia care unit (PACU) stays, and other outcomes. Furthermore, funding and reimbursement for certain procedures (*e.g.* chronic pain therapy) may be increasingly restricted or determined by evaluation of quality and assessment of value using outcome data.

Outcome measures are typically defined as those changes, either favorable or adverse, that occur in actual or potential health status after prior or concurrent care.⁹ Concepts of health status include not only physical and physiologic parameters (such as death, cardiac arrest, perioperative myocardial infarction, dural puncture headache, or duration of intensive care unit [ICU] or PACU stay), but also psychosocial functions (such as patient satisfaction and duration of disruption of productive and social life). Anesthesiologists have focused on physical and physiologic outcome events, but it is being increasingly recognized that patient satisfaction is a legitimate measure upon which anesthesia management can be valued. Improved quality of care and better patient satisfaction can be achieved by reducing the incidence of common, relatively minor, non-life-threatening adverse events related to anesthesia.^{10,11} This is particularly important in ambulatory surgical procedures where the occurrence of minor adverse events leads to patient dissatisfaction.¹² While it is important to focus efforts to avoid such adverse clinical outcomes to improve patient care, it must be acknowledged that other factors, such as the friendliness of a facility staff, may be equally if not more important than some clinical outcomes.¹³ A reduction in serious adverse anesthetic outcomes has a variable economic impact on overall costs, depending on different assumptions regarding case mix, the added expense of improving perioperative care and/or preventing complications, the frequency of occurrence of adverse complications, and the relative overall costs of the uncomplicated surgical procedure.¹⁴ Nonetheless, focusing on reduction of minor but frequent perioperative anesthesia-related incidents, events, and complications can be economically beneficial, since these are significant predictors of postanesthesia care utilization in terms of PACU length of stay.¹⁵

Even when published studies provide data to evaluate outcome effects of new therapies or interventions, determination of relative clinical utility remains difficult. Statistical power, sample size requirements, and related analytic issues are often confusing and sometimes make it difficult to place study results in proper perspective. What may appear to be a large clinically important difference may not be statistically significant if a study sample size is small, whereas less meaningful clinical differences may be highly statistically significant if the sample size is large enough. Special caution must be exercised when interpreting clinical differences that are reported as a relative risk reduction or relative change. For example, if intervention A is associated with a 25% actual reduction in the incidence of a complication (*e.g.*, 0.5 to 0.25) and intervention B is associated with a 1% actual reduction in the incidence of another complication (*e.g.*, 0.02 to 0.01), both could still be described as producing the same relative improvement (50%) despite different clinical utility. This has profound importance for the assessment of cost-effectiveness. A specified anesthetic or antiemetic might need to be administered to just four patients to prevent one episode of nausea and vomiting (hypothetical intervention A), whereas 100 or more costly spinal needles might be needed to prevent one case of post-dural puncture headache (hypothetical intervention B). Calculation of the “number needed to treat” is an important concept when examining cost differences between clinical alternatives.¹⁶

Anesthesiology is a medical specialty well suited to the application of service attributes as measures of outcome. Some attributes that can be measured to assess value include reliability, satisfaction, ability to handle unusual situations, ability to remedy failures, and cost consistent with service. A number of important characteristics and factors determine the validity and usefulness of outcome measures in assessing value in health care. Ideally, outcomes should reliably reflect the quality of care of the provider and should have limited dependence on correction for severity of illness. Outcome measures should also have construct validity, adequate statistical power, and be uniformly defined, observed, and recorded.¹⁷ Outcome measures such as unadjusted complications and mortality have inherent limitations as direct reflections of provider quality of care. The “failure to rescue” rate (rate of death after complications) has been proposed as a further refined measure of quality of care that focuses on how complications are handled by the provider and de-emphasizes the cause of the complication (which is typically highly related to patient characteristics). Generally there are poor correlations between severity-adjusted death rates and severity-adjusted complication rates, and the rate of failure to rescue can be used to identify differences in quality of care among providers. For example, a reduced failure to rescue from complications has been associated with a higher percentage of board-certified anesthesiologists in a health facility¹⁸ as well as the presence of an anesthesiologist compared to other physician providers of medical direction for anesthesia services.¹⁹

The value of any outcome rather than another in a given clinical situation may differ markedly according to the needs and preferences of a given patient. For example, evidence of prolonged intense sympathetic block may be a positive outcome for patients with reflex sympathetic dystrophy, but a negative outcome with respect to the postoperative course after a herniorrhaphy performed under lumbar epidural anesthesia. A specific type of substantial negative outcome is a “sentinel event,” which is an unusual or unexpected outcome that should not occur under prevailing conditions of care. Sentinel events are often used to detect potential defects in the process or structure of care.

Anesthesia-related outcomes must specify which outcome of what process at what time is being examined. Specification of the process being employed must be explicit if causal relationships between any given outcome and process variable are to be critically evaluated. The salience of whether outcome is related to process cannot be overstated. Absent this relationship, the study of outcome is not useful as a guide for improving the value of anesthetic care. When adverse outcomes are

poorly linked to specific anesthetic practices in given clinical circumstances, this only underscores the need for additional rigorous research to establish the causal link of process to outcome using techniques such as well-controlled clinical trials. Although such trials are accepted as the ideal methodology for evaluating a given therapy or process of care, this may be nearly impossible because of sample size requirements and statistical power limitations when the outcome of interest occurs at a low rate.¹⁶ Nonetheless, with sufficiently large populations, variations in outcome can often be attributed to structure and process. Risk stratification organizes a multitude of patient variables to control for structure changes when determining how process affects outcome. The use of observational databases may be the only practical method of linking process to outcome when the outcome in question is rare. Although analysis of observational data can never prove causation as strongly as can randomized trials, reproducible strong associations between process and outcome may be sufficient to guide clinical practice in many instances. The widespread collection of computerized data combined with powerful analytic programs has facilitated outcome assessment for departmental quality improvement and increasingly for evaluation by health care purchasers and the public.

Evaluating Outcomes in Clinical Practice

There are two main sources of outcome information for clinicians: data published in the literature and data collected and analyzed from practice experience. Computerized information management systems are important tools to track outcomes and analyze the cost and benefits of specific aspects of health care delivery.²⁰ Effective electronic clinical information systems facilitate data analysis by allowing ready access to large amounts of data for queries and trend reports. Practitioners can readily apply statistical process control principles to evaluate outcomes in their individual practice settings. This is particularly important because published data may not exist regarding the outcome effects of a particular medical process or because published data may not be applicable to the practitioners' practice environment. As such, use of control charts and cause-and-effect diagrams can assist in defining variation in outcomes and formulating scientifically valid conclusions to facilitate improvement in outcome.

Cause-and-effect diagrams track the events in a process and allow them to be related to various outcomes. [Figure 6-3](#) illustrates the use of such a diagram to outline the analysis of factors contributing to postoperative nausea and vomiting in a surgicenter setting. Data would be collected and managed in a computerized database. The flow chart and respective database then serve as a substrate for improvement of outcome by identifying sources of variability and then indicating where better control needs to be applied. The departmental database should ideally track as many of the factors identified in the flow diagram as possible.

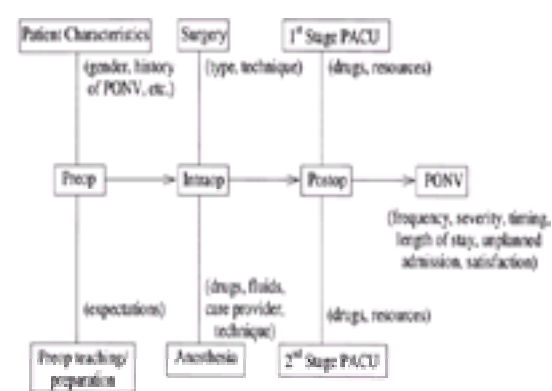

Figure 6-3. Cause-and-effect diagram for postoperative nausea and vomiting (PONV).

Outcomes related to the adverse event can be tracked over time and examined to determine overall frequencies of events and control limits. If there is significant variability in the frequency or severity of an outcome (such as postoperative nausea and vomiting) by individual clinicians, adjusted for surgical case mix and patient characteristics, the cause-and-effect database can be used to identify variations within the process of care provided by an individual anesthesiologist (drugs, technique, etc.) to several patients. This approach helps reduce the bias entered by analysis of a single case, and provides more insight into the overall process of clinical care.

Control charts are a practical tool for assessing the impact on outcome of observed variation in the process being monitored.²¹ Control charts graph the frequency of the outcome of interest on the y-axis versus time intervals on the x-axis ([Fig. 6-4](#)). A horizontal line indicates the mean of the observed measured values while dotted horizontal lines above and below the mean depict the upper and lower control limits (usually 2 or 3 standard deviations above or below the mean value). Use of narrower control limits incurs the risk of a Type I statistical error (concluding that a process of care yields results out of control range) while use of wider limits may be associated with a Type II error (concluding that the process results in outcomes within control when it does not).

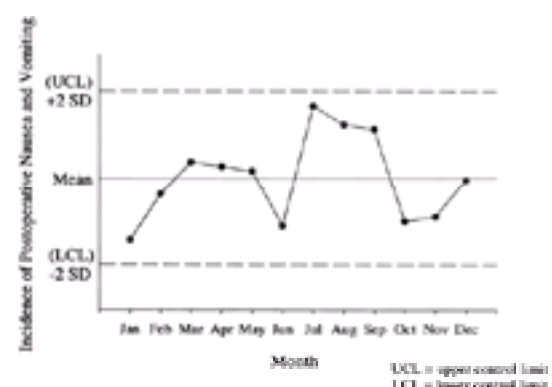

Figure 6-4. Statistical control chart for incidence of postoperative nausea and vomiting.

A fundamental application of statistical control charting in individual practice settings is improvement of a health care process to optimize outcomes. This requires an understanding of the process, defining, measuring, and analyzing process indicators, and implementing changes in the process to subsequently measure as an improved outcome. Intermeshed with process improvement are the concepts of quality health care and outcomes management. The principles of continuous quality improvement promoted by Deming,²² which profoundly influenced Japan's post-World War II manufacturing rebirth, are being applied in the health care industry. Deming's approach focused on statistical approaches to quality assessment and management by evaluating variation in outcome measures that are considered meaningful. Variation can arise either from common or from special causes. Common cause variation reflects the aggregate sum of small variations inherent to the process and determines the limits and capabilities of current operation.²¹ For example, length of PACU or ICU stay can be summarized for a given diagnosis over some time period (e.g., monthly, quarterly). This defines an average length of recovery time that is inherent for treating a specific condition, as well as its standard deviation. If the average duration for recovery is deemed excessive, independent of the monitoring period (e.g., monthly, quarterly), common causes of variation require identification and analysis to reduce this variability. Large variability, suggested by a large standard deviation, is readily identifiable. In contrast, a large change in the complication rates between time periods may indicate special cause variations, which are not a continual part of the process. A large increase in the incidence of emergency reintubation or an unexpected frequency of negative-pressure pulmonary edema in the immediate recovery period might indicate problems with the processes of emergence from anesthesia such as variations in pharmacologic reversal of neuromuscular blockade or premature extubation in the OR. These types of problems can be resolved by addressing their specific etiologies rather than the overall process of care delivery itself. If the data outliers indicate a change toward worse outcome, this should prompt evaluation of the various processes defined in the cause-and-effect diagram in order to improve outcome. If the outliers indicate a change for the better, this also suggests that the variation in the process resulting in the beneficial outcome should be identified and incorporated more broadly into clinical practice.

It is important to recognize that interventions to alter processes of care may also be indicated even if all data points fall within the upper and lower control limits (special cause variation has been eliminated and the system is in stable statistical control). For example, an outpatient facility may have a stable frequency of postoperative nausea and vomiting with little variation but the mean occurrence rate is increased. This may indicate poor quality relative to comparable external benchmark data, thus initiating an evaluation of processes of care to reduce the frequency of that adverse outcome to levels achievable in other similar practice settings.²³ The source of such benchmarking data may be from published scientific studies, unpublished data obtained from other comparable practice settings, or from national databases that evaluate the outcome(s) in question and define a broader basis for outcomes benchmarking. The determination of whether published data apply to an individual clinician's practice setting requires a careful, organized, evaluative approach.^{24,25,26,27,28} While the use of statistical control charts is not the only method for individual

practitioners to evaluate the quality of the services they provide, they do encourage continual assessment of outcomes and emphasize the importance of comparing performance over time (both internally and to potentially changing external standards). Continuous collection of outcome data, with results of performance information on quality improvement efforts reported to health care personnel in economic terms, can also be useful to highlight the relative value of various interventions and to promote practitioner involvement in outcomes management.

The context sensitivity of outcome measurements is exceedingly important. Responses to anesthetic management (such as effects on pulmonary function or the stimulation of nausea and vomiting) will differ, depending on whether they are measured one hour, one day, or three days afterwards. Although true for all health care outcomes, it is especially relevant for anesthesiology-related outcomes to note that the longer the period of observation, the weaker the connection between the observed outcomes and the processes of care. The plausible link between process and outcome is threatened significantly as the assessment period expands. The further one gets from direct and short-term outcome measurements, the less useful these measurements are for drawing valid conclusions about causality. Some complications related to anesthesia care, however, may not occur for a significant period of time. For example, a case of non-A, non-B hepatitis resulting from an “unnecessary” transfusion would go undetected in most hospital reviews, since the patient would probably be discharged before the condition was diagnosed. On the other hand, evaluation of nausea and vomiting in the ambulatory recovery area alone may be inadequate to determine the effects of anesthetic management unless further evaluations are made during the 24-hour period after patient discharge.²⁹ Specification of the point in time at which outcome is measured is a prerequisite for the validity of that measurement.

Another major consideration that characterizes outcome data is specification of its value content. This means that outcome must be examined for its relative value to whom, for what purpose, at what time, and under what circumstances. Anesthetic interventions may have considerable value for certain subsets of patients with highly specific indications or characteristics, but little or no value (even negative value) when applied to other subsets of patients. The main consideration is that the value of a given outcome must be defined and, where possible, quantified in relation to a specific purpose. If this is not done, the tendency is to overgeneralize and invalidly attribute outcome value to applications where it may not be warranted. Generalization about the beneficial effects (or lack thereof) of one anesthetic technique compared to another without due consideration to the specifics of time and circumstances can lead to incorrect conclusions. For example, it may be that regional anesthesia *per se* is not any more beneficial to outcome in high-risk patients compared to general anesthesia, but that the use of regional techniques extended into the postoperative period for analgesia is beneficial compared to general anesthesia followed by “routine” parenteral pain control.³⁰

The value or importance of a given anesthesia-related outcome also depends on whether it is viewed from the perspective of the primary customer or a secondary customer (Table 6-1). When considering nausea and vomiting after outpatient surgery, the patient can be considered a primary customer and the significance of this adverse outcome relates to the severity and frequency of its occurrence and the delay it causes in resumption of daily activities. In this situation, the health care facility is, by contrast, a secondary customer of anesthesia services and the outcomes relevant to nausea and vomiting include the rate of unanticipated admissions, patient satisfaction, the timing of onset of nausea and vomiting (and the subsequent impact on discharge time if vomiting occurs prior to discharge versus after discharge), as well as personnel costs and drug costs involved in managing this adverse event. Although anesthetic management relating to prophylaxis and/or treatment of postoperative nausea and vomiting varies among providers, the process of evaluating customer requirements and balancing those needs to achieve a high degree of satisfaction for all customers is essential to optimize the value of the medical services provided by anesthesiologists. Similarly, the context sensitivity of outcomes related to the establishment and use of an anesthesia preoperative evaluation clinic (APEC) depends on the viewpoint of the customer primarily affected by this service (Table 6-1). In this instance, the health care facility and surgical staff may be considered the primary customers, who consider the impact of this service on outcomes such as OR efficiencies, frequency of cancellations or delays, and reduction in preoperative testing costs as well as the frequency of need for additional medical specialist consultation (important in a capitated payment system).^{31,32} Conversely, outcomes applicable to the patient (a secondary customer of these services) would include degree of satisfaction and other factors such as efficacy of preoperative education.

| Primary Customer | Secondary Customer |
|---|---|
| <p>Primary Customer</p> <ul style="list-style-type: none"> Health care facility (Patient) <p>Secondary Customer</p> <ul style="list-style-type: none"> Health care facility (Patient) | <p>Primary Customer</p> <ul style="list-style-type: none"> Health care facility (Patient) <p>Secondary Customer</p> <ul style="list-style-type: none"> Health care facility (Patient) |

Table 6-1. IMPORTANT OUTCOMES AND VALUES FOR PRIMARY AND SECONDARY CUSTOMERS

Application of Outcome Data to Manage Costs: Defining Effectiveness and Efficiency

Generalizability of outcome data can be described by the concepts of efficacy and effectiveness.³³ *Efficacy* reflects the beneficial effects of a process of medical care as measured by the outcome achieved in a specific population of patients. *Effectiveness* is defined as the outcome likely to be observed when that process of care is applied into wider clinical practice. Further distinctions must be made among evaluations of efficacy (can it work?), effectiveness (does it work?), and efficiency (is it worth it?). As described, an intervention can be efficacious but not effective, especially if there are difficulties transferring its application from the research setting to actual medical practice. The homogeneity often sought in well-controlled trials in an effort to validly link outcome with process can be at odds with the heterogeneity of the broader base of anesthetic practice. Equally importantly, an intervention can be effective but not efficient if there are other alternative interventions that achieve the same outcome at lower overall cost.

The slope of the overall cost-benefit curve (see Fig. 6-1) becomes more favorable if components of increasing expenditures that have minimal or no incremental benefit (flat slopes) or result in more harm than benefit (negative slopes) are eliminated. In addition to redistribution of resources from services with some benefit to services with greater benefit relative to cost, a more complicated approach to improving the composite cost–benefit relationship involves improving efficiency by altering processes of care to selectively eliminate more costly services and replace them with less costly interventions of equal benefit. In the macroeconomic view, total costs equal the product of unit costs times quantity. The reduction of total health care costs must consider both of these factors, as illustrated by the case of laparoscopic cholecystectomy. The use of laparoscopic techniques has significantly shortened the time required for postoperative recuperation after cholecystectomy. Reduced length of hospital stay and better outcomes with less pain and disability allowing a more rapid return to function appear to be a classic example of improved efficiency (lower costs and better outcomes). However, in the macroeconomic view, aggregate cost savings have not been realized because, with the advent of laparoscopic techniques, the rates of cholecystectomy have dramatically increased as a result of the greater desirability of this procedure among patients and a lower threshold among surgeons for removing gallstones from mildly or intermittently symptomatic patients. In one health maintenance organization (HMO), the cholecystectomy rate increased by almost 60% over a 5-year period, and even though the average cost per cholecystectomy decreased by 25%, the total cost for all cholecystectomies increased by 11% because of the increase in surgical volume.³⁴ This example illustrates the complex nature of defining efficiency and cost saving, including the necessity of defining whether the basis of the analysis is microeconomic or macroeconomic. In addition, it highlights the need for physicians (including anesthesiologists) to balance the perspective of needs of individual patients with the overall needs of the population served by the health care system.

Strategies to contain costs may be applied by the health care system itself or by the individual health provider unit. Third-party payers have aggressively developed strategies to contain costs. The use of prospective payments and implementation of diagnosis-related groups (DRGs) have been adopted to manage care by reducing hospital utilization and limiting total allowable charges. Implementation of utilization review procedures, applying incentives to increase efficiency, and restricting resource accessibility are all tactics employed to contain costs, although resource constraints do not address the process or cost-effectiveness of care. Public insurers can mandate resource restriction, but private insurers do not have that mandate and therefore restrict what they will pay for a service, compelling provider units to contain costs to accommodate reduced charges. Providers generally apply cost-containment maneuvers that either restrain resource utilization or increase the cost-effectiveness and efficiency of various processes (Table 6-2). Examples of such strategies include shifting or optimizing case mix (e.g., redistribution of specialized care to improve cost-effectiveness) and restraint or optimization of resource utilization by physicians. Limiting the availability of staff, beds, new programs, and technology may be used to contain costs and/or enhance revenues by increasing efficiency. Optimizing resource utilization by anesthesiologists involves their active participation in policymaking, protocols, and patient management, not only in the OR, but in the pre- and postoperative arenas as well. This requires physician education regarding the direct and variable costs of patient care and a method of providing feedback about performance.³⁵ Such information is essential for physicians to analyze the effectiveness of changes in the processes of care as well as the impact of technology assessment to ensure that technology is being used wisely and effectively. Providers not only desire to use the most reliable and proven technologies, but also wish to maintain a competitive edge by employing the latest technologies to improve outcome.

- Shifting or optimizing case mix
- Restraining or optimizing resource utilization
- Optimizing technology application via technology assessment
- Improving technology acquisition and maintenance procedures
- Utilization review, including outcome management and total quality improvement

Table 6-2. STRATEGIES FOR COST CONTAINMENT

Maintenance of cost-effectiveness while simultaneously introducing new technologies is a continual dilemma for anesthesiology and critical care, by virtue of the heavy deployment of technology. A number of experts have emphasized the need for technology assessment before widespread use.^{36,37} Such assessment must evaluate the technology's feasibility, efficacy, effectiveness, and economic impact. Information derived from such assessment can be utilized to improve technology acquisition and maintenance procedures, which should also help reduce costs. Establishment of technology assessment committees within institutions can be helpful in this regard by setting priorities, reviewing and recommending equipment requests, avoiding duplicative technologies, and reviewing feasibility, efficacy, and effectiveness data. Eventually, decisions must be made with regard to the economic impact of technology or health care interventions, which requires an understanding of basic methods of economic evaluation.

METHODS OF CLINICAL ECONOMIC ANALYSIS

Although current data to help the clinician decide on the best way to spend the health care dollar are limited, a few basic analytic techniques can help in the assessment of the clinical economic effects of various testing paradigms, drugs, devices and monitors, organizational systems, and other services. These include the use of cost-minimization, cost-benefit, cost-effectiveness, or cost-utility analysis (Table 6-3) and examination of outcome data that are needed to perform these analyses.^{38,39} In discussing cost analyses, a brief review of terminology is warranted. *Variable costs* are those costs that change as a function of the volume of services provided. Examples of variable costs in the OR and PACU include those for supplies, drugs, and supplemental nursing services. *Fixed costs* are the ongoing costs of providing service, which are unrelated to volume and include items such as the salary of an OR manager and the costs of capital equipment such as OR and PACU monitors. Variable costs are much more responsive to cost-containment strategies; the challenge is to limit these variable costs without adversely affecting quality and outcome. In addition to classifying costs as fixed versus variable, the concept of direct versus indirect cost allocation is important. *Direct costs* can be explicitly quantitated and unambiguously attributed to the service rendered, whereas *indirect costs* are those of goods and services subsidiary to the primary service. Indirect costs are related to the consequences of the primary service and are frequently difficult to identify and quantitate, but include items such as increased turnover time of ORs, increased PACU time, unanticipated hospital admissions, and costs of drugs to treat side effects as well as time and resources lost from productive or consumptive activities. Finally, the differences between costs and charges must be acknowledged, recognizing that charges are often not a useful surrogate indicator of resource costs incurred with application of a specified health care intervention. Although charges are often used as proxies for cost, and cost-to-charge ratios are frequently applied to convert charges to costs, these conversion factors vary from institution to institution and even within an institution. The cost-to-charge ratio typically varies widely between service areas such as laboratory testing (traditionally small cost-to-charge ratios), pharmacy services, or the OR (commonly large cost-to-charge ratios). Cost center shifting is common in hospitals and can make it difficult to identify true costs of a service (such as the OR), since charges are often not distributed evenly and may even reflect costs of services in other areas of the hospital where reimbursement does not exist or is inadequate to cover cost. The methods of cost shifting in place at any time in a given institution determine if any hospital unit (such as the OR) appears as a revenue generator or a revenue loser. For example, in a managed care or fixed (global) reimbursement environment, if radiology and laboratory services are attributed to the OR, these common elements of preoperative testing no longer represent a source of revenue; rather, such preoperative testing will be solely regarded as a cost attributable to anesthesia and OR services.

| Type of Economic Analysis | Appropriate Application | Limitations |
|--|--|---|
| COST-MINIMIZATION ANALYSIS Identifies least costly of equally effective alternatives | Identifying among equally effective alternatives | Identical clinical effectiveness to not consider cost in some variable patients |
| COST-BENEFIT ANALYSIS Compares effectiveness to monetary units, assigning monetary value to outcomes ("dollars to pay") | Identifying intervention with greatest net benefit or best cost-benefit ratio while comparing outcomes with different attributes or outcomes | Difficult to assign monetary value of life or health state |
| COST-EFFECTIVENESS ANALYSIS Simultaneously evaluates incremental gain in health derived from additional unit, measuring effectiveness in terms of units (e.g., life years gained), or ability to avoid/deference costs in competing regimens | Identifying among regimens with different clinical effectiveness when all regimens have the same cost or when cost can be assessed using some cost index (number of effectiveness) | Not applicable to all types of outcomes; some regimens generally not comparable to cost-effectiveness analysis across disease processes |
| COST-UTILITY ANALYSIS Multidimensionally evaluates effects of interventions on both quality and quantity of life and measures effectiveness in terms of quality-adjusted units, as post-traditional life-years (QALY) | Aggregating multiple outcomes into a single standard measure of effectiveness allows comparison of effectiveness of interventions in different medical fields | Difficult to compare utility across individual units; problems for health state ratios with medical condition |

Table 6-3. COMMON METHODS OF MEDICAL ECONOMIC ANALYSIS

Cost-minimization analysis does not consider indirect costs and is the least useful analytic technique because it assumes identical consequences of each intervention. Historically, cost-minimization analysis has been the first-pass technique applied, because it is the easiest to perform and implementation does not require considerations other than absolute acquisition costs or other direct costs. However, the limitation of such analysis alone is illustrated by the distorted conclusions it might provide (e.g., ketamine and morphine would be preferable to propofol and fentanyl for outpatient surgery). Variations in case mix (type of surgical procedure and patient condition) are generally not assessed when using "cost per case" to compare direct costs among anesthesia providers. Adjustments for case mix that account for type and duration of surgical procedure as well as patient demographics can be applied to define a "cost per unit" which allows a fairer comparison of direct costs among individual providers, anesthesia groups, and health care facilities.⁴⁰ However, when considering overall surgical costs for commonly performed low-to-moderate risk surgical procedures, severity of coexisting medical disease has less impact on resource consumption than the consequences of surgical decisions and techniques (e.g. the cost of a specific orthopedic joint prosthesis selected by the surgeon).⁴¹

Traditional cost-benefit analysis uses simple economic values, comparing dollar differences between competing costs with the economic values of benefits. The central feature of cost-benefit analysis is the translation of outcome quantities into dollar values. Although this concept is appealing, there are major practical limitations in placing monetary values on theoretic benefits to patients. For example, a healthy patient undergoing a brief surgical procedure probably places less value on avoidance of nausea than a patient undergoing intensive chemotherapy.

Cost-effectiveness analysis relates monetary costs to attributes of health benefits (effectiveness). Effectiveness is not valued in monetary terms, and a decision-maker, not the cost-effectiveness analyst, must make value judgments. A summary of the important elements of cost-effectiveness analyses is shown in Table 6-4. Effectiveness can be defined by whether an intervention does more good than harm, highlighting the role of outcome measurement as a major management tool in determining cost-effectiveness. Cost-effectiveness cannot be judged without a fundamental understanding of clinical effectiveness. It is essential to define a threshold of acceptability for clinical effectiveness because low-cost/low-effectiveness (low-quality) regimens may reflect the same quantitative cost-effectiveness ratios as regimens characterized by higher costs and higher effectiveness (high quality). The cost differential between interventions divided by the differential clinical unit change translates to the "value" by which the intervention is measured. Even if interventions are associated with additional costs, they may be cost-effective and represent greater value if improvement in outcome is adequate to decrease unit costs. The importance of considering indirect cost in overall cost-effectiveness analysis is exemplified by the scenario where greater pharmacy preparation time and administration costs for one drug with a low acquisition cost could (depending on the differential between direct and indirect costs) result in reduced cost-effectiveness than another drug of equal safety, effectiveness, and spectrum of activity but greater acquisition cost.

- Identification of all clinical strategies and alternative interventions
- Stipulation of the target population
- Determination of all costs for each intervention
- Determination of all benefits for each intervention
- Application of discounting if extended time frames of analysis
- Calculations of cost-effectiveness (utility) ratios
- Testing stability of predictions with sensitivity analysis

Table 6-4. COMPONENTS OF COST-EFFECTIVENESS (UTILITY) ANALYSIS

Classic cost-effectiveness analysis calculates net costs as the aggregate of direct medical and health care costs—including costs of hospitalization, physician time, medications, laboratory and other ancillary services, costs associated with adverse side effects of an intervention, and costs of treating diseases that would not have occurred if the patient had not lived longer as a result of the original intervention—then subtracts the cost savings in health care, rehabilitation, and custodial costs due to prevention or alleviation of disease. The cost-effectiveness ratio is then calculated as the net cost of one intervention versus another placed over the denominator of their respective outcome differences. Most calculations of net costs do not include lost wages due to missed time from work, despite the fact that loss of productivity may have profound financial consequences for individuals and society (e.g., the difference of returning to work 5 days sooner because of application of a newer intervention such as laparoscopic cholecystectomy). Costs are generally adjusted to account for the difference between present and future monetary values, and discounting of future costs is commonly applied not only to account for inflation, but also to account for the fact that dollars not currently spent can be invested to yield a larger number of real dollars in the future. Because of controversy over the appropriate rate for discounting, most cost-effectiveness analyses test a range of discount rates.

Cost-utility analysis relates economic costs to utility units, which aggregate multiple outcomes into a single adjusted measure of effectiveness and represent the health improvement attributable to the intervention—e.g., dollars spent per quality-adjusted life year (QALY) gained. QALYs represent the number of years of life expected, multiplied by a fraction representing the decrement in quality of life because of less than perfect health. For example, 2 years of life rated as 85% of perfect health translates to 1.7 QALYs. The use of QALYs as a measure of outcome permits comparison of the effectiveness of interventions in different medical fields.

A significant fraction of the published literature on the cost-effectiveness of medical technology utilizes decision analysis as the basis of comparison for various alternative clinical interventions (see Fig. 6-5). Decision analysis focuses on alternative interventions for a given clinical problem and their consequences, subsequent actions required, the consequences of these actions, and so on, until specific definable outcomes are achieved.⁴² Probabilities are assigned to the consequences of the interventions, and costs are identified for each of the alternatives. Decision analysis is most useful in comparing interventions A and B, when studies directly comparing A to B are not available or when using data from studies comparing A to C and data from studies comparing B to C (or D). Because it is often difficult to compare studies of varying methodology, statistical methods such as meta-analysis may be required to permit pooling of data from multiple studies. Decision analysis requires explicit identification and stipulation of all possible clinical events that may occur. Each outcome is assigned a quantitative value to allow comparison with other possible outcomes (e.g., survival, intermediate states of health, and morbidity). The values for the probabilities and the outcomes are typically based on estimates from the literature or expert consensus. Sensitivity analysis can be applied to the decision model to determine its stability as the underlying parameters are varied singly or simultaneously, allowing application of such models to specific clinical environments. Decision analysis and subsequent application of sensitivity analysis can thus be used to calculate and then evaluate the cost-effectiveness ratios for all alternatives to address a clinical problem. For example, decision analysis has been applied to determine cost-effectiveness ratios for ondansetron, droperidol, and metoclopramide for the prevention of postoperative nausea and vomiting and suggests that the relative cost-effectiveness of prophylactic use of each of these drugs depends significantly on the expected pretreatment incidence of vomiting.⁴³ The relative cost-effectiveness of these and other drugs depends on the chosen measurement end points; it has been suggested that unplanned hospital admissions after outpatient surgery, patient satisfaction, and duration of recovery period are potentially more crucial outcome measures than the incidence of vomiting alone when assessing the relative economic value of various choices for antiemetic prophylaxis or therapy.⁴⁴

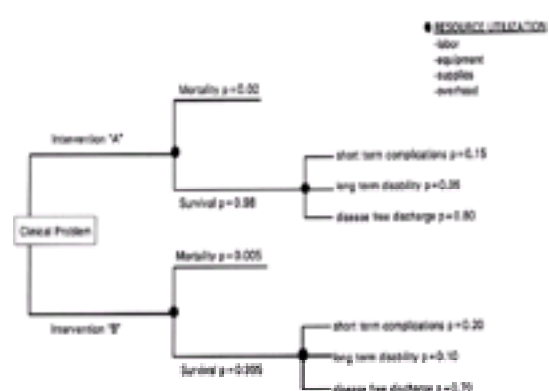

Figure 6-5. Example of decision analysis that can be used to assess cost-effectiveness

When evaluating these types of economic analyses, direct benefits and costs are the easiest factors to quantitate. Short- or long-term survival or reduction of hospital or overall direct costs can be examined as markers of benefit. In contrast, a specified technology or health care intervention may have certain indirect benefits, which are often difficult to measure. For example, better coagulation monitoring or the use of drugs such as aprotinin may mean less blood product usage and less hepatitis in the future, but it is profoundly difficult to quantitate the avoidance of future morbidity. Therefore, potential reduction of future morbidity and improvement in quality of life are rarely evaluated as indirect benefits of health care interventions. Indirect costs are just as difficult to measure as indirect benefits. When a monitor or test is used to obtain physiologic data that prompt the performance of multiple additional tests and interventions, it is often unknown how to figure in these costs. This difficulty is faced when assessing nearly every technology and testing protocol in the current high-tech practice of medicine. Preanesthetic evaluation, intraoperative management, and postoperative care are three major areas of practice of anesthesiology where clinical economic analysis can be applied to assess value.

COST-EFFECTIVE PREOPERATIVE PRACTICES

The historical practice of routine preoperative hospital admission of even medically stable patients before major operations, including cardiac, thoracic, joint replacement, and major abdominal or urologic procedures, has been replaced with the contemporary practice of “a.m. admission” processes. This has reduced costs without any demonstrable adverse effect on surgical or anesthetic outcome.⁴⁵ Other preoperative practices have been modified because of cost and efficiency concerns. For example, the cost-effectiveness of preoperative autologous blood donation has been examined both for cardiac and for several types of major noncardiac surgery.^{46,47,48} Decision analyses utilizing a large number of clinical variables have determined that the cost of autologous blood donation may vary from \$40,000 to over \$23 million per QALY saved, with the differences between autologous blood collections and transfusion requirements explaining the majority of the variation in cost-effectiveness among the surgical procedures studied.^{46,47,48} These types of analyses have altered clinical practice by demonstrating that the collection and processing of a large number of autologous units for operations with low transfusion requirements can make preoperative autologous blood donation far less cost-effective than allogeneic transfusions.⁴⁸ The cost per year of life saved (QALY) by preoperative autologous blood donation is several-fold greater than the cost-effectiveness (utility) estimates of many other common and accepted medical practices such as coronary revascularization to treat three-vessel or left-main coronary disease (\$6,000/QALY) or screening for cervical cancer every 4 years (\$11,000/QALY).⁴⁷

Laboratory testing is a common aspect of both inpatient and outpatient preoperative assessment as well as postoperative care of the critically ill surgical patient. It has been estimated that several billion dollars are spent in North America on preoperative testing (and the subsequent follow-up evaluations initiated secondary to that testing) and that a sizable portion of these costs could be saved by the selective ordering of tests based on patient history or findings of the physical exam.⁴⁹ Relatively few abnormalities are unsuspected after a thorough preanesthetic visit, and even then, these abnormalities alter perioperative management in only a very small fraction of cases.^{49,50} Nonselective ordering of tests neither results in beneficial changes in perioperative care nor serves as an effective screen for detection of unsuspected disease, and most clinicians currently agree that many preoperative tests can be safely eliminated by ordering only those based on specific abnormalities in the history

and physical exam.^{49,51}

Extra testing not indicated by history or physical findings bears not only additional direct cost, but also potential extra indirect costs in the form of greater liability risks if abnormalities detected on preoperative screening are not pursued. In addition, assuming that the results of laboratory results are independent of one another, the more tests ordered, the greater likelihood that abnormal results will appear. For example, assuming specificity for laboratory testing of 97%, if 6 tests are ordered, there is almost a 20% chance [$100 \times (0.97)^6$] that at least one of the tests will be abnormal. Such abnormalities can often generate hidden preoperative costs in addition to the cost of the screening tests themselves. Selective preoperative testing is necessary to reduce direct costs and potentially improve the efficiency of OR schedules by eliminating the need to pursue falsely positive or slightly abnormal results that do not affect perioperative management.

Anesthesiologists are uniquely suited to perform or oversee preoperative evaluative processes because of their knowledge and experience in the effects of perioperative interventions on patient physiology (e.g., the hemodynamic effects of spinal or epidural anesthesia compared to general anesthesia in patients with critical aortic stenosis). Although a primary care physician may understand optimal health status for daily life, this may not represent an optimal preoperative condition. Involvement of anesthesiologists in preoperative assessment maximizes the appropriate application of individualized diagnostic and therapeutic regimens according to the patient's condition and the surgical and anesthetic requirements, thus optimizing cost-effectiveness by reducing the incidence of either too much or too little preoperative evaluation and preparation. Perioperative evaluation and management under the guidance of an anesthesiologist may not have the lowest direct cost, but it may be more cost-effective than ordering tests nonselectively or experiencing unnecessary and costly OR delays related to suboptimal preoperative preparation that could have been avoided by consulting with an anesthesiologist.

The Anesthesia Preoperative Evaluation Clinic: A Model for Value-Based Anesthesia Practice

An anesthesia preoperative evaluation clinic (APEC) which provides near-complete perioperative medical assessment for complex patients can result in impressive institutional savings, despite start-up and operating expenses, because of more focused use of diagnostic testing and medical consultation as well as subsequent improvements in OR efficiency.^{31,32} When the anesthesiologist takes the leading role in determining the appropriateness of the patient for anesthesia and surgery, OR utilization and efficiency can be improved by reducing the number of unanticipated delays related to inadequate preoperative evaluation. Delays and cancellations in the OR adversely impact optimal OR utilization and efficiency, and create financial problems related to lost revenues unbalanced by matching reduced costs. When an operating suite is not utilized efficiently, costs may actually increase because personnel costs can increase for work conducted after regularly scheduled hours. Inadequate preoperative preparation can result in inefficiencies in the OR even when patients arrive at the appropriate time prior to surgery. The optimal timing of ambulatory preoperative assessment is dependent on the individual facility. Completion of preoperative assessments in a very early time frame may not reduce OR cancellation rates compared to completion more proximate to the date of scheduled surgery, although it may provide greater flexibility in scheduling surgery by resulting in a pool of patients to fill slots of OR time that would otherwise be underutilized.⁵² Conversely, strict adherence to protocols that define time-based performance criteria for completion of specific preoperative processes can help anticipate problems that are likely to result in a cancellation on the day of surgery, potentially allowing time for correction of the problem and avoiding cancellation. Typically, inadequate preoperative preparation for the OR is manifest by the detection during the immediate preanesthesia assessment of medical problems that require additional evaluation and management, thereby delaying elective surgery; however, other nonmedical issues as simple as incomplete financial information also can create significant delays in the OR. Such nonmedical issues may seem less relevant, but they are important factors that must be considered in developing an effective, efficient operating room management scheme.

While the medical evaluation of the patient prior to anesthesia and surgery, with reduction of wasted resources by eliminating unnecessary preoperative testing and consultations, is the central element of effective preoperative preparation, other key elements in the process include centralized reporting of all important preoperative information (diagnostic and laboratory test results, consult reports, admission and financial information) as well as patient and family education regarding anesthesia and the perioperative experience. The APEC model is an effective means for anesthesiologists to be more active in perioperative medicine, enhance the value of their services, and potentially improve patient satisfaction secondary to streamlining of the preoperative process. In addition, patient anxiety may be reduced because of more in-depth patient education than that feasible when the anesthesiologist first encounters an ambulatory patient immediately prior to surgery.

The concepts utilized by an APEC generally require selective modification to fit the individual characteristics of each health care facility. Depending on resources and needs, prespecified criteria vary with respect to which patients are formally processed through an APEC, based upon clinical guidelines for preoperative assessment. All patients should generally undergo some form of minimal preoperative screening with central collection of important medical and administrative data early enough prior to elective surgery so that the OR schedule can be adjusted to avoid an unfilled OR due to inadequate preoperative patient preparation. Finally, in the context of overall OR management, a successful preoperative preparatory process provides the mechanism for all important information to be available to the appropriate members of the OR team. For example, not only would the anesthesiologist scheduled to attend to the patient intraoperatively be made aware of the specific preanesthesia evaluation prior to the day of surgery, but the surgeon would also be notified in a timely manner of any special recommendations that might impact scheduling for subsequent management (e.g., if the anesthesiologist recommended overnight intensive monitoring in a high-risk orthopedic patient). Efficient OR management also mandates that requirements for any special equipment or medical device be communicated to the responsible staff well in advance of the scheduled procedure, to avoid delays related to unavailability of specialized surgical instruments, prostheses or implants, or other special equipment.

EFFECTIVE RESOURCE UTILIZATION IN THE OPERATING ROOM

Anesthetic Drugs and Supplies

Anesthesia drug expenses represent a small fraction of total perioperative costs, but the large number of doses administered contributes to substantial aggregate costs. In the aggregate, cost savings associated with prudent drug selection can be substantial. If just \$20 were saved in every anesthetic delivered in the U.S., about \$500 million of direct costs would be saved annually. Total annual world expenditure for inhaled anesthetics (excluding nitrous oxide) has been estimated to be \$450 million.⁵³ Uniformly reducing fresh gas flows from 5 to 2.5 L/min would save approximately \$100 million annually in the U.S. and about \$225 million worldwide.^{53,54} This example illustrates how relatively simple measures can have significant impact on cost reduction without markedly impairing styles of clinical practice. Cost-saving measures such as this generate relatively little controversy, are easy to implement, and apply to large numbers of cases. However, anesthesiologists are more frequently confronted with choices between modes of anesthesia care that produce similar acceptable outcomes but at different levels of cost-effectiveness. The decisions involved in making these choices are significantly more complicated and contentious than resolving to conserve resources by reducing fresh gas flows while delivering the same inhalation anesthetics.

When considering the costs of anesthetic drugs and other technologies, a number of variables must be evaluated when comparing "expensive" drugs to apparently cheaper alternatives (Table 6-5). The costs of anesthetic drugs include the cost of the drug itself as well as adjuvant agents, equipment and supplies (e.g., infusion devices or special vaporizers), and the amount of drug wastage that occurs during typical use. In addition, there are other indirect costs associated with a given anesthetic drug that can be difficult to quantitate and are frequently not considered. These include the indirect cost of drug preparation and setup time (which may prolong OR turnover time) as well as the costs of extended PACU stay or additional drug therapy to treat postoperative side effects. Controversy exists over the relative impact of anesthetic drug choices on such indirect costs, intangible costs, or future health care costs.⁵⁵

| Direct Costs | Indirect Costs |
|--|---|
| Acquisition of drug or monitor | Rescue therapy for complications |
| Adjust agents or required materials | Delay in resumption of normal activities (not productive) |
| Drug or material wastage | Extended PACU, ICU, or hospital stay (especially if complications) |
| Consumable equipment and supplies for drug delivery or application of monitoring | Excess operating room or facility turnover time (drug preparation/ drug recovery and preparation, initiation of monitors) |
| Monitors and other capital equipment | Drug and equipment storage preparation and setup, including labor |
| Labor related to insertion and use of monitors (e.g., PAC, SEP, TEE) | Maintenance and repair of monitoring and drug delivery equipment, including labor |
| | Drug- or monitoring-related complications |

PAC, pulmonary artery catheter; SEP, somatosensory-evoked potentials; TEE, transesophageal echocardiography

Table 6-5. REPRESENTATIVE COSTS OF ANESTHESIA DRUGS AND MONITORS

Direct costs of anesthetic drugs and supplies typically constitute a very small fraction of total perioperative costs; however, they are frequently questioned by health facility administrators, and justification for the use of more expensive drugs generally requires examining the total cost of a therapeutic strategy rather than only drug acquisition costs.^{56,57} For example, induction agents such as propofol may have greater initial acquisition costs than alternatives but can potentially save overall hospital

costs when used appropriately for outpatient surgery and when patient care protocols allow for less intense and shorter duration nursing care with fewer complications and earlier dismissal of patients. Conversely, propofol infusions utilized for long, major operations in patients who require postoperative hospitalization may not provide for earlier ambulation and discharge and may not be as cost-effective in this situation as alternative anesthetics. The impact of shorter-acting drugs and those with fewer side effects on overall costs is context sensitive. During long surgical procedures, such drugs may not offer significant advantages over older, less expensive longer-acting counterparts.^{14,58} Under these circumstances, simply promoting cost consciousness using education can reduce total expenditures for a given category of drugs,⁵⁹ although long-acting neuromuscular blocking drugs may be associated with residual neuromuscular blockade and longer postoperative recovery time.⁶⁰ The greater direct costs of an anesthetic agent must be balanced against the direct and indirect costs of alternative anesthetics that may be associated with a greater frequency of side effects such as postoperative nausea and vomiting. In a fast-paced ambulatory setting, rapid-acting drugs with decreased side effect profiles may theoretically improve OR efficiency by decreasing times between short surgical procedures and reducing facility discharge time (especially when “fast-tracking” with bypass of phase I recovery is feasible).⁶¹ This is particularly important at the end of the workday to reduce recovery room personnel costs.

Many alternative drug choices are available to anesthesiologists, and drugs in the same therapeutic class commonly have widely differing costs. The acquisition costs may vary 40- or 50-fold in any anesthetic pharmacologic category, and it is estimated that the 10 highest expenditure drugs may account for more than 80% of anesthetic drug expenses at many institutions.⁶² Surveys indicate that physicians are interested in reducing the cost of drug therapy, but they desire more knowledge of relative acquisition costs and other cost information to make more informed drug selection decisions.⁶³ Selection and utilization of older but nonetheless effective opioids and muscle relaxants may be associated with considerable savings, especially during longer operations.⁶⁴ Such savings may, however, be offset by other costs if there is unanticipated or unplanned prolongation of recovery from anesthesia or requirement of pharmacologic therapy for reversal of prolonged drug effects (or side effects) associated with the use of longer-acting agents.⁶⁵ Although newer, typically shorter-duration and more specific-acting drugs are often very useful in short- to intermediate-duration procedures, the marginal benefit of their use may be reduced in longer operations, especially in healthy patients. There is little doubt that newer and more “expensive” drugs are often easier to use, but there are essentially no data to support or refute the hypothesis that most patients would have an equally satisfactory experience when older, less expensive drugs are titrated to effect based on an understanding of pharmacokinetics, pharmacodynamics, and perioperative physiology. It is the bias of many experienced clinicians that prompt awakening can be achieved with a variety of general anesthetics, if they are utilized optimally by experienced clinicians and not compared in a rigid, artificial study protocol. Similarity of awakening times, however, does not necessarily translate to other aspects of recovery profiles.

Disciplined application of pharmacoeconomic and pharmacoepidemiologic principles is required to define the relative value of new drugs. This not only necessitates evaluation of efficacy and side effects, but also involves assessment of parameters such as the time until resumption of normal physical or mental activity as well as other measures of outcome. Studies evaluating recovery-related productivity losses are important because these losses, like direct health care expenditures, have an economic impact on society. Even if prevention of a postoperative side effect (such as nausea and vomiting by an expensive antiemetic or a particular anesthetic drug) costs more than the medical costs of treatment of this problem, the preventive approach might be far more economically favorable when the potential economic losses of patients are considered. Such analyses are complex and difficult to perform, and the value of a given intervention will vary among patients in relation to their underlying condition, the anticipated surgical procedure, and the postoperative care requirements.

Beyond drug costs, there is significant potential for cost savings associated with reduction of waste in disposable equipment and materials. Examination of clinical practice patterns to eliminate wasteful and unnecessary practices can result in sizable cost savings without any compromise in quality of medical care. For example, use of computerized tracking methods for continuous monitoring of OR supplies and ongoing evaluation of prepackaged, customized surgical supply packs (permitting nurses to alter preference lists as surgeons' preferences evolve) can result in large savings (more than 60% related to decreased wastage of disposable items such as sutures).⁶⁶ Another method that has been demonstrated to be successful in reducing costs has been implementation of the requirement that users provide a justification for the more costly choice among several alternatives for disposable supplies or pharmaceuticals (e.g., neuromuscular blocking drugs).^{67,68} Behavior modification programs based on education of staff about costs and general guidelines for equipment and drug utilization have reported variable long-term success.^{62,66} This success may be enhanced not only by frequent reinforcement, but also by making clinicians cognizant of the concept of opportunity costs: with limited resources, those utilized for one commodity cannot be used for others that might produce potentially greater benefits.

The concept of opportunity costs is illustrated by data comparing the aggregate annual cost savings of using ionic (versus nonionic) contrast in low-risk patients.⁶ The \$3.5 million savings per year associated with use of only ionic contrast could alternatively be used to fund breast cancer screening to save 450 female life years (35 deaths), cervical cancer screening to save 2600 female life years (100 deaths), or cholesterol management to prevent 13 sudden deaths, 105 myocardial infarctions, and 250 cardiac events.⁶ In the prospective payer market, opportunity costs are an important focus when deciding how to spend limited resources. Rather than abandoning new and useful technology (e.g., drugs, devices) that has improved the current quality of anesthesia care, methods should be focused on eliminating wastage and unnecessary use of valuable but limited resources. In economic terms, it is conceptually useful to relate the cost of the latest unit of health service produced (the marginal cost) to the price that consumers are willing to pay for it (the marginal price). The theoretical point where marginal cost equals marginal price defines the level of service at which clinicians should begin the process of trimming waste and eliminating interventions that cost more than they are worth (valued).

Anesthetic Techniques: Cost Considerations

Value-based anesthesia management, when applied to the choice of anesthetic techniques, requires balancing the benefits and risks of these techniques against the total costs resulting from these choices. When assessing choices for anesthetic techniques, value can be attributed either to similar outcomes at lower total cost (both direct and indirect) or to better outcomes even if total costs are higher. Occasionally, anesthesiologists are able to utilize anesthetic techniques by which improved outcomes can be achieved at lower total cost, but this is less common. Despite general agreement about the definable end points used to quantitate the concept of increased value, the process of deriving value-based decisions regarding choice of anesthetic technique remains complex.

Certain conditions surrounding the planned surgical intervention often supersede cost considerations and predetermine the choice of anesthesia. For example, patient requests (desire to be awake versus asleep) and patient conditions (hypovolemia, severe coagulopathy), as well as provider skill, surgical requirements, and technology available may determine or limit the potential choices for anesthesia. Despite these limiting conditions, many surgeries are possible with two or more different techniques. Although there are a number of potential choices of techniques, the most common are general anesthesia, regional anesthesia (peripheral nerve block, central neuraxial or intravenous regional with or without sedation), combined general-regional anesthesia, local anesthesia with sedation, sedation alone, or local anesthesia alone. The last two choices are utilized only for minor or very limited procedures and are associated with apparent economy,⁶⁹ especially when local anesthesia alone is feasible.

Commonly, the choice is between general and regional techniques, especially when the surgical procedure is suitable for either technique. Examples of surgical procedures that can be readily accomplished with either regional or general techniques include lower or upper extremity orthopedic and vascular procedures, genitourinary procedures, and herniorrhaphies. Assessment of the value of specific anesthetic management strategies for such procedures is often difficult and requires analysis of the impact of a given technique on total costs, outcome, and perioperative efficiency. In addition, patients, payers, administrators, surgeons, and anesthesiologists may value alternative outcomes differently.

Currently, data on total costs of alternative anesthetic techniques are not widely available. Some data on total charges are obtainable, but as noted above, much caution must be exercised in the application of charge data. Analysis of some of the available cost data suggests that regional anesthesia may be more economical with regard to direct costs than general anesthesia.⁷⁰ However, more data are necessary before firm conclusions can be derived about the impact of anesthetic technique on total costs (including intraoperative, postoperative, and morbidity costs). Systematic evaluation of direct costs of various anesthetic techniques (drugs, equipment, and services) has not been conducted, and these costs may differ widely among institutions. In addition, indirect costs such as out-of-hospital costs (e.g., recovery time at home away from work) or expenses of treating complications related to provision of a given anesthetic technique are largely unquantified. These gaps in our current knowledge are compounded by the likelihood that total costs and benefits may be substantially different for a given anesthetic technique applied to different surgical populations. For example, although several benefits have been attributed to epidural anesthesia and analgesia, and it appears that some of these positive effects may be attributable to postoperative influences after major operative procedures in high-risk patients,^{30,71,72,73} actual cost analyses are either rudimentary or absent.

Unfortunately, anesthesia outcome data are currently incomplete; therefore, many comparisons of anesthetic techniques remain somewhat controversial. Few studies have quantitated outcome characteristics that reflect the value patients may place on their anesthetic and surgical experience. Such attributes as “patient satisfaction” or “time until resumption of normal activities” are difficult to measure and have not been commonly reported, although determination of the value of a specific anesthetic technique requires assessment of how these techniques affect patient experiences (e.g., nausea potentially resulting from general anesthesia and headaches potentially resulting from spinal or epidural anesthesia). In addition, the impact of anesthetic technique on the duration or requirement for postanesthesia monitoring, the overall efficiency of perioperative care, staffing requirements, and the cost of complications must be assessed. Accounting for both direct costs (e.g., equipment and material costs, drug costs, labor costs) and indirect costs (e.g., costs of rescue therapy to treat complications, labor and facility costs generated because of prolonged or complicated postoperative recovery) will enable anesthesiologists to determine the relative value of different anesthetic techniques in a given practice setting. The relative value of a specific intervention will vary in different clinical settings and be affected by patient characteristics, surgical considerations, and health facility constraints. Even the impact of an intervention such as forced air warming on net total perioperative costs depends on patient and surgical characteristics and institutional factors related to cost accounting.⁷⁴ Since most OR costs are fixed or semivariable⁵⁷ the reduction of time involved in postanesthesia recovery by maintaining core normothermia^{74,75} may not decrease overall costs unless the aggregate time in the OR or recovery room is reduced sufficiently to decrease staffing or

actually allow additional cases to be performed without increasing personnel costs. The influence of various anesthetic interventions on outcomes, perioperative efficiency, and total cost is an important area in which anesthesiologists can define value to patients, surgical colleagues, payers, and health facilities.

Costs of Monitoring

The costs of monitoring include the cost of the anesthesiologist, monitors, consumable items, OR time, maintenance costs, and the costs of complications (see [Table 6-5](#)). Capital equipment used for monitoring, assuming a long operational period and a high degree of utilization, generally does not contribute to significant cost on a per-case or per-hour basis. On the other hand, the costs of consumable items as well as the cost of operating time during the placement of invasive monitors can be significant, especially if no other patient-related activity is simultaneously occurring.

Clinical and economic guidelines have been proposed for evaluation of technology (such as monitoring equipment) prior to adoption and implementation.⁷⁶ Application of such an analysis requires inclusion of all relevant outcomes and incremental costs of alternative technologies, appropriate discounting of costs and clinical outcomes, and performance of sensitivity analyses. This approach has been criticized, but such guidelines provide a preliminary methodology for systematic economic comparison of various technologies. Such types of analyses have been applied to determine the cost per QALY of applying mechanical ventilation in the elderly (older than 85 years)⁷⁷ as well as in patients with various types of cancers.⁷⁸

The magnitude of the problems of evaluating high-cost technology is exemplified by the pulmonary artery (PA) catheter. More than \$2 billion is spent annually in the U.S. on hospital charges for the catheter and introducer sheath, sterile setup, transducers, and disposable thermodilution cardiac output supplies; physician charges for insertion of the catheter; and lab charges for mixed venous blood gas tension analyses. Despite the paucity of prospective, randomized trials suggesting beneficial outcome effects with use of the PA catheter to achieve specific therapeutic goals, application of this technology is widespread.^{79,80,81} Although the economic issues associated with the routine use of PA catheters are obviously important, the analysis is extremely complex. Application of cost-utility analysis and sensitivity analysis techniques to evaluate the economic impact of PA catheterization in patients undergoing coronary artery revascularization suggests that cost-effectiveness would be less than \$50,000 per QALY if PA catheterization reduced mortality by 30.2%, even if the incremental cost of PA catheterization were as high as \$500 compared to central venous catheterization alone.⁸² Although this compares favorably with some other accepted technologies (albeit in this theoretical derivation, the cost per QALY was greater than the estimated cost-effectiveness of three-vessel CABG surgery itself⁴⁶), the sample size requirements (200,000) would be prohibitively large to test the hypothesis of such an effect of PA catheterization on mortality in a randomized clinical trial.⁸²

Superficial analysis might suggest tremendous cost savings if significant numbers of patients with good ventricular function underwent CABG surgery without routine use of a PA catheter. In at least two studies, more than 1200 patients (68%) did not receive routine PA catheter monitoring,^{83,84} which conservatively translates into more than \$750,000 of direct cost savings in those studies alone. If one half of nearly 400,000 patients undergoing CABG annually in the U.S. did not routinely receive a PA catheter, this would represent approximately \$150 million of direct cost reduction each year. However, the indirect costs of use and, if not used, the indirect costs of failure to provide optimal cardiopulmonary support must be assessed. For example, if invasive monitoring helps prolong the life of terminally ill patients, it will be associated with enormous increases in direct costs and may provide limited benefit. On the other hand, if patients who would have died or suffered life-threatening complications can be spared because of precisely titrated care made possible by invasive monitoring, then the benefit is enormous. The direct costs of using PA catheters may therefore be trivial compared with the potential indirect savings. Although the “conservative” approach of selectively using invasive monitors is encouraged in the current medicoeconomic climate, such conservatism may represent a false economy both fiscally and in terms of outcome in certain patients. Practice parameters that guide physicians to the proper use of such technology may not only improve quality of care, but also help decrease costs by reducing unnecessary variability and suboptimal application of technology in clinical practice.^{79,80,81,85}

The pulse oximeter is another example of technology that has found widespread use because of the belief that it contributes to better patient outcome. In contrast to the PA catheter, however, simple amortization of the acquisition and maintenance costs (estimated at \$3500 and \$500, respectively) of a pulse oximeter with a finger probe reused in a single OR for 2000 patients over 2 years yields a cost of approximately \$2 per patient. Although the specific cost per case will vary depending on the purchase price, maintenance costs, and utilization rate, the estimated cost per patient of the pulse oximeter is orders of magnitude less than the cost of a PA catheter. Analogous to the PA catheter, there are as yet no prospective controlled investigations that have conclusively demonstrated in a scientific manner that pulse oximetry itself actually makes a difference in morbidity and mortality. A randomized multicenter trial of pulse oximetry in Denmark, which involved 20,802 patients divided into two groups, did not demonstrate an effect of that monitoring on actual morbidity and mortality, except for a decreased incidence of intraoperative myocardial ischemia.⁸⁶ For the most serious postoperative complications, anesthesia-related death and myocardial infarction, with incidences of 0.034% and 0.15%, respectively, the sample size requirement to achieve a statistical power of 90% in the latter study would have been more than 1 million and 500,000, respectively. To effectively assess the utility of pulse oximetry, outcome studies would need sample populations many-fold larger than used in the Danish study, would have to include a significantly greater proportion of patients at risk for adverse outcomes (e.g., ASA status III and IV, age over 60 years), and are unlikely to be conducted.

In the absence of such outcome studies, the decision to incorporate pulse oximetry as an ASA standard for basic intraoperative (as well as postanesthesia care unit) monitoring has been motivated primarily by evidence that pulse oximetry is superior to clinical judgment in providing early warning of hypoxic events and because retrospective review of anesthetic management associated with adverse events indicates that a large fraction of negative outcomes could be prevented by application of this technology. Significantly fewer patients have experienced “recovery room impact events” such as hypotension or dysrhythmias after pulse oximetry was introduced into the OR.⁸⁷ Another study found 11 major anesthesia-related mishaps in an analysis of more than 1 million anesthetics delivered to ASA I and II patients.⁸⁸ In this study eight anesthesia-related accidents involving inadequate ventilation or oxygenation and five deaths occurred during the 9.5 years before routine use of pulse oximetry and only one accident and no deaths occurred during the 3 years after use of pulse oximetry. Other evidence also suggests that pulse oximetry is associated with a reduction in anesthesia-related complications and unanticipated ICU admissions, primarily those related to the need to rule out myocardial infarction,⁸⁹ possibly because pulse oximetry facilitates early identification of hypoxemic, hypotensive, or low-perfusion states before subsequent ischemic changes become manifest or persist long enough to be of concern. This postulate is consistent with the Danish multicenter study demonstrating that angina or ECG ischemia occur in significantly fewer patients monitored with pulse oximetry than in a control group not monitored with pulse oximetry.⁸⁶ Although the marginal cost of additional ICU time has not been quantified,⁸⁹ a tremendous cost savings associated with the use of pulse oximetry is apparent even if we consider only the reduction in the rate of ICU admissions to rule out myocardial events.

Another retrospective analysis of the benefits of pulse oximetry, by the Closed Claims Project of the Professional Liability Committee of the ASA, determined that of 348 “preventable” injuries or deaths, “pulse oximetry . . . would have been efficacious in preventing injury in 138 cases.”⁹⁰ In contrast, monitors other than pulse oximetry or capnometry (e.g., the PA catheter or automated blood pressure devices) were considered potentially preventative in just 7% of the preventable injuries or deaths. The findings of the Closed Claims Project and those of other studies previously cited^{87,88,89} have considerable economic consequences; that is, if use of pulse oximetry is associated with reduction of preventable injury or death, not only will the indirect cost savings to patients and their families be great (especially in the case of permanently disabling injury), but the direct cost savings will also be substantial. Based on closed claims data, the median total cost of settlement or judgment was 11 times greater for injuries judged preventable by additional monitoring (\$250,000) compared with those judged not preventable (\$22,500).⁹⁰ This reduction in the cost of adverse outcomes has been recognized by medical liability insurance underwriters, so that the “liability insurance relativity factor,” an industry index of relative risk, subsequently decreased significantly for the specialty of anesthesiology.

Although there is still no published cost-benefit analysis of pulse oximetry, the type of data reviewed above strongly suggest that pulse oximetry improves the safety and outcome of anesthesia care and is probably cost-effective in this manner. Because of the low incidence of critical events and the presence of confounding factors such as other changes in technology, new drugs, and an overall increased awareness of risk management issues with an emphasis on increased vigilance, it will probably never be scientifically proved that pulse oximetry is an independent factor improving safety and outcome after anesthesia. Nonetheless, the weight of evidence supports the contention that the widespread application of pulse oximetry during anesthesia is associated with fewer cases of serious anesthesia-related morbidity and mortality and subsequently with significant cost savings. In contrast, widespread reduction in liability costs have not been attributed to devices such as the PA catheter; to the contrary, complications associated with the insertion and use of this monitor may occasionally increase costs.^{79,80,81}

OPERATING ROOM MANAGEMENT

Operating room management is an activity that is vital to the successful function of health facilities; it is also an activity in which anesthesiologists should participate because of their extensive knowledge and experience in the multiple aspects of the perioperative process. Anesthesiologists, acting in the role of physician-managers, can add significant value to the overall OR process by improving efficiencies in resource utilization and simultaneously, quality of care. Effective OR management requires examination of a process that begins when a surgical procedure is scheduled and encompasses examination and consideration of outcomes, cost-effectiveness, and customer satisfaction ([Table 6-6](#)). Construction of the daily OR schedule must be based on the optimum combination of supply and demand of limited and expensive resources (personnel, equipment, drugs, supplies) that contribute substantially to the overall cost of surgical services. Modifications of customary processes are often necessary to improve OR efficiency. For example, one approach to increase OR efficiency and potentially reduce costs in a large facility is the institution of “staggered” start times in alternating ORs for initial cases of the day. For the anesthesiologist responsible for more than one patient simultaneously, staggered start times minimize starting delays related to attending to more than one patient at time, a scenario that otherwise frequently occurs with simultaneously scheduled anesthetic inductions. This approach can be effective when staffing is flexible so that some OR and recovery room nurses can start at later times and split shifts. Such staggered staffing can also secondarily improve staff morale and enhance nursing coverage over broader ranges of hours without incurring extra costs. If

preoperative or postoperative facility space is limited and it is occupied at or above capacity, staggered start times can also reduce delays related to patient “bottlenecks” in the preoperative holding area and/or the PACU.

Table 6-6. EXAMPLES OF ACTIVITIES INVOLVED IN OPERATING ROOM (OR) MANAGEMENT

Effective OR management must address preadmission processing, preoperative assessment, OR scheduling, patient intake on the day of surgery, postanesthesia care (including PACU, ICU, and pain management) as well as coordination of nonsurgical support services (radiology, laboratory, clinical instrumentation, housekeeping, and transport [Fig. 6-6]). While the OR plays an essential role in most surgical services, all upstream and downstream activities must be integrated into a coordinated management approach. This is illustrated by the observation that nearly 50% of delays in PACU discharge of greater than 30 minutes, which can result in a backup of OR cases, occur in association with nonmedical factors (lack of bed availability, transport delays, unavailability of outpatient's escort to go home, unavailability of physician to write discharge orders/prescriptions, and so on).⁹¹ Because of the multifaceted nature of surgical services, effective coordination of the various components requires clearly defined reporting structures and rules of governance, as well as a well-functioning information management system. A well-managed OR can minimize unplanned delays that increase costs and create dissatisfaction among all OR users (patients, nurses, physicians).

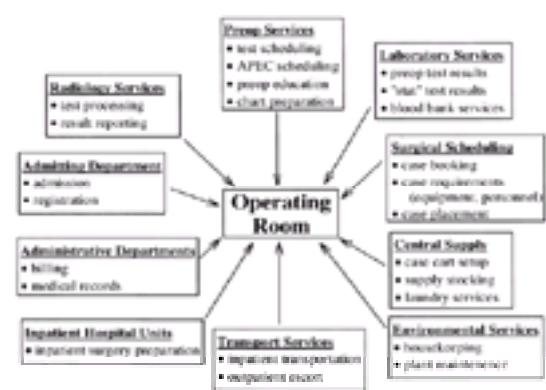

Figure 6-6. Multidisciplinary input into operating room processes.

Besides improved preoperative preparation in advance of patient arrival,³² improvements in OR efficiency can be achieved by analyzing OR data for causes of delays, devising strategies for minimizing the common types of delays and subsequently measuring delay data to determine if improvements are achieved and maintained.⁹² Successful implementation of such an approach requires personal accountability and multidisciplinary teamwork aimed at streamlining procedures with parallel rather than serial task performance (e.g., bringing patients into the OR for anesthetic preparation while OR nurses perform tasks simultaneously, rather than waiting until nursing tasks are completed).

Collection of accurate, minimally biased data to assess the etiology of delays is essential to developing process improvement plans. It may not be possible to exclude all bias from data collected by OR personnel, especially if data are self-reported as in the case of nursing delays. It is conceivable that more accurate data and improved efficiency can be obtained with the use of electronic patient tracking devices that monitor patient location as they move through the health facility.^{93,94} Such realtime patient tracking information may be used to make frequent, continual adjustments to OR and personnel assignments to avoid delays and optimize efficient allocation of resources. The problem of collecting accurate data is compounded by inconsistent definitions of various OR times. Definitions of start time and turnover time vary according to individual perspectives (see Table 6-7), and the specific definition of these events must be considered when developing process improvement plans.⁹⁵ The Association of Anesthesia Clinical Directors has developed a glossary of procedural times to help promote application of a common language for these terms.⁹⁶

| Perspective | Start Time | Turnover Time |
|---|------------------|---|
| OR nurses | OR "ready" time | Interval when OR unoccupied |
| Anesthesiologists | Induction time | Interval between PACU report and subsequent patient induction |
| Surgeons | Incision time | Interval between wound closure/dressing applied and subsequent patient incision |
| Association of Anesthesia Clinical Directors* | Patient OR entry | Interval between patient OR departure and subsequent patient OR entry |

Table 6-7. VARIABLE DEFINITIONS OF OPERATING ROOM TIMES*

Operating room utilization as a measure of efficiency can be defined as the time the OR is being used (set-up, occupied by patient, clean-up) divided by the length of time that OR is available with regular staffing. Other definitions of OR utilization that do not include set-up and clean-up time (raw utilization) results in lower percentage utilization for blocks of OR time with many cases and frequent room turnovers. Operating room utilization rates >70% are generally considered acceptable, with lower rates reflecting the need for management interventions to improve OR scheduling or other process improvement measures. Optimization of OR utilization requires consideration of variables such as average case duration, average patient waiting time for surgery, number of hours in each OR block time, number of blocks assigned to a surgeon/surgical group, and the specific scheduling strategy applied. Although OR utilization is used as a means to assess global OR efficiency, it may not reflect the impact of certain OR activities that contribute to inefficiency. An example of this occurs when a slow surgeon with long operating times fills his or her assigned block time, which will be reflected in a high rate of OR utilization despite contributing to inefficient use of overall OR time. The importance to cost reductions of shortening operative times cannot be overemphasized, since OR time has a large variable cost component and contributes one-third or more of total OR costs.⁵⁷

Achievement of efficiency in OR use must incorporate consideration of the satisfaction of all customers of the facility. A common problem encountered in developing an efficient OR scheduling algorithm is the difficulty in matching OR availability with the needs of surgeons' non-OR schedules (e.g., clinic practice, OR time at other surgical facility). This commonly results in surgical requests for scheduling in a horizontal fashion, typically resulting in multiple, overlapping requests for early start times. While some flexibility is required on the part of surgeons, use of a more vertical system of arranging cases can lead to improved efficiency, with significant conservation of resources, depending upon the economic structure within an OR facility. When large economic benefits can accrue by applying this strategy, an effective physician-manager may be required to persuade some surgeons to schedule clinic hours in the morning in order to reduce competition for early OR start times

and facilitate vertical OR scheduling.

Computer simulation suggests that OR utilization can be maximized by allocating block time for elective cases based on expected total hours of elective cases and scheduling patients into the first available date when open block time is available.⁹⁷ Implementing such a strategy requires flexibility on the part of the patient and the operating surgeon. It has been proposed that large increases in OR utilization can theoretically be realized by increasing the time patients wait prior to the scheduled date of surgery, although the larger the number of ORs available, the less prolongation of surgical wait time necessary to achieve improved scheduling efficiency.⁹⁷ To maximize OR utilization, as many add-on elective cases must be scheduled into any unused OR time slots. Although a variety of algorithms can be used to schedule such add-on cases,⁹⁸ all approaches can be constrained by equipment, personnel, and facility limitations, especially when there is overlapping need for specialized but limited resources. For example, although a particular OR can accommodate the addition of a 4-hour add-on elective case, if that case requires the use of extracorporeal circulation, but all cardiopulmonary bypass machines are in use, that case cannot be scheduled as desired. All scheduling strategies aimed at increasing OR utilization must also consider the availability of ORs for urgent or emergent cases and specific mechanisms to schedule surgeons who do not have block time.

In order to more accurately assess and correct any sources of inefficiency, the discrete individual functional events that occur as a patient is processed through the OR must be identified. Once these individual steps are identified (see [Table 6-8](#)), process analysis can be applied to individual patients to identify on a case-by-case basis at which step the delay occurred. Mean and median values for the time required for each step can be evaluated over time using process control methods. Both internal and external benchmarks can be applied for comparison. When a pattern of avoidable causes for delays is identified, efforts can be focused on individual steps in a process to improve performance. Examination of rates and causes for cancellation rates, for example, can be used to identify a list of common factors contributing to case cancellations, some of which may be easily correctable (e.g., better preoperative patient education regarding NPO status). Whenever avoidable and potentially correctable problems are identified, administrative expertise and intervention in the relevant discipline are required without losing sight of the multidisciplinary/multifaceted nature of these complex processes ([Fig. 6-6](#)). These analyses must account for known differences that exist in benchmark data for individual types of surgery. For example, complex orthopedic, neurosurgical, and cardiothoracic procedures consistently require longer periods of time for anesthetic induction, establishment of monitoring, and patient positioning than other types of operative procedures.^{92,99} Use of information systems to track perioperative outcomes and process quality assurance data can be effective in improving outcomes and reducing costs when clinicians are provided regular, personal feedback derived from these systems.¹⁰⁰

-
- Health facility registration if same day/ambulatory patient
 - Transport to preoperative holding area
 - Preanesthesia preparation by anesthesia team (including immediate preprocedural assessment of medical condition and lab evaluation)
 - Transport of patient into OR
 - Anesthesia induction, including insertion of additional catheters and monitoring devices
 - Patient positioning and sterile preparation
 - Operative procedure
 - Intraoperative diagnostic procedures (e.g., obtaining fluoroscopy, intraoperative ultrasound)
 - Anesthesia emergence
 - Transfer out of OR area to PACU or ICU
 - Report of patient status to subsequent care provider
 - PACU stay
 - Transfer from PACU to hospital room or home
-

Table 6-8. PROCESSES IN PATIENT FLOW THROUGH THE OPERATING ROOMS

Anesthesia-controlled time typically represents a small fraction (10–20%) of the total case time,^{14,92} the remainder (>80%) being surgeon- and nurse-controlled. Actual data for average operating time for a particular surgeon, actual average room turnover time (clean-up and set-up), and actual average anesthesia preparation and positioning times all vary according to the complexity of a particular operative procedure. Incorporation of actual data for these various processes will result in a more accurate prediction for efficient scheduling of OR resources. Avoidance of underutilization or overutilization will permit the maximum number of operations during regular working hours and minimize variable and semi-fixed costs. In the short term, variability in clinical practice can influence an individual surgeon's OR utilization, so that examination of relatively long epochs of block time usage may be more appropriate than evaluation of shorter epochs. Application of time series analysis indicates that the average of twelve successive 4-week periods of total hours of elective cases can be used to reliably predict the OR staffing required to complete a surgical groups' elective caseload during regular scheduled OR hours or to allocate to appropriate hours of block time to minimize OR labor costs.^{101,102} Indeed, improving the accuracy of OR scheduling based upon realistic surgical times may have greater positive impact on OR efficiency than OR personnel performance improvements. Inaccurately scheduled OR time contributes to inefficient OR utilization either by leading to gaps of time where ORs are not used or by delaying subsequent procedures with increased staffing costs incurred after regular hours which could be avoided by more appropriate scheduling of cases. In the broader perspective, the cost to a facility resulting from a minute delay in the arrival of the surgeon overshadows the direct costs associated with a 2-hour infusion of propofol.¹⁰³

The relative contribution of reductions in OR turnover time to overall cost savings depends on several interrelated factors. The most significant portion of operating costs is related to fixed personnel costs. If actual turnover time reduction were 30 minutes per day per OR, that may not be sufficient to permit addition of another revenue-producing case to be scheduled during the usual 8-hour shift.^{14,99} Furthermore, if OR staffing is flexible, and partially driven by scheduled caseload, then the relative contribution of OR turnover time can achieve greater economic potential. Operating rooms with more frequent turnovers and greater numbers of short-duration cases yield a greater aggregate time and cost savings because extra cases are more likely to be scheduled in this scenario. Whenever high fixed costs exist, adjusting or shifting fixed costs to match patient consumption is necessary to maintain efficiency.

Although using more accurate length of case information to improve scheduling accuracy, reducing variability in OR turnover times, and eliminating day-to-day variation in the number of hours of add-on cases can all improve OR utilization, computer analysis suggests that the most effective strategy to maximize OR utilization may be to select the days that elective cases are to be performed in order to best match OR caseload with staffing of OR personnel.¹⁰⁴

Another important component of OR management is materials management. Common objectives of efficient materials management are reduction in standing inventory of equipment and supplies as well as standardization of equipment, drugs, and supplies to avoid duplication, consolidate purchasing, and take advantage of volume pricing. Active involvement of physicians to compare and evaluate products of various vendors is essential so that informed decisions can be made about relative equivalency of products. In addition, effective contractual negotiations can often be successful in identifying the most favorable arrangement for cost reductions when multiple suppliers are offered the opportunity to negotiate lower prices for their product in a competitive bidding procedure.

POSTOPERATIVE ANESTHETIC AND CRITICAL CARE MANAGEMENT

The value of the anesthesiologist as an effective manager to arrange the OR schedule to improve efficiency of OR utilization lies not only in the impact on OR costs, but also in a profound influence on PACU costs at the end of the day. The impact of different temporal distributions of PACU admissions on costs is also determined by patient-to-nurse ratios, peak numbers of patients, and peak admission times. For example, if peak admission rates occur only early in the day, reduction in discharge times may not substantially affect the peak number of patients and subsequently have less direct impact on personnel costs. In contrast, if admission rates are distributed more evenly and continue into the afternoon, peak numbers of patients would decrease, and depending on the patient-to-nurse ratio, the staffing requirements may be reduced. The impact of reducing discharge time on personnel costs will depend not only on the temporal distribution of PACU admissions, but also on the management paradigms employed to distribute nursing personnel in a dynamic environment.

As competition for contracted health care becomes progressively more intense and focused not only on comparisons of the performance of doctors, hospitals, and other health care providers, but also on overall costs, anesthesiologists are confronted with the responsibility of defining the impact of anesthetic management on the efficiency and the overall cost of recovery after surgery. The economic impact of newer anesthetic drugs possessing pharmacokinetic and pharmacodynamic properties resulting in less complicated and more rapid recovery requires systematic investigation, considering overall costs and outcomes, in order to develop evidenced-based practice guidelines and protocols, and ultimately reduce costs ([Fig. 6-7](#)). When direct cost analysis indicates that a given alternative to patient care is more expensive than another, failure to quantitate or consider indirect cost savings may result in failure of government and third-party payers to fund that alternative unless an outcome benefit can be demonstrated compared to a "cheaper" alternative. Earlier return of patients to functional status after anesthesia and surgery can save societal costs and should be considered when evaluating overall costs.¹⁰⁵

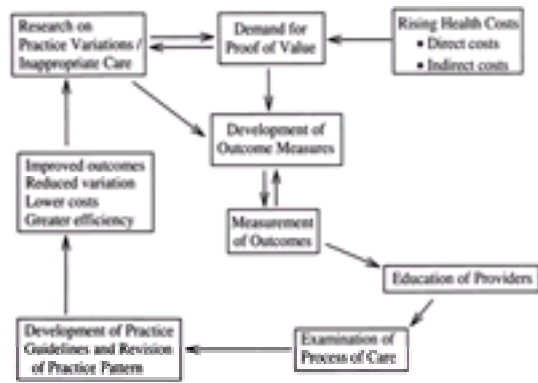

Figure 6-5. Use of outcome data to improve efficiency and reduce costs.

Strategies for Cost-Effective Postoperative Management

Evaluation of strategies to improve cost-effectiveness of perianesthetic management has consistently demonstrated that personnel costs represent the predominant fraction of overall expenditures. Computer simulations using published times to discharge with “fast recovery” drugs predict that use of such drugs would decrease PACU costs primarily if administered in ORs running later each day so that earlier discharge from the PACU would result in less PACU personnel utilization (assuming that the PACU would then close after a single patient was discharged).¹⁰⁶ If use of less expensive drugs is associated with the need for more prolonged postoperative nursing care owing to slower recovery or the need to manage more side effects, there will be a variable increase in the overall costs depending on whether staffing is semi-fixed or more flexible and whether the recovery room is at full occupancy.¹⁰⁶ In the latter instance, prolonged recovery room stay can have negative effects on upstream events, causing back-up of patient flow through the OR and markedly increasing cost. If the recovery room is not at full patient capacity and staffing of nurses is semi-fixed, there may be minimal impact on overall costs of even a 30-minute longer average time until recovery room discharge. Under these circumstances nonselective use of “fast recovery” drugs would probably not substantially diminish PACU costs compared to arranging an OR schedule to optimize admission patterns and reduce the amount of PACU personnel costs, especially at the end of the regular workday.¹⁰⁶ Conversely, if fast-tracking recovery protocols are not employed, even though awakening from anesthesia may be faster with newer, more expensive drugs, actual discharge from the ambulatory facility may not be quicker and overall costs will not be reduced.^{106,107} This is analogous to the role of anesthetic management to facilitate fast-tracking of cardiac surgical patients with reduced costs, improved resource utilization, and preserved outcomes.^{108,109} Improved resource utilization in all settings, whether involving complex in-patient procedures or relatively “simple” ambulatory procedures, requires a multidisciplinary team approach.

Assessment of high-volume, high-cost medical activities such as CABG surgery must include measures of several distinct aspects of quality: necessity, appropriateness, effectiveness, satisfaction, and efficiency. We can measure the impact of anesthetic and critical care of CABG patients on some of these characteristics. Most techniques currently employed to anesthetize patients for CABG surgery are “effective” in producing the basic elements of general anesthesia: unconsciousness, muscular relaxation, and attenuation of reflex responses to noxious surgical stimuli. Although choice of anesthetic agent *per se* has not been demonstrated to critically influence cardiac or noncardiac outcome after CABG surgery,^{110,111} anesthesiologists are being asked to make decisions about anesthetic management based in part on evaluation of customer satisfaction and the overall efficiency of care during and especially after an operation such as the CABG procedure. Outcomes research can facilitate development of practice guidelines to streamline perioperative management and make the recovery process as efficient as possible.

It has been suggested that ICU stays can be shortened if ventilator time is reduced and extubation is performed within a few hours after CABG surgery in awake, stable patients who have acceptable cardiopulmonary status and minimal chest tube drainage. Although anesthetic management with or without the use of more expensive drugs can allow early extubation (1–4 hours postoperatively) after cardiac surgery,¹¹² this alone will not reduce overall costs unless the overall recovery program (clinical pathway) allows extubated patients to move to the next phase of recovery in an expedited manner compared to patients who are extubated later (10–12 hours).¹⁰⁸ Intraoperative clinical process variables as well as intraoperative and postoperative morbidity overshadow the effect of preoperative risk factors as key determinants of the feasibility of early extubation and ICU length of stay.^{113,114} Coordinating early extubation with other aspects of hospitalization for CABG surgery is necessary to improve the efficiency of postoperative processes and to maximize the cost savings of this approach. If there is no impact of anesthetic drug on ultimate outcome after cardiac surgery, it may be cost-effective to use longer-acting anesthetic drugs with lower acquisition costs (compared with more costly, short-acting drugs) if recovery from anesthesia and tracheal extubation can be achieved within a time frame that does not interfere with the overall efficiency of fast-track recovery pathways.¹¹² As with other expensive and lengthy procedures, drug costs and turnaround time have less impact on overall costs of the CABG procedure compared to shorter-duration, less costly procedures. Other factors, such as the feasibility of using a cardiac surgery recovery area rather than a standard ICU for postoperative recovery, will result in significantly larger cost reductions. Furthermore, modifications of anesthetic and surgical technique to permit myocardial revascularization without extracorporeal circulation may reduce the need for transfusion, OR time, and length of ICU and hospital stay. The latter factors contribute the greatest fraction of total hospital cost for the CABG procedure. Therefore, while the use of additional pharmaceuticals or special equipment to accomplish coronary artery surgery without cardiopulmonary bypass may potentially increase total OR costs (even after considering the costs avoided by not using a cardiopulmonary bypass device), these additional costs are likely to be offset by the overall hospital cost reduction associated with this approach. This example underscores the importance of considering overall costs and illustrates how modifications of clinical practice can be cost-effective even when portions of direct costs increase.

Clinical pathways are based on an organized team approach to patient management and typically are developed by a multidisciplinary group composed of physicians, nurses, pharmacists, administrators, and others who are involved in the patient’s experience. These instruments serve as management plans that outline goals for patients and are generally based upon “best practice” experience, clinical practice consensus, and evidence from the scientific literature. They define the ideal sequence and timing of interventions to achieve the prespecified goals with optimal efficiency. Clinical pathways address the variability in practice by standardizing practice in the individual health care setting according to an agreed-upon common regime of clinical interventions. Every detail is important to the success of a clinical pathway, so that all aspects of care can be coordinated to increase efficiency and achieve optimal outcome with expeditious patient discharge. Rapid discharge is important not only for hospitalized patients, but also for patients undergoing ambulatory surgical procedures. Most current clinical pathways are “vertically” directed toward accomplishment of specific goals in a timely fashion. The role of the anesthesiologist is key in many critical pathways so that emergence from anesthesia is prompt and so that intensive physiologic support can be discontinued as expeditiously as possible. This typically facilitates movement of the patient to the next successive goal(s) of the recovery phase. Adequate perioperative analgesia can also facilitate recovery and enhance early mobilization, ambulation, and rehabilitation with the goal of resuming normal activity. The clinical pathway concept applied to perioperative anesthetic patient management with standardization of system management, drugs, and equipment as well as incorporating fast-tracking and phase I recovery bypass options have been shown to be effective in containing costs, enhancing process efficiency, and improving patient outcomes in ambulatory orthopedic surgery.¹¹⁵

Recovery after Ambulatory Surgery

Provision of analgesia and avoidance of side effects such as postoperative nausea and vomiting are especially critical in ambulatory surgery so that patients can be promptly discharged home. Postoperative analgesia must be provided and must be effective as soon as possible upon emergence from the OR. Failure to accomplish this can lengthen duration of stay in the PACU, delay home discharge in the ambulatory setting, and result in customer dissatisfaction. In this sense, the customer is not only the patient, but also the facility, which must manage patients efficiently to be competitive in the health delivery market. Judicious use of preoperative and intraoperative analgesics (opioid and nonopioid), application of local anesthetics to the surgical site and regional anesthesia all can facilitate an efficient recovery and high levels of customer satisfaction. Although substantial variability exists among patients’ rating of preferences for anesthesia outcomes, avoiding nausea and vomiting appears to be a high priority for most patients, who would be willing to spend more to avoid that outcome compared to some other adverse events.¹¹ Such information can be applied to guide the choice of anesthetic drugs to provide the greatest value and achieve the highest level of customer satisfaction. This information also highlights that value is context sensitive. The anesthesiologist may place greater value on the intraoperative aspects of managing a complex patient and lesser importance on postoperative nausea after a challenging operative procedure. However, not addressing this issue will potentially result in a failure to meet an important customer expectation (minimal nausea and pain). Even though the anesthesiologist may place greater importance on other aspects of care in this scenario, the value of the anesthesiologist as viewed by the patient (customer) will be diminished unless such expectations are realized. The context sensitivity of values depends on the individual perspective of each customer of anesthesia services, as reflected by the examples illustrated in [Table 6-1](#). The characteristics of a product or service that customers perceive as contributing to value are dynamic, and successful strategies to maintain and continually improve the value of anesthesiology services requires anticipation of future needs of customers that will change perceptions of value.

New drugs or techniques that are associated with less frequent or less severe side effects, prompter recovery, and decreased mean times to discharge may permit total nursing hours to be adjusted downward. Significant cost savings without any change in outcomes can be achieved by avoiding routine admission to first-stage postanesthesia care units and using selective admission to phase II recovery units based upon whether the patient meets specific criteria in the OR at the end of the surgical procedure. If patients meet discharge criteria typically used at the end of a PACU stay, they could be transferred from the OR directly to a less labor-intensive

second-stage recovery unit, reducing both postoperative time until discharge and costs. In addition to achieving appropriate physiologic status (satisfactory motor strength and mental status with acceptable vital signs and oxygen saturation while breathing room air), anesthetic management that facilitates bypass of phase I PACU must also be focused on emergence from surgery with no vomiting and minimal pain or nausea. Under these circumstances, use of drugs with greater acquisition costs that have better recovery profiles than drugs with less direct cost can be associated with reduced overall costs and improved customer satisfaction. If the same or a better outcome cannot be achieved with a less expensive drug, the more expensive drug is more cost-effective because it decreases overall unit cost. Maximal cost savings by using drugs with favorable recovery profiles are unlikely to be realized—despite reductions of PACU discharge times or reductions in the peak numbers of patients in the PACU—unless nursing personnel can be shifted, depending on patient load, from one area of perioperative patient care to another (ambulatory admitting, ambulatory Phase I or Phase II recovery). Such a flexible core-staffing model is based on a dynamic distribution of resources, improving the efficiency of personnel utilization. Other methods of decreasing costs involve increasing patient-to-nurse ratios whenever possible, directly decreasing personnel requirements. Such an alternative is feasible if patients awaken promptly and have less complicated recovery profiles (e.g., less nausea and vomiting), necessitating less intense nursing interventions. Elimination or modification of predefined requirements for a minimum number of nurses to staff a recovery area (regardless of whether even a single uncomplicated patient is present) can also reduce costs. Since personnel costs represent a major fraction of PACU costs, less expensive teams of personnel headed by a staff nurse can be utilized in the recovery setting with preservation of quality care. This is especially feasible when greater numbers of patients leave an operating room ready or near-ready for immediate phase II recovery. Because of institutional variability, decision analysis and sensitivity analysis can be useful to determine how various assumptions in nursing staffing and recovery room capacity would affect overall costs when comparing anesthetic techniques with different recovery and side-effect profiles.⁵⁶

Cost Issues in the ICU

Outside of the OR, anesthesiologists who practice in the ICU work in a setting that is a major contributor to escalating health care expenditures. Critical care units account for nearly one-fifth of total hospital costs and one-twelfth of the total U.S. health care.¹¹⁶ ICU patients constitute the minority of all surgical patients but consume almost half of all surgical resources. The disproportionate share of health care resources devoted to the critically ill is related to the high labor intensity and technological dependence of ICU care. The magnitude of resources consumed has created intense interest in cost analysis in the ICU. Anesthesiologists practicing critical care medicine in an ICU may be able to demonstrate the value of their services by documenting optimization of processes of care, improved patient outcomes and reduced consumption of resources.^{117,118}

Restricting ICU admissions as a method to reduce costs is difficult since, in most cases, it is not possible to accurately predict nonsurvivors from survivors on admission to the ICU, despite the development of many severity-of-illness scoring systems. Nonetheless, some data suggest that ICU bed availability reductions, either by design or demand, can result in fewer patients' being admitted for monitoring alone, with a shift in patient acuity to a higher level but no change in mortality.^{119,120} Unfortunately, unlike some inpatient services, such as various elective surgical procedures that can be shifted to the outpatient setting, most critical care is usually inelastic and can be provided only in the ICU environment.

Currently, it is an easier endeavor to diminish charges in the ICU than to restrict admissions. Selective, rather than routine, ordering of so-called "screening" tests is one means of reducing costs. Deletion of standing orders for such tests as blood gases, glucose, electrolytes, complete blood count with differential, ECGs, and chest x-rays can make a large impact on cost reduction, usually with no increase in ICU morbidity rate, length of stay, or cost of medications.¹²¹ For example, in the patient who has cardiopulmonary stability, the use of standing orders for arterial blood gas tension analysis (e.g., beginning of nursing shifts, after every ventilator change) is probably not cost-effective. Replacement of frequent blood gas tension analyses with monitoring using capnometry and oximetry may be more cost-effective, but this requires implementation of formal and standardized guidelines for the most efficient use of such noninvasive monitoring.¹²² As with preoperative and intraoperative management, the utility of eliminating "small ticket items" can be great when the cumulative number of these items is large.

Just as routine preoperative testing is inefficient and wasteful of costly resources, routine ordering of postoperative tests must also be avoided, especially when this behavior results from the perceived need to have test results be part of a potential medicolegal record rather than of practical patient value. Similar principles should guide the postoperative use of diagnostic technology such as echocardiography, electroencephalography, and PA catheterization. Such diagnostic technology should be used only if it might change a diagnostic or treatment strategy. Tests with high sensitivity work best for confirming a suspected diagnosis, and those with high specificity are best for excluding a diagnosis. When two technologies have equal diagnostic accuracy, consideration should be given to using the one with the lower cost if patient risks are the same. All of this requires familiarity with the cost, sensitivity, and specificity of the various diagnostic and monitoring technologies we utilize. Teaching these concepts and use of probabilistic reasoning is more effective than simple cost-containment education in improving the efficiency of clinical decisions such as test ordering.¹²³ Published estimates of sensitivity and specificity cannot be trusted blindly, because a given test or monitor may be very sensitive and moderately specific in one hospital but moderately sensitive and very specific in another, depending on the patient population and how the test or monitor is used. Implementation of practice guidelines and information management systems based on these considerations should help achieve substantial and significant reductions in diagnostic testing of hospitalized patients without adverse effects on quality of care as measured by clinical outcome.¹²¹

The most difficult issue in containing ICU costs is not that of reducing expenditures on diagnostic testing or monitoring, but involves identification of nonsurvivors as early as possible after ICU entry. This requires dynamic evaluation and has potential for cost containment with little if any change in outcome. Although most physicians, patients, and families want to avoid ordering more and more tests and performing more and more procedures in attempts to "fix something" without changing the outcome of patients who are destined to be nonsurvivors, identification of nonsurvivors remains a difficult process. The application of high levels of technology to patients who are hopelessly ill with essentially no chance of meaningful recovery is being challenged not only by health care economists, but by the public as well. Debate on the use of futile and/or inappropriate intensive care has intensified in the last few years, and many believe that minimizing futile care is one of the first necessary steps in health care reform.¹²⁴ Although the savings from reduced use of futile care may be modest,¹²⁵ cost savings from reducing inappropriate care may be substantial.^{126,127} Inappropriate expectations of medical care sometimes motivate excessive use of diagnostic and therapeutic modalities in the ICU. The course of action dictated by comparing costs with benefits inevitably involves compromise and requires adjustment of expectations of physicians, patients, and those who fund critical care. Alternative methods of patient management such as intensive home care may more cost-effectively bring hospital-level intervention to some patients in their homes or as outpatients. Provision of intravenous nutrition, ventilator support, dialysis, and management of heart failure (e.g., chronic infusions of inotropes) at home with avoidance of long-term hospitalization may not only allow greater patient comfort, but also potentially contribute to large cost savings, especially in patients who require prolonged support but have irreversible disease processes. Significant progress in reducing costs of managing ventilator-dependent patients has already been documented, including the use of step-down, intermediate care units, and general medical floors with lower staff-to-patient ratios and less overhead costs, without changing eventual outcome.¹²⁸

CONCLUSIONS

Value-based anesthesia management focuses on patient needs and expectations to optimize efficiency of care for individual patients. This is a dynamic process that requires the proactive involvement of anesthesiologists in multiple aspects of preoperative, intraoperative, and postoperative care. Intelligent cost-containment measures require efficient use of existing resources and selectivity in perioperative testing, drug choices, and monitoring (Table 6-9). This can be done only with sufficient knowledge of medical economic analysis and data that define the necessary amount of testing and monitoring for effective patient care and eliminate excessive use of technology unless there is compelling evidence that more expensive alternatives are of greater benefit. Indirect costs or benefits of patient management paradigms must be considered: the economic impact of parameters such as the delay in the resumption of normal activities after anesthesia and surgery can be substantial. In addition, both allocative and operational efficiency must be addressed. Reducing length of stay in the ambulatory care unit after hernia surgery is just as important as reducing the length of stay after CABG surgery.

-
- Focus on costs, not charges
 - Consider all costs (direct and indirect) for all clinical alternatives
 - Identify all potential benefits and risks for all clinical alternatives
 - Evaluate allocative efficiency as well as operational efficiency
 - Adopt clinical strategies that eliminate ineffective diagnostic and therapeutic procedures (e.g., apply selective discipline in ordering tests and consultations)
 - Reduce use of high-cost strategies whose advantage over lower-cost strategies is debatable
 - Apply all available cost-effectiveness data to define nature of anesthesia services and clinical strategies
 - Develop clinician-generated practice guidelines with an emphasis on real outcomes
 - Assume a proactive role in OR, ICU, and facility management
 - Eliminate administrative waste
-

Table 6-9. APPROACHES TO ACHIEVE VALUE-BASED ANESTHESIA MANAGEMENT

Eliminating waste and increasing flexibility in the administrative aspects of perioperative care are also essential to provide value-based anesthesia services. Replacing rigid protocols such as the requirement of a minimal designated time in a Phase I recovery area (with protocols that apply physiologic end points for discharge criteria) may be required to definitively demonstrate the potential impact of newer, shorter-acting drugs on overall costs. Application of disciplined logic must replace the use of standardized protocols. Practice parameters, based on outcome data that define what really works for patients, can facilitate informed medical decisions but should not mandate individual patient care.

The increasing application of global payment methodologies has created an environment that encourages collaborative economic efficiency. In this regard, a multidisciplinary approach to improving preoperative patient preparation, reducing turnaround time between surgical cases, optimizing OR utilization, and reducing duration of recovery time will help control direct costs as well as lessen overhead costs. Such improvements in efficiency with institutional cost savings have the secondary benefit of making a practice setting more competitive in the medical marketplace. Operating room management is important for successful function of health facilities and is an activity in which anesthesiologists should participate because of their knowledge and experience in the multiple aspects of the perioperative process. As cost constraints on every aspect of health care delivery become more stringently imposed, establishment of a value-based practice of anesthesia requires that the anesthesiologist act pivotally as the perioperative physician with the broadest knowledge and expertise linking the preoperative, intraoperative, and postoperative phases of patient care.

INTRODUCTION

The introduction of general anesthetics into clinical practice 150 years ago stands as one of the seminal innovations of medicine. This single discovery facilitated the development of modern surgery and spawned the specialty of anesthesiology. Despite the importance of general anesthetics and despite over 100 years of active research, the molecular mechanisms responsible for anesthetic action remain one of the unsolved mysteries of pharmacology.

Why have mechanisms of anesthesia been so difficult to elucidate? Anesthetics, as a class of drugs, are challenging to study for three major reasons:

1. Anesthesia, by definition, is a change in the responses of an *intact animal* to external stimuli. It has proved very difficult to definitively link anesthetic effects observed *in vitro* to the anesthetic state observed and defined *in vivo*.
2. There are no apparent structure–activity relationships among anesthetics; a wide variety of structurally unrelated compounds, ranging from steroids to elemental xenon, are capable of producing clinical anesthesia. It is thus unclear whether there are many mechanisms of anesthesia or, as the unitary theory of anesthesia (see [Chemical Nature of Anesthetic Targets](#)) suggests, a single mechanism.
3. Anesthetics work at very high concentrations in comparison to drugs, neurotransmitters, and hormones that act at specific receptors. This implies that if anesthetics do act by binding to specific receptor sites, they must bind with very low affinity and probably stay bound to the receptor for very short periods of time. Low-affinity binding is much more difficult to observe and characterize than high-affinity binding.

Despite these difficulties, molecular and genetic tools are now available that should allow for major insights into anesthetic mechanisms to occur in the next decade. The aim of this chapter is to provide a conceptual framework for the reader to catalog current knowledge and integrate future developments about mechanisms of anesthesia. Five specific questions will be addressed in this chapter:

1. What is anesthesia and how do we measure it?
2. What is the anatomic site of anesthetic action in the central nervous system?
3. What are the cellular neurophysiologic mechanisms of anesthesia (e.g., effects on synaptic function *versus* effects on action potential generation) and do anesthetic effects on ion channels and neuromodulatory chemical second messenger systems underlie these mechanisms?
4. What are the molecular targets of anesthetics?
5. How are the molecular and cellular effects of anesthetics linked to the behavioral effects of anesthetics observed *in vivo*?

WHAT IS ANESTHESIA?

General anesthesia can broadly be defined as a drug-induced reversible depression of the central nervous system resulting in the loss of response to and perception of all external stimuli. Unfortunately, such a broad definition is inadequate for two reasons. First, the definition is not actually broad enough. Anesthesia is not simply a deafferented state; amnesia and unconsciousness are important aspects of the anesthetic state. Second, the definition is too broad, as all general anesthetics do not produce equal depression of all sensory modalities. For example, barbiturates are considered to be anesthetics, but they are not particularly effective analgesics. These conflicting problems with definition, can be bypassed by a practical definition of the anesthetic state as a collection of “component” changes in behavior or perception. The components of the anesthetic state include unconsciousness, amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimulation.

Regardless of which definition of anesthesia is used, it is clear that anesthesia is always defined by drug-induced changes in behavior or perception. As such, anesthesia can only be defined and measured in the intact organism. Changes in behavior such as unconsciousness or amnesia can be intuitively understood in higher organisms such as mammals, but become increasingly difficult to define as one descends the phylogenetic tree. Thus, while it is known that anesthetics have effects on organisms ranging from worms¹ to man, it is difficult to map with certainty the effects of anesthetics observed in lower organisms to any of our behavioral definitions of anesthesia. This contributes to the difficulty of using simple organisms as models in which to study the molecular mechanisms of anesthesia. Similarly, any cellular or molecular effects of anesthetics observed in higher organisms can be extremely difficult to link with the constellation of behaviors that constitute the anesthetic state. The absence of a simple and concise definition of anesthesia is clearly one of the stumbling blocks to elucidating the mechanisms of anesthesia at a molecular and cellular level.

HOW IS ANESTHESIA MEASURED?

In order to study the pharmacology of anesthetic action, it is absolutely essential that there be a quantitative measurement of anesthetic potency. To this end, Eger and colleagues have defined the concept of MAC, or minimum alveolar concentration. MAC is defined as the alveolar partial pressure of a gas at which 50% of humans will not respond to a surgical incision.² In animals, MAC is defined as the alveolar partial pressure of a gas at which 50% of animals will not respond to a noxious stimulus, such as tail clamp,³ or at which they lose their righting reflex. The use of MAC as a measure of anesthetic potency has two major advantages. First, it is an extremely reproducible measurement that is remarkably constant over a wide range of species.² Second, the use of end-tidal gas concentration provides an index of the “free” concentration of drug required to produce anesthesia, since there should be an equilibrium between end-tidal gas concentration and free concentration in plasma. There are also several important limitations to the MAC concept, particularly when trying to relate MAC values to anesthetic potency observed *in vitro*. First, the end point in a MAC determination is quantal: a subject is either anesthetized or unanesthetized; it cannot be partially anesthetized. Furthermore, MAC represents the average response of a whole population of subjects rather than the response of a single subject. The quantal nature of the MAC measurement makes it very difficult to compare MAC measurements to concentration–response curves obtained *in vitro*, where the graded response of a single preparation is measured as a function of anesthetic concentration. The second limitation of MAC measurements is that they can only be directly applied to anesthetic gases. Parenteral anesthetics (barbiturates, neurosteroids, propofol) cannot be assigned a MAC value, making it difficult to compare the potency of parenteral and volatile anesthetics. A MAC equivalent for parenteral anesthetics is the free concentration of the drug in plasma required to prevent response to a noxious stimulus in 50% of subjects; this value has been estimated for several parenteral anesthetics.⁴ The third limitation of MAC is that it is highly dependent on the anesthetic end point used to define it. For example, if loss of response to a verbal command is used as an anesthetic end point, the MAC values obtained (MAC_{awake}) will be much lower than classic MAC values based on response to a noxious stimulus. Indeed, it is likely that each behavioral component of the anesthetic state will have a different MAC value. Despite its limitations, MAC remains the most robust measurement and the standard for determining the potency of volatile anesthetics.

The foregoing discussion of MAC brings forth an important and somewhat controversial question. What drug concentration should be measured when determining anesthetic potency? When measuring potency of intravenous anesthetics, the answer to this question is relatively simple. One would like to relate the free

concentration of the drug at its site of action (the biophase) to the drug's effect. It is, of course, not practical to measure the drug's concentration in the extracellular fluid of the brain, so free concentration in plasma is used as an approximation of the biophase concentration. This allows one to compare the concentration of drug required to produce anesthesia in humans to the concentrations required to produce specific effects *in vitro*. With the volatile anesthetics, potency is defined by MAC, which is measured in units of partial pressure. Since the partial pressure of a dissolved gas is directly proportional to the free concentration of that gas in a liquid, alveolar partial pressures are accurate reporters of the free anesthetic concentrations in plasma and in brain tissue. However, as one lowers temperature, anesthetic gases become much more soluble in plasma; at a given anesthetic partial pressure the free concentration of anesthetic will markedly increase as one lowers temperature. Thus, anesthetic potency increases significantly as one lowers temperature if potency is defined using MAC values.⁵ Most of this apparent increase in potency is due to increased anesthetic solubility; anesthetic potency increases only slightly at lower temperatures, if potency is defined using free concentrations of anesthetic.⁶ This issue becomes important in *in vitro* studies of anesthetic mechanisms where experiments are carried out at a variety of temperatures. Anesthetic partial pressures that are considered clinically relevant at room temperature (25°C) are approximately half the partial pressures needed to produce anesthesia at body temperature (37°C). In contrast, the free anesthetic concentrations that should be considered clinically relevant show only small variation with temperature.

WHERE IN THE CENTRAL NERVOUS SYSTEM DO ANESTHETICS WORK?

In principle, general anesthesia could result from interruption of nervous system activity at myriad levels. Plausible targets include peripheral sensory receptors, spinal cord, brain stem, and cerebral cortex. Of these potential sites, only peripheral sensory receptors can be eliminated as an important site of anesthetic action. Animal studies have shown that fluorinated volatile anesthetics have no effect on cutaneous mechanosensors in cats⁷ and can even sensitize nociceptors in monkeys.⁸ Furthermore, selective perfusion studies in dogs have shown that MAC for isoflurane is unaffected by the presence or absence of isoflurane at the site of noxious stimulation, provided that the central nervous system is perfused with blood containing isoflurane.⁹

Spinal Cord

It is clear that anesthetic actions at the spinal cord cannot explain either amnesia or unconsciousness. However, several lines of evidence indicate that the spinal cord is probably the site at which anesthetics act to inhibit purposeful responses to noxious stimulation. This is, of course, the end point used in most measurements of anesthetic potency. Rampil and colleagues have shown that MAC values for fluorinated volatile anesthetics are unaffected in the rat by either decerebration¹⁰ or cervical spinal cord transection.¹¹ Antognini and colleagues have used the strategy of isolating the cerebral circulation of goats to explore the contribution of brain and spinal cord to the determination of MAC. They found that when isoflurane is administered only to the brain, MAC is 2.9%, whereas when it is administered to the entire body, MAC is 1.2%.¹² Surprisingly, when isoflurane was preferentially administered to the body and not to the brain, isoflurane MAC was reduced to 0.8%.¹³ The actions of volatile anesthetics in the spinal cord are mediated, at least in part, by direct effects on the excitability of spinal motor neurons. This has been demonstrated in rats,¹⁴ goats,¹⁵ and humans¹⁶ by showing that volatile anesthetics depress the amplitude of the F wave in evoked potential measurements (F-wave amplitude correlates with motor neuron excitability). These provocative results suggest not only that anesthetic actions at the spinal cord underlie the determination of MAC, but that anesthetic actions on the brain may actually sensitize the cord to noxious stimuli. The plausibility of the spinal cord as a locus for anesthetic effect is also supported by several electrophysiologic studies showing inhibition of excitatory synaptic transmission in the spinal cord.^{17,18,19 and 20}

Reticular Activating System

It has long been speculated that the reticular activating system, a diffuse collection of brain stem neurons involved in arousal behavior, is involved in the effects of general anesthetics on consciousness. Evidence to support this notion came from early whole animal experiments showing that electrical stimulation of the reticular activating system could induce arousal behavior in anesthetized animals.²¹ A role for the brain stem in anesthetic action is supported by studies examining somatosensory evoked potentials. Generally, these studies show that anesthetics produce increased latency and decreased amplitude of cortical potentials, indicating that anesthetics inhibit information transfer through the brain stem.²² In contrast, studies using brain stem auditory evoked potentials have shown variable effects ranging from depression to enhancement of information transfer through the reticular formation.^{23,24 and 25} While there is evidence that the reticular formation of the brain stem is a locus for anesthetic effects, it cannot be the only anatomic site of anesthetic action for two reasons. First, as discussed above, the brain stem is not even required for anesthetics to inhibit responsiveness to noxious stimuli. Second, the reticular formation can be largely ablated without eliminating awareness.²⁶

Cerebral Cortex

The cerebral cortex is the major site for integration, storage, and retrieval of information. As such, it is a likely site at which anesthetics might interfere with complex functions like memory and awareness. Anesthetics clearly alter cortical electrical activity, as evidenced by the consistent changes in surface EEG patterns recorded during anesthesia. Anesthetic effects on patterns of cortical electrical activity vary widely among anesthetics,²⁷ providing an initial suggestion that all anesthetics are not likely to act through identical mechanisms. *In vitro* electrophysiologic studies examining anesthetic effects on different cortical regions support the notion that anesthetics can differentially alter neuronal function in various cortical preparations. For example, volatile anesthetics have been shown to inhibit excitatory transmission at some synapses in the olfactory cortex²⁸ but not at others.²⁹ Similarly, whereas volatile anesthetics inhibit excitatory transmission in the dentate gyrus of the hippocampus,³⁰ these same drugs can actually enhance excitatory transmission at other synapses in the hippocampus.³¹ Anesthetics also produce a variety of effects on inhibitory transmission in the cortex. A variety of parenteral and inhalation anesthetics have been shown to enhance inhibitory transmission in olfactory cortex²⁹ and in the hippocampus.³² Conversely, volatile anesthetics have also been reported to depress inhibitory transmission in hippocampus.³³ One area of the brain that has been postulated as a potential site of anesthetic action is the thalamus. The thalamus is important in relaying sensory modalities and motor information to the cortex *via* thalamocortical pathways. There is a developing body of evidence that inhalational anesthetics can depress the excitability of thalamic neurons, thus blocking thalamocortical communication.³⁴ This is a potential mechanism for anesthetic-induced loss of consciousness.

Summary

Anesthetics are able to produce effects on a variety of anatomic structures in the CNS, including spinal cord, brain stem, and cerebral cortex. Whereas certain anesthetic effects may be attributable to specific anatomic locations (*e.g.*, purposeful response to noxious stimulation maps to the spinal cord), there is no basis for identifying a single anatomic site responsible for anesthesia. It is plausible that this difficulty in identifying a site for anesthesia results from the fact that various components of the anesthetic state are being produced by anesthetic effects in different regions of the CNS. Nevertheless, the difficulty in identifying a common anatomic site for anesthesia has led investigators to look for other unifying principles in anesthetic action. Specifically, attention has been focused on identifying common cellular or molecular anesthetic targets that may have a wide anatomic distribution, explaining the ability of anesthetic to affect nervous system function in an anatomically diffuse manner.

HOW DO ANESTHETICS INTERFERE WITH THE ELECTROPHYSIOLOGIC FUNCTION OF THE NERVOUS SYSTEM?

In the simplest terms anesthetics inhibit or "turn off" vital central nervous system functions. They must do this by acting at specific physiologic "switches." A great deal of investigative effort has been devoted to identifying these switches. In principle, there are several ways in which the CNS could be switched off:

1. By depressing those neurons or pattern generators that subserve a pacemaker function in the CNS.
2. By reducing neuronal excitability; either by changing resting membrane potential or by interfering with the processes involved in generating an action potential.
3. By reducing communication between neurons; specifically, by either inhibiting excitatory synaptic transmission or enhancing inhibitory synaptic transmission.

Pattern Generators

There is limited information concerning the effects of anesthetics on pattern-generating neuronal circuits in the CNS, but it is likely that clinical concentrations of anesthetics do have significant effects on these circuits. The simplest evidence for this is the observation that most anesthetics exert profound effects on respiratory rate and rhythm, strongly suggesting an effect on respiratory pattern generators in the brain stem. Experimental evidence from invertebrate studies suggests that volatile anesthetics can selectively inhibit the spontaneous firing of specific neurons. As shown in [Figure 7-1](#), halothane (1.0 MAC) completely inhibits spontaneous action potential generation by one neuron in the right parietal ganglion of the great pond snail while producing no observable effect on the firing frequency of adjacent neurons.³⁵

Figure 7-1. Selectivity of volatile anesthetic inhibition of neuronal automaticity. Halothane (1 MAC) reversibly inhibits the spontaneous firing activity of a neuron from the parietal ganglion of *Lymnaea stagnalis* (Panel A). The same concentration of halothane has no effect on the firing activity of an adjacent, and apparently identical, neuron (Panel B). Note that in Panel A, halothane markedly reduces resting membrane potential in addition to inhibiting firing. (Reprinted with permission from Franks NP, Lieb WR: Mechanisms of general anesthesia. *Environ Health Perspect* 87:204, 1990.)

Neuronal Excitability

The ability of a neuron to generate an action potential is determined by three parameters: resting membrane potential, the threshold potential for action potential generation, and the function of voltage-gated sodium channels. There is strong evidence that anesthetics can hyperpolarize (create a more negative resting membrane potential) both spinal motor neurons and cortical neurons,^{36,37} and this ability of anesthetics to hyperpolarize neurons correlates with anesthetic potency. In general, the increase in resting membrane potential produced by anesthetics is small in magnitude and is unlikely to have an effect on axonal *propagation* of an action potential. Small changes in resting potential may, however, inhibit the *initiation* of an action potential either at a postsynaptic site or in a spontaneously firing neuron. Indeed, hyperpolarization is responsible for the inhibition of spontaneous action potential generation shown in [Figure 7-1](#). Recent evidence also indicates that isoflurane hyperpolarizes thalamic neurons, leading to an inhibition of tonic firing of action potentials.³⁴ There is no evidence indicating that anesthetics alter the threshold potential of a neuron for action potential generation. Similarly, most evidence indicates that clinically relevant concentrations of anesthetics do not alter the function of the voltage-gated channels involved in action potential generation.³⁸ A possible exception to this is the recent work of Duch showing that clinical concentrations of fluorinated inhalational anesthetics suppress voltage-elicited currents in rat brain sodium channels expressed in a mammalian cell line.³⁹

Consistent with the evidence that anesthetics do not have major effects on voltage-gated channels, most experimental evidence indicates that clinically relevant concentrations of anesthetics do not inhibit axonal propagation of action potentials. This was first shown in a classic paper by Larabee and Posternak, in which they demonstrated that concentrations of ether and chloroform that completely block synaptic transmission in mammalian sympathetic ganglia have no effect on presynaptic action potential amplitude.⁴⁰ Similar results have been obtained with fluorinated volatile anesthetics in several mammalian brain preparations.^{28,30} For completeness, it should be noted that clinical concentrations of general anesthetics have been shown to produce modest depression of action potential amplitude in unmyelinated CNS fibers.⁴¹ In principle, this small amount of action potential depression could lead to reduced synaptic neurotransmitter release.

Synaptic Function

It is widely believed that anesthetic action results from effects on chemical synapses in the CNS rather than on axonal conduction. General anesthetics have been shown to inhibit excitatory synaptic transmission in a variety of preparations, including sympathetic ganglia,⁴⁰ olfactory cortex,²⁸ hippocampus,³⁰ and spinal cord.¹⁹ The anesthetic concentrations required to inhibit excitatory synaptic transmission in these preparations are one-fifth to one-tenth those required to inhibit axonal conduction. In contrast, there is also experimental evidence showing that anesthetics have no effect on excitatory synaptic function and that they can, in an agent- and synapse-specific manner, *enhance* excitatory transmission.³¹ In a similar fashion, general anesthetics have been shown to both enhance and depress inhibitory synaptic transmission in various preparations. In a classic paper in 1975, Nicoll showed that barbiturates enhanced inhibitory synaptic transmission by prolonging the decay of the GABAergic inhibitory postsynaptic current.⁴² Enhancement of inhibitory transmission has also been observed with many other general anesthetics including halothane²⁹ and neurosteroids.⁴³ Although anesthetic enhancement of inhibitory currents has received a great deal of attention as a potential mechanism of anesthesia,⁴ it is important to note that there is also a large body of experimentation showing that clinical concentrations of general anesthetics can depress inhibitory postsynaptic potentials in hippocampus^{33,44,45} and in spinal cord.²⁰ Anesthetics do appear to have preferential effects on synapses, but there is a great deal of heterogeneity in the manner in which anesthetic agents affect different synapses. This is not surprising given the large variation in synaptic structure, function (*i.e.*, efficacy), and chemistry (neurotransmitters, modulators) extant in the nervous system.

Presynaptic Effects

The effects of anesthetics on synaptic function may result from actions affecting a number of cellular processes. Anesthetics could alter presynaptic neurotransmitter release by affecting transmitter synthesis, storage, or secretion.⁴⁶ Current evidence suggests that anesthetics can inhibit the release of both excitatory transmitters^{47,48} and inhibitory transmitters.⁴⁹ For example, a study by Perousansky and colleagues conducted in mouse hippocampal slices showed that halothane inhibited excitatory postsynaptic potentials elicited by presynaptic electrical stimulation, but not those elicited by direct application of glutamate. This indicates that halothane must be acting to prevent the release of excitatory neurotransmitter.⁵⁰ There have also been some reports that general anesthetics can enhance the release of the inhibitory neurotransmitter GABA.^{51,52} The effects of anesthetics on neurotransmitter release do not appear to be mediated by reduced neurotransmitter synthesis or storage, but rather by a direct effect on the process of neurosecretion. Although it is difficult to dissect the mechanism for reduced neurosecretion in intact CNS preparations, work in neuroendocrine cells suggests that anesthetics inhibit neurosecretion by inhibiting the entry of calcium into the cell rather than by depressing the calcium-dependent stimulation of the secretory process.^{53,54} and ⁵⁵ More recent work, using genetic approaches in lower organisms, implicates the proteins involved in vesicle release (syntaxin, synaptobrevin, SNAP-25) as potential sites of presynaptic anesthetic action.⁵⁶

Postsynaptic Effects

Anesthetics can also affect synaptic function by altering the postsynaptic response to released neurotransmitter. The effects of general anesthetics on excitatory neurotransmitter action vary depending on neurotransmitter type, anesthetic agent, and preparation. Richards and Smaje examined the effects of several anesthetic agents on the response of olfactory cortical neurons to application of glutamate, the major excitatory neurotransmitter in the CNS.⁵⁷ They found that while pentobarbital, diethylether, methoxyflurane, and alphaxalone depressed the electrical response to glutamate, halothane was without effect. In contrast, when acetylcholine was applied to the same olfactory cortical preparation, halothane and methoxyflurane stimulated the electrical response whereas pentobarbital had no effect; only alphaxalone depressed the electrical response to acetylcholine.⁵⁸ The effects of anesthetics on neuronal responses to inhibitory neurotransmitters are more consistent. A wide variety of anesthetics, including barbiturates, etomidate, neurosteroids, propofol, and the fluorinated volatile anesthetics, have been shown to enhance the electrical response to exogenously applied GABA (for a review, see Tanelian *et al.*⁵⁹). For example, [Figure 7-2](#) illustrates the ability of enflurane to increase both the amplitude and the duration of the electrical response elicited by application of GABA to hippocampal neurons.⁶⁰

Figure 7-2. Enflurane potentiates the ability of GABA to activate a chloride current in cultured rat hippocampal cells. This potentiation is rapidly reversed by removal of enflurane (wash) (Panel A). Enflurane increases both the amplitude of the current (Panel B) and the time ($t_{1/2}$) it takes for the current to decay (Panel C). (Reproduced

Summary

Attempts to identify a physiologic “switch” at which anesthetics act have suffered from their own success. Anesthetics produce a variety of effects on many physiologic processes that might logically contribute to the anesthetic state, including neuronal automaticity, neuronal excitability, and synaptic function. It is generally thought that the synapse is the most likely target of anesthetic action. Existing evidence indicates that even at this one target, anesthetics produce various effects, including presynaptic inhibition of neurotransmitter release, inhibition of excitatory neurotransmitter effect, and enhancement of inhibitory neurotransmitter effect. Furthermore, the effects of anesthetics on synaptic function differ among various anesthetic agents, neurotransmitters, and neuronal preparations.

ANESTHETIC ACTIONS ON ION CHANNELS

All of the various effects of anesthetics described in the previous section are likely to result from the actions of anesthetics on the machinery used to generate neuronal electrical activity: ion channels, pumps, and transporters. With the advent of patch clamp techniques in the early 1980s, it became possible to examine the function of specific kinds of ion channels and even to look at the currents resulting from single ion channel proteins. It was attractive to think that anesthetic effects on a small number of ion channels might help to explain the complex physiologic effects of anesthetics that we have already described. Accordingly, during the 1980s and 1990s a major effort was directed at describing the effects of anesthetics on the various kinds of ion channels. The following section summarizes and distills this effort. For the purposes of this discussion, ion channels are cataloged according to the stimuli to which they respond by opening or closing (*i.e.*, their mechanism of gating).

Anesthetic Effects on Voltage-Dependent Ion Channels

A variety of ion channels can sense a change in membrane potential and respond by either opening or closing their pore. These channels include voltage-dependent sodium, potassium, and calcium channels, all of which share significant structural homologies. Voltage-dependent sodium and potassium channels are largely involved in generating and shaping action potentials. The effects of anesthetics on these channels have been extensively studied by Haydon and colleagues in the squid giant axon.^{38,61} These studies show that sodium channels and potassium channels are remarkably insensitive to volatile anesthetics. For example, 50% inhibition of the peak sodium channel current required halothane concentrations 8 times those required to produce anesthesia. The delayed rectifier potassium channel was even less sensitive, requiring halothane concentrations more than 20 times those required to produce anesthesia. Similar results have been obtained in a mammalian cell line (GH₃ pituitary cells) where both sodium and potassium currents were inhibited by halothane only at concentrations greater than 5 times those required to produce anesthesia.⁶² A recent study by Rehberg and colleagues challenged the notion that voltage-dependent sodium channels are insensitive to anesthetics. They expressed a rat brain IIA sodium channel in a mammalian cell line, and showed that clinically relevant concentrations of a variety of inhalational anesthetics suppressed voltage-elicited sodium currents.³⁹ The minimal effect of anesthetics on voltage-dependent sodium and potassium channels that is generally observed is consistent with the observation that anesthetics do not substantively interfere with action potential generation or axonal conduction. The ability of anesthetics to suppress sodium currents in some systems leaves open the possibility that action potential generation or propagation could mediate some anesthetic effects.

Voltage-dependent calcium channels (VDCC) serve to couple electrical activity to specific cellular functions. In the nervous system, VDCCs located at presynaptic terminals respond to action potentials by opening. This allows calcium to enter the cell, activating calcium-dependent secretion of neurotransmitter into the synaptic cleft. There are at least six types of calcium channels (designated L, N, P, Q, R, and T) identified on the basis of electrophysiologic properties and a larger number based on molecular biologic studies.⁶³ N-, P-, Q-, and R-type channels, as well as some of the untitled channels, are preferentially expressed in the nervous system and are thought to play a major role in synaptic transmission. L-type calcium channels, although expressed in brain, play a predominant role in excitation–contraction coupling in cardiac, skeletal, and smooth muscle and are thought to be less important in synaptic transmission. The effects of anesthetics on L- and T-type currents have been well characterized,^{62,64,65} and there are some reports concerning the effects of anesthetics on N- and P-type currents.^{66,67} and ⁶⁸ As a general rule, these studies have shown that volatile anesthetics inhibit VDCCs (50% reduction in current) at concentrations two to five times those required to produce anesthesia in humans. This makes VDCCs more sensitive to anesthetics than are voltage-dependent sodium or potassium channels, but suggests that there is less than 20% inhibition of calcium current at clinical concentrations of anesthetics (Fig. 7-3). There have, however, been reports of VDCCs that are extremely sensitive to anesthetics. Takenoshita and Steinbach reported a T-type calcium current in dorsal root ganglion neurons that was inhibited by subanesthetic concentrations of halothane.⁶⁹ Additionally, French-Mullen and colleagues have reported a VDCC of unspecified type in guinea pig hippocampus that is inhibited by pentobarbital at concentrations identical to those required to produce anesthesia.⁷⁰

Figure 7-3. Halothane inhibition of voltage-dependent Ca²⁺, Na⁺, and K⁺ currents. The Ca²⁺ channels are L-type channels from GH₃ cells, and the Na⁺ and K⁺ channels are from the squid giant axon. The closed circles show the concentrations of halothane required to anesthetize humans. Note that the Ca²⁺ currents are inhibited about 20% by clinical concentrations of halothane whereas the Na⁺ and K⁺ currents are not inhibited at all. (Reproduced by permission from Franks NP, Lieb WR: Molecular and cellular mechanisms of anesthesia. Nature 367:607, 1994, Macmillan Magazines Ltd.)

Summary

Existing evidence suggests that VDCCs are modestly sensitive to anesthetics, but there is likely to be significant heterogeneity in the anesthetic sensitivity of specific channel types and subtypes. It is attractive to hypothesize that anesthetic effects on VDCCs could explain the observed inhibition of neurotransmitter release that occurs at some synapses with some anesthetics. Additional experimental data will be required to establish whether anesthetic-sensitive VDCCs are localized to specific synapses at which anesthetics have been shown to inhibit neurotransmitter release.¹⁹

Anesthetic Effects on Ligand-Gated Ion Channels

Fast excitatory and inhibitory neurotransmission is mediated by the actions of ligand-gated ion channels. Synaptically released glutamate or GABA diffuse across the synaptic cleft and bind to channel proteins that are opened as a consequence of neurotransmitter release. The channel proteins that bind GABA (GABA_A receptors) are members of a superfamily of structurally related ligand-gated ion channel proteins that includes nicotinic acetylcholine receptors, glycine receptors, and 5-HT₃ receptors.⁷¹ Based on the structure of the nicotinic acetylcholine receptor, each ligand-gated channel is thought to be composed of five nonidentical subunits. The glutamate receptors also comprise a family, each receptor thought to be a tetrameric protein composed of structurally related subunits.⁷² The ligand-gated ion channels provide a logical target for anesthetic action, because selective effects on these channels could inhibit fast excitatory synaptic transmission and/or facilitate fast inhibitory synaptic transmission. The effects of anesthetic agents on ligand-gated ion channels are thoroughly cataloged in a recent review by Krasowski and Harrison.⁷³ The following section provides a brief summary of this body of work.

Glutamate-Activated Ion Channels

Glutamate-activated ion channels have been classified, based on selective agonists, into three categories: AMPA receptors, kainate receptors, and NMDA receptors.

Molecular biologic studies indicate that a large number of structurally distinct glutamate receptor subunits can be used to form each of the three categories of glutamate receptors.⁷⁴ This structural heterogeneity is probably reflected in functional heterogeneity within each category of glutamate receptor. AMPA and kainate receptors are relatively nonselective cation channels involved in fast excitatory synaptic transmission, whereas NMDA channels are somewhat selective for calcium and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity. Studies from the early 1980s in mouse and rat brain preparations showed that AMPA- and kainate-activated currents are insensitive to clinical concentrations of halothane,⁷⁵ enflurane,⁷⁶ and the neurosteroid 3- α -OH-DHP.⁷⁷ In contrast, kainate- and AMPA-activated currents were shown to be more sensitive to barbiturates; in rat hippocampal neurons, 50 μ M pentobarbital (pentobarbital produces anesthesia at approximately 50 μ M) inhibited kainate and AMPA responses by 50%.⁷⁷ More recent studies using cloned and expressed glutamate receptor subunits show that submaximal agonist responses of GluR3 (AMPA-type) receptors are inhibited by fluorinated volatile anesthetics whereas agonist responses of GluR6 (kainate-type) receptors are enhanced.⁷⁸ In contrast both GluR3 and GluR6 receptors are inhibited by pentobarbital. The directionally opposite effects of the volatile anesthetics on different glutamate receptor subtypes may explain the earlier inconclusive effects observed in tissue, where multiple subunit types are expressed. The directionally opposite effects of the volatile anesthetics on GluR3- and GluR6-containing receptors have also been used as a strategy to identify critical sites on the molecules involved in anesthetic effect. By producing GluR3/GluR6 receptor chimeras (receptors made up of various combinations of sections of the GluR3 and GluR6 receptors) and screening for volatile anesthetic effect, specific areas of the protein required for volatile anesthetic potentiation of GluR6 have been identified. Subsequent site-directed mutagenesis studies have identified a specific glycine residue (Gly-819) as critical for volatile anesthetic action on GluR6-containing receptors.⁷⁹

NMDA-activated currents also appear to be insensitive to most anesthetics. Electrophysiologic studies show virtually no effects of clinical concentrations of volatile anesthetics,^{75,76} neurosteroids, or barbiturates⁷⁷ on NMDA-activated currents. It should be noted that there is some evidence from flux studies that volatile anesthetics may inhibit NMDA-activated channels. A study in rat brain microvesicles showed that anesthetic concentrations (0.2–0.3 mM) of halothane and enflurane inhibited NMDA-activated calcium flux by 50%.⁸⁰ In contrast to other anesthetics, ketamine is a potent and selective inhibitor of NMDA-activated currents. Ketamine stereoselectively inhibits NMDA currents by binding to the phencyclidine site on the NMDA receptor protein.^{81,82} and ⁸³ The anesthetic effects of ketamine in intact animals show the same stereoselectivity as that observed *in vitro*,⁸⁴ suggesting that the NMDA receptor may be the principal molecular target for the anesthetic actions of ketamine. Two other recent findings suggest that NMDA receptors may be an important target for specific anesthetic agents. These studies show that N₂O^{85,86} and xenon⁸⁷ are potent and selective inhibitors of NMDA-activated currents. This is illustrated in [Figure 7-4](#), showing that N₂O inhibits NMDA-elicited, but not GABA-elicited, currents in hippocampal neurons.

Figure 7-4. Nitrous oxide inhibits NMDA-elicited, but not GABA-elicited, currents in rat hippocampal neurons. *Panel A:* 80% N₂O has no effect on holding current (upper trace), but inhibits the current elicited by NMDA. *Panel B:* N₂O causes a rightward and downward shift of the NMDA concentration–response curve, indicating a mixed competitive/noncompetitive antagonism. *Panel C:* 80% N₂O has little effect on GABA-elicited currents. In contrast, an equipotent anesthetic concentration of pentobarbital markedly enhances the GABA-elicited current. (Reproduced with permission from Jevtovic-Todorovic V, Todorovic SM, Mennerick S *et al*: Nitrous oxide (laughing gas) is an NMDA antagonist, neuroprotectant, and neurotoxin. *Nature Medicine* 4:460, 1998.)

GABA-Activated Ion Channels

GABA is the most important inhibitory neurotransmitter in the mammalian central nervous system. GABA-activated ion channels (GABA_A receptors) mediate the postsynaptic response to synaptically released GABA by selectively allowing chloride ions to enter, and thereby hyperpolarize, neurons. GABA_A receptors are multisubunit proteins consisting of various combinations of α , β , γ , δ , and ϵ subunits, and there are many subtypes of each of these subunits. The function of GABA_A receptors is modulated by a wide variety of pharmacologic agents including convulsants, anticonvulsants, sedatives, anxiolytics, and anesthetics.⁸⁸ The effects of these various drugs on GABA_A receptor function varies across brain regions and cell types. The following section briefly reviews the effects of anesthetics on GABA_A receptor function.

Barbiturates, anesthetic steroids, benzodiazepines, propofol, etomidate, and the volatile anesthetics all modulate GABA_A receptor function.^{60,88,89,90} and ⁹¹ These drugs produce three kinds of effects on the electrophysiologic behavior of the GABA_A receptor channels: potentiation, direct-gating, and inhibition. *Potentiation* refers to the ability of anesthetics to markedly increase the current elicited by low concentrations of GABA, but to produce no increase in the current elicited by a maximally effective concentration of GABA.^{75,92} Potentiation is illustrated in [Figure 7-5](#), showing the effects of halothane on currents elicited by a range of GABA concentrations in dissociated cortical neurons. Anesthetic potentiation of GABA_A currents generally occurs at concentrations of anesthetics within the clinical range. *Direct gating* refers to the ability of anesthetics to activate GABA_A channels in the absence of GABA. Generally, direct gating of GABA_A currents occurs at anesthetic concentrations higher than those used clinically, but the concentration–response curves for potentiation and for direct gating can overlap. It is not known whether direct gating of GABA_A channels is either required for or contributes to the effects of anesthetics on GABA-mediated inhibitory synaptic transmission *in vivo*. In the case of anesthetic steroids, there is strong evidence indicating that potentiation, rather than direct gating of GABA_A currents, is required for producing anesthesia.⁹³ Anesthetics can also inhibit GABA-activated currents. *Inhibition* refers to the ability of anesthetics to prevent GABA from initiating current flow through GABA_A channels, and has generally been observed at high concentrations of both GABA and anesthetic.^{94,95} Inhibition of GABA_A channels may help to explain why volatile anesthetics have, in some cases, been observed to inhibit rather than facilitate inhibitory synaptic transmission.³³

Figure 7-5. The effects of halothane (Hal), enflurane (Enf), and fluorothyl (HFE) on GABA-activated chloride currents in dissociated rat CNS neurons. *Panel A:* Clinical concentrations of halothane and enflurane potentiate the ability of GABA to elicit a chloride current. The convulsant fluorothyl antagonizes the effects of GABA. *Panel B:* GABA causes a concentration-dependent activation of a chloride current. Halothane shifts the GABA concentration–response curve to the left (increases the apparent affinity of the channel for GABA) whereas fluorothyl shifts the curve to the right (decreases the apparent affinity of the channel for GABA). (Reproduced with permission from Wakamori M, Ikemoto Y, Akaike N: Effects of two volatile anesthetics and a volatile convulsant on the excitatory and inhibitory amino acid responses in dissociated CNS neurons of the rat. *J Neurophysiol* 66:2014, 1991.)

The effects of anesthetics have also been observed on the function of single GABA_A channels. These studies show that barbiturates,⁸⁹ propofol,⁹¹ and volatile anesthetics⁹⁶ do not alter the conductance (rate at which ions traverse the open channel) of the channel, but that they increase the frequency with which the channel opens and/or the average length of time that the channel remains open. Collectively, the whole cell and single channel data are most consistent with the idea that clinical concentrations of anesthetics produce a change in the conformation of GABA_A receptors that increases the affinity of the receptor for GABA. This is consistent with the ability of anesthetics to increase the duration of inhibitory postsynaptic potentials (IPSPs), since higher affinity binding of GABA would slow the dissociation of GABA from postsynaptic GABA_A channels. It would not be expected that anesthetics would increase the amplitude of a GABAergic IPSP, since synaptically released GABA probably reaches very high concentrations in the synapse. Higher concentrations of anesthetics can produce additional effects, either directly activating or inhibiting GABA_A channels. Consistent with these ideas, a study by Banks and Pearce showed that isoflurane and enflurane simultaneously increased the duration and decreased the amplitude of GABAergic inhibitory postsynaptic currents in hippocampal slices.⁹⁷

Despite the similar effects of many anesthetics on GABA_A receptor function, there is significant evidence that the various anesthetics do not act by binding to a single common binding site on the channel protein. First, even anesthetics that directly activate the channel probably do not bind to the GABA binding site. This is most clearly demonstrated by molecular biologic studies in which the GABA binding site is eliminated from the channel protein but pentobarbital can still activate the channel.⁹⁸ Direct radioligand binding studies have demonstrated that benzodiazepines bind to the GABA_A receptor at nanomolar concentrations and that other anesthetics can modulate binding, but do not bind directly to the benzodiazepine site.^{59,88} A series of more complex studies examining the interactions between barbiturates, anesthetic steroids, and benzodiazepines indicate that these three classes of drugs cannot be acting at the same sites.⁸⁸ The actions of anesthetics on GABA_A receptors are further complicated by the observation that steroid anesthetics can produce different effects on GABA_A receptors in different brain regions.⁹⁹ This suggests the possibility that the specific subunit composition of a GABA_A receptor may encode pharmacologic selectivity. This is well illustrated by benzodiazepine sensitivity, which requires the presence of the $\alpha 2$ subunit subtype.¹⁰⁰ Similarly, sensitivity to etomidate has been shown to require the presence of a $\beta 2$ or $\beta 3$ subunit.¹⁰¹ More recently, it has been shown that the presence of a δ or ϵ subunit in a GABA_A receptor confers insensitivity to the potentiating effects of some anesthetics.^{102,103}

Interestingly, GABA_A receptors composed of γ -type subunits (referred to as GABA_C receptors) have been shown to be inhibited rather than potentiated by volatile anesthetics.¹⁰⁴ This property has been exploited, using molecular biologic techniques, by constructing chimeric receptors composed of part of the γ receptor coupled to part of an α , β , or glycine receptor subunit. By screening these chimeras for anesthetic sensitivity, regions of the α , β , and glycine subunits responsible for anesthetic sensitivity have been identified. Based on the results of these chimeric studies, site-directed mutagenesis studies were performed to identify the specific amino acids responsible for conferring anesthetic sensitivity. These studies revealed two critical amino acids, near the extracellular regions of transmembrane domains 2 and 3 (TM2, TM3) on the glycine and GABA_A receptors, that are required for volatile anesthetic potentiation of agonist effect.¹⁰⁵ It is not yet clear if these amino acids represent a volatile anesthetic binding site, or whether they are sites critical to transducing anesthetic-induced conformational changes in the receptor molecule. Interestingly, one of the amino acids shown to be critical to volatile anesthetic effect (TM3 site) has also been shown to be required (in the $\beta 2/\beta 3$ subunit) for the potentiating effects of etomidate.¹⁰⁶ In contrast, the TM2 and TM3 sites do not appear to be required for the actions of propofol, barbiturates, or neurosteroids.¹⁰⁷ Interestingly, a distinct amino acid in the TM3 region of the $\beta 1$ subunit of the GABA_A receptor has been shown to selectively modulate the ability of propofol to potentiate GABA agonist effects.¹⁰⁷ Collectively, these molecular biologic data provide strong evidence that there are multiple unique binding sites for anesthetics on the GABA_A receptor protein.

Other Ligand-Activated Ion Channels

Other members of the ligand-gated receptor superfamily include the nicotinic acetylcholine receptors (muscle and neuronal types), glycine receptors, and 5-HT₃ receptors. A large body of work has gone into examining the effects of anesthetics on nicotinic acetylcholine receptors. The muscle type of nicotinic receptor has been shown to be inhibited by anesthetic concentrations in the clinical range¹⁰⁸ and to be desensitized by higher concentrations of anesthetics.¹⁰⁹ The muscle nicotinic receptor is an interesting model to study because of its abundance and the wealth of knowledge about its structure. It is, however, not expressed in the central nervous system and hence not involved in the mechanism of anesthesia. There is a neuronal type of nicotinic receptor, which is widely expressed in the nervous system, and might plausibly be involved in anesthetic mechanisms. Older studies looking at neuronal nicotinic receptors in molluscan neurons¹¹⁰ and in bovine chromaffin cells¹¹¹ indicate that these channels are inhibited by clinical concentrations of volatile anesthetics. More recent studies using cloned and expressed neuronal nicotinic receptor subunits have shown a high degree of subunit and anesthetic selectivity. Acetylcholine-elicited currents are inhibited, in receptors composed of various combinations of $\alpha 2$, $\alpha 4$, $\beta 2$, and $\beta 4$ subunits, by *subanesthetic* concentrations of halothane¹¹² or isoflurane.¹¹³ In contrast, these receptors are relatively insensitive to propofol. Most interestingly, receptors composed of $\alpha 7$ subunits are completely insensitive to both isoflurane and propofol.¹¹³ The sensitivity of neuronal nicotinic receptors to subanesthetic concentrations of the volatile anesthetics makes it unlikely that these receptors are involved in producing unconsciousness or loss of response to noxious stimuli; it is conceivable that neuronal nicotinic receptors may be involved in other anesthetic effects, such as analgesia.¹¹⁴

Glycine is an important inhibitory neurotransmitter, particularly in the spinal cord and brain stem. The glycine receptor is a member of the ligand-activated channel superfamily that, like the GABA_A receptor, is a chloride-selective ion channel. A large number of studies have shown that clinical concentrations of volatile anesthetics potentiate glycine-activated currents in intact neurons⁷⁵ and in cloned glycine receptors expressed in oocytes.^{115,116} The volatile anesthetics appear to produce their potentiating effect by increasing the affinity of the receptor for glycine.¹¹⁶ Propofol,⁹¹ alphaxalone, and pentobarbital also potentiate glycine-activated currents, whereas etomidate and ketamine do not.¹¹⁵ Potentiation of glycine receptor function may contribute to the anesthetic action of volatile anesthetics and some parenteral anesthetics. 5-HT₃ receptors are also members of the genetically related superfamily of ligand-gated receptor channels. Clinical concentrations of volatile anesthetics potentiate currents activated by 5-hydroxytryptamine in intact cells¹¹⁷ and in cloned receptors expressed in oocytes.¹¹⁸ In contrast, thiopental inhibits 5-HT₃ receptor currents¹¹⁷ and propofol is without effect on these receptor channels.¹¹⁸ 5-HT₃ receptors may play some role in the anesthetic state produced by volatile anesthetics, and may also contribute to some unpleasant anesthetic side effects such as nausea and vomiting.

Summary

Several ligand-gated ion channels are modulated by clinical concentrations of anesthetics. Ketamine, N₂O, and xenon inhibit NMDA-type glutamate receptors, and this effect of the anesthetics may play a major role in their mechanism of action. There is a large body of evidence showing that clinical concentrations of many anesthetics potentiate GABA-activated currents in the central nervous system. This suggests that GABA_A receptors are a probable molecular target of anesthetics. Other members of the ligand-activated ion channel family, including glycine receptors, neuronal nicotinic receptors, and 5-HT₃ receptors, are also affected by clinical concentrations of anesthetics and remain plausible anesthetic targets.

Anesthetic Effects on Second Messenger-Activated Ion Channels

Ion channels can be activated by ligands present in the cytoplasm as well as by ligands present in the extracellular space. The intracellular ligands that activate these channels are generally chemical second messengers, including cyclic nucleotides, Ca²⁺ ions, inositol phosphates, and ATP. The structure of second messenger-activated ion channels is not as well understood as that of the voltage- or ligand-activated channels, and there is little information about anesthetic effects on these channels.

One type of second messenger-activated channel, the calcium-dependent channels, has been shown to be inhibited by clinical concentrations of anesthetics.¹¹⁹ These large conductance potassium channels open in response to increases in cytoplasmic Ca²⁺ concentration and are important in modulating the shape and frequency of action potentials in the central nervous system. While a wide variety of anesthetics inhibit channel opening, this would tend to excite neurons, and is thus unlikely to be important in the depressant effects of anesthetics. Anesthetic effects on these channels may contribute to the excitatory effects of low concentrations of anesthetics and to the convulsant properties of some anesthetic agents. Several other potassium-selective ion channels are also activated by second messengers, including ATP-activated channels and channels activated by muscarinic acetylcholine receptors, but the effects of anesthetics on these channels has not been delineated.

There is a potassium-selective channel (referred to as I_{K(an)}), found in snail neurons, that has many of the properties of a second messenger-activated channel and that is activated by clinical concentrations of volatile anesthetics.^{110,120,121} I_{K(an)} shares many biophysical properties with a second messenger-activated potassium channel found in *Aplysia* neurons that is referred to as the S channel. Recent work by Spencer Yost and colleagues has shown that the S channel is also activated by clinical concentrations of volatile anesthetics.¹²² The importance of volatile anesthetic activation of second messenger-activated potassium channels in invertebrates has now become apparent with the discovery of a large family of so-called "background potassium channels" in mammals. These mammalian potassium channels have a unique structure with two pore-forming domains in tandem plus four transmembrane segments (2P/4TM; Fig. 7-6C).¹²³ TOK1, a member of this family, was first shown by Yost and colleagues to be activated by volatile anesthetics.¹²⁴ The laboratory of Michel Lazdunski has studied the effects of a variety of volatile anesthetics on

several members of the 2P/4TM family. They found that TREK-1 channels were activated by clinical concentrations of chloroform, diethyl ether, halothane, and isoflurane (Fig. 7-6B). In contrast, closely related TRAAK channels were insensitive to all the volatile anesthetics, and TASK channels were activated by halothane and isoflurane, inhibited by diethyl ether, and unaffected by chloroform. These authors went on to show that the C-terminal regions of TASK and TREK-1 contained amino acids essential for anesthetic actions on TASK and TREK-1 channels.¹²⁵ Activation of background K⁺ channels in mammalian vertebrates could be an important mechanism through which anesthetics regulate neuronal resting membrane potential and thereby excitability; this effect could plausibly be a significant contributor to some components of the anesthetic state.

Figure 7-6. Volatile anesthetics activate background K⁺ channels. *Panel A:* Halothane reversibly hyperpolarizes a pacemaker neuron from *Lymnaea stagnalis* (the pond snail) by activating I_{Kan}. *Panel B:* Halothane (300 μM) activates human recombinant TREK-1 channels expressed in COS cells. The figure shows current–voltage relationships with reversal potential (V_{rev}) of -88 mV, indicative of a K⁺ channel. *Panel C:* Predicted structure of a typical subunit of the mammalian background K⁺ channels. Note the four transmembrane spanning segments (in black) and the two pore-forming domains (P1 and P2). Some but not all of these 2P/4TM K⁺ channels are activated by volatile anesthetics. *Panel D:* Phylogenetic tree for the 2P/4TM family. (Reproduced with permission from Franks NP, Lieb WR: Background K⁺ channels: An important target for anesthetics? *Nature Neurosci* 2:395, 1999.)

Summary

Second messenger-activated ion channels are a plausible target for anesthetic action. Recent evidence suggests that members of the 2P/4TM family of background potassium channels are likely to be important in producing some components of the anesthetic state.

ANESTHETIC EFFECTS ON CHEMICAL SECOND MESSENGER GENERATION AND EFFECT

As discussed above, anesthetics alter the function of at least several types of ion channels. This panoply of effects could be efficiently explained by an anesthetic effect on either the synthesis or the actions of a single modulatory substance that acts on all of the affected channels. A variety of substances, referred to as second messengers, are known to modulate the function of ion channels. These second messengers alter channel function either by directly binding to the channel protein or by changing the phosphorylation state of the channel. This section briefly reviews current knowledge of anesthetic effects on chemical second messengers.

Calcium

Calcium ions are among the most important intracellular chemical second messengers. Cytoplasmic Ca²⁺ concentration ([Ca²⁺]_i) is tightly regulated at ~100 nM and can be rapidly elevated by release of Ca²⁺ from intracellular stores or by influx of extracellular Ca²⁺. It has long been hypothesized that anesthetics might increase resting [Ca²⁺]_i, thereby activating Ca²⁺-dependent potassium channels and hyperpolarizing neurons. Studies in a variety of preparations have now shown that while volatile anesthetics can transiently increase resting [Ca²⁺]_i by releasing Ca²⁺ from intracellular stores,^{126,127} clinical concentrations of anesthetics produce little, if any, sustained effect on resting [Ca²⁺]_i.^{55,128,129} and ¹³⁰ Additionally, anesthetics generally inhibit rather than enhance receptor- or depolarization-stimulated increases in [Ca²⁺]_i. It is thus highly unlikely that elevations in resting [Ca²⁺]_i make a significant contribution to the mechanism of anesthesia.

G-Proteins

The actions of most cell surface receptors are transduced via intracellular GTP-binding proteins (G-proteins), which when activated can stimulate a variety of effector molecules including ion channels, adenylyl cyclase, and phospholipase C. The G-proteins are a family of proteins, which show specificity both in terms of the receptors to which they couple and the effectors that they activate. G-proteins would provide an attractive target for anesthetic action, because their actions at proximal steps in a number of signaling cascades could explain the promiscuous molecular effects of anesthetics. There have been several studies indicating that volatile anesthetics^{131,132} and barbiturates¹³³ can interfere with G-protein function in the brain. Unfortunately, the anesthetic concentrations used in these studies were significantly higher than those used clinically. Studies using clinical concentrations of halothane have failed to show any effect on G-protein function in either rat brain slices¹³⁴ or clonal pituitary cells.⁵⁵ There is no compelling evidence at the current time to suggest that G-proteins are an important target of anesthetic action in the central nervous system.

Inositol Phosphates

A variety of cell surface receptors act via G-proteins to activate a phosphatidylinositol-specific phospholipase C. This enzyme produces two important messenger molecules—inositol trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ activates an intracellular, ligand-activated calcium channel (the IP₃ receptor) which allows release of Ca²⁺ from intracellular stores. DAG binds to and activates protein kinase C. There is evidence from two systems that clinical concentrations of halothane do not affect phospholipase C activity. In rat brain slices¹³³ and in clonal pituitary cells,⁵⁵ clinical concentrations of halothane have no effect on either basal or agonist-stimulated accumulation of inositol phosphates. This indicates that the activity of phospholipase C is not affected by halothane and therefore that the rates of production of both IP₃ and DAG are unaffected by halothane. Interestingly, studies using a human neuroblastoma cell line have shown that volatile anesthetics (halothane and isoflurane) increase basal and agonist-stimulated concentrations of IP₃ without affecting total inositol phosphate accumulation.¹³⁵ This suggests that while the anesthetics do not affect phospholipase C activity, they may inhibit the breakdown of IP₃. Indeed, there is some evidence that halothane can inhibit inositol 1,4,5-trisphosphatase, the major enzyme involved in IP₃ degradation.¹³⁶ In pituitary cells, there is also evidence showing that halothane does not alter the actions of IP₃; changes in [Ca²⁺]_i resulting from receptor-stimulated IP₃ generation were completely unaffected by clinical concentrations of halothane.⁵⁵ In summary, current evidence does not suggest a major role for second messengers derived from the phosphatidylinositol system in the mechanism of anesthesia.

Cyclic Nucleotides

Cyclic AMP (cAMP) and cyclic GMP (cGMP) are important second messengers that can alter ion channel function. The cyclic nucleotides can either directly bind to channel proteins or can activate specific protein kinases (cAMP-dependent and cGMP-dependent protein kinase) which can selectively phosphorylate ion channels and other proteins, leading to changes in protein function. Numerous studies have examined the effects of anesthetics on tissue levels of cAMP and cGMP. Although the results of these studies have been somewhat variable, the general trend is to show increased levels of cAMP and decreased levels of cGMP in brain.^{137,138} In contrast, studies done in brain slices show minimal effect of clinical concentrations of halothane on basal or agonist-stimulated cyclic nucleotide concentrations.¹³⁴ One exception to this is a recent study examining the effects of halothane on NMDA-stimulated changes in nitric oxide and cGMP generation in rat cerebellar slices. This study showed that halothane inhibited NMDA-induced increases in cGMP, but not nitric oxide.¹³⁹ This suggests that halothane may affect the ability of nitric oxide to stimulate guanylate cyclase activity. Overall, most of the alterations in cyclic nucleotide levels observed *in vivo* probably reflect anesthetic-induced changes in neuronal activity rather than direct effects on the enzymatic machinery involved in synthesizing and metabolizing cAMP and cGMP. Current evidence does not indicate that cyclic nucleotide generation or metabolism plays a significant role in the mechanism of anesthetic action.

Protein Kinases and Phosphatases

Phosphorylation is the most important known mechanism for regulation of ion channel function. There are many protein kinases, each of which can phosphorylate

specific sites on specific ion channels, producing dramatic changes in channel function. There are also a variety of protein phosphatases, which can selectively remove phosphate groups from specific sites on specific ion channels, reversing the effects of the protein kinases. The balance between the activity of protein kinases and protein phosphatases determines the phosphorylation state of specific sites on channel proteins and thus determines the functional state of those channels. It is entirely plausible that anesthetics could produce their effects on the function of ion channels (and other proteins) *via* an action on specific protein kinases or phosphatases. Unfortunately, there is a surprising paucity of data concerning the effects of anesthetics on protein kinases and phosphatases. There is some information concerning the effects of anesthetics on protein kinase C (PKC). This kinase is of particular interest, since it is activated by lipids (DAG, phosphatidylserine, arachidonic acid) and thus may contain hydrophobic sites at which anesthetics might interact. Studies by Slater and colleagues have shown that several anesthetics inhibit purified brain PKC, and that they act *via* an effect on the regulatory (lipid-binding) subunit rather than the catalytic subunit.¹⁴⁰ A conflicting study showed that halothane and propofol *stimulate* purified brain PKC under most assay conditions and cause only modest inhibition under any conditions.¹⁴¹ Subsequent studies have shown that halothane has two distinct actions on brain PKC: stimulation of PKC activity and potentiation of activation-induced PKC translocation and downregulation.¹⁴² These competing effects may, in part, explain the dissimilar results obtained in various studies examining the effects of volatile anesthetics on PKC activity. It should also be appreciated that PKC purified from animal tissue is a mixture of at least several subtypes (including α , β_1 , β_2 , and γ) and that studies with the purified isotypes will be required to understand the effects of anesthetics on the biologic activity of PKC. To date, there is limited information available on the actions of anesthetics on protein phosphatase activity. In summary, inhalational anesthetics can affect the activity of protein kinase C in a complex fashion. The importance of this effect to mechanisms of anesthetic action is not known.

Nitric Oxide

Nitric oxide is an important chemical second messenger generated from L-arginine by the enzyme nitric oxide synthase (NOS). Nitric oxide acts by stimulating the enzyme guanylyl cyclase to produce cGMP, and is known to play an important role as an endothelial-derived vasodilator and as a neuromodulator. Studies from the early 1990s showed that systemic administration of the NOS inhibitor, L-NAME, reduced the MAC for halothane by approximately 30%.¹⁴³ Subsequent studies showed that an inhibitor specific for neuronal NOS produced a similar MAC-sparing effect for both isoflurane and halothane.¹⁴⁴ In both studies NOS inhibition did not produce anesthesia on its own and produced a maximal MAC reduction of 30–40%. A subsequent study examined the effects of NOS inhibitors on isoflurane MAC in mice lacking the gene for neuronal NOS. These animals were found to have the same MAC for isoflurane as control mice. The control mice did show a reduction of MAC following administration of a NOS inhibitor while the “neuronal NOS knockout” mice did not.¹⁴⁵ These data indicate that while the nitric oxide pathway can modulate the response to anesthetics, it is not essential to anesthetic action.

WHAT IS THE CHEMICAL NATURE OF ANESTHETIC TARGET SITES?

The Meyer-Overton Rule

Almost 100 years ago, Meyer and Overton independently observed that the potency of gases as anesthetics was strongly correlated with their solubility in olive oil (Fig. 7-7).^{146,147} This observation has significantly influenced thinking about anesthetic mechanisms in two ways. First, since a wide variety of structurally unrelated compounds obey the Meyer-Overton rule, it has been reasoned that all anesthetics are likely to act at the same molecular site. This idea is referred to as the *Unitary Theory of Anesthesia*. Second, it has been argued that since solubility in a specific solvent strongly correlates with anesthetic potency, the solvent showing the strongest correlation between anesthetic solubility and potency is likely to most closely mimic the chemical and physical properties of the anesthetic target site in the CNS. Based on this reasoning, it has been assumed that the anesthetic target site is hydrophobic in nature.

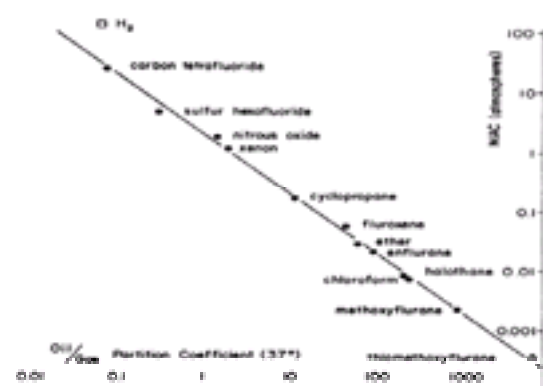

Figure 7-7. The Meyer-Overton rule. There is a linear relationship (on a log–log scale) between the oil/gas partition coefficient and the anesthetic potency (MAC) of a number of gases. The correlation between lipid solubility and MAC extends over a 70,000-fold difference in anesthetic potency. (Reproduced with permission from Tanifuji Y, Eger EI, Terrell RC: Some characteristics of an exceptionally potent inhaled anesthetic: thiomethoxyflurane. *Anesth Analg* 56:387, 1977.)

The Meyer-Overton correlation suffers from two limitations: (1) it only applies to gases and volatile liquids, since olive oil/gas partition coefficients cannot be determined for liquid anesthetics; (2) olive oil is a poorly characterized mixture of oils. To circumvent these limitations, attempts have been made to correlate anesthetic potency with water/solvent partition coefficients. To date, the best correlation that has been demonstrated is between the anesthetic potency of a compound and its octanol/water partition coefficient. This correlation holds for a variety of classes of anesthetics and spans a 10,000-fold range of anesthetic potencies.¹⁴⁸ The properties of the solvent octanol suggest that the anesthetic site is likely to be amphipathic, having both polar and nonpolar characteristics.

Exceptions to the Meyer-Overton Rule

Halogenated compounds exist that are structurally similar to the inhaled anesthetics, and are convulsants rather than anesthetics.¹⁴⁹ There are also convulsant barbiturates¹⁵⁰ and neurosteroids.¹⁵¹ One convulsant compound, fluoroethyl (hexafluoro-diethylether) has been shown to cause seizures in 50% of mice at 0.12 vol%, but to produce anesthesia at higher concentrations ($EC_{50} = 1.22$ vol%).¹⁵² The concentration of fluoroethyl required to produce anesthesia is approximately predicted by the Meyer-Overton rule. In contrast, several polyhalogenated alkanes have been identified that are convulsants, but that do not produce anesthesia. Based on the olive oil/gas partition coefficients of these compounds, anesthesia should have been achieved within the range of concentrations studied.¹⁵³ The end point used to determine the anesthetic effect of these compounds was movement in response to a noxious stimulus (MAC). Interestingly, some of these polyhalogenated compounds do produce amnesia in animals.¹⁵⁴ These compounds are thus referred to as *nonimmobilizers* rather than as nonanesthetics. Several polyhalogenated alkanes have also been identified that anesthetize mice, but only at concentrations 10 times those predicted by their oil/gas partition coefficients¹⁵⁵; these compounds are referred to as *transitional* compounds. The nonimmobilizers and transitional compounds have been proposed as a “litmus test” for the relevance of anesthetic effects observed *in vitro* to those observed in the whole animal.

In several homologous series of anesthetics, anesthetic potency increases with increasing chain length until a certain critical chain length is reached. Beyond this critical chain length, compounds are unable to produce anesthesia, even at the highest attainable concentrations. In the series of *n*-alkanols, for example, anesthetic potency increases from methanol through dodecanol; all longer alkanols are unable to produce anesthesia.¹⁵⁵ This phenomenon is referred to as the *cutoff effect*. Cutoff effects have been described for several homologous series of anesthetics including *n*-alkanes, *n*-alkanols, cycloalkanemethanols,¹⁵⁶ and perfluoroalkanes.¹⁵⁷ While the anesthetic potency in each of these homologous series of anesthetics shows a cutoff, a corresponding cutoff in octanol/water or oil/gas partition coefficients has not been demonstrated. Therefore, compounds above the cutoff represent a deviation from the Meyer-Overton rule.

A final deviation from the Meyer-Overton rule is the observation that enantiomers of anesthetics differ in their potency as anesthetics. Enantiomers (mirror-image compounds) are a class of stereoisomers that have identical physical properties, including identical solubility in solvents such as octanol or olive oil. Animal studies with the enantiomers of barbiturate anesthetics,^{158,159} ketamine,⁸⁴ neurosteroids,⁹³ etomidate,¹⁶⁰ and isoflurane¹⁶¹ all show enantioselective differences in anesthetic potency. These differences in potency range in magnitude from a >110-fold difference between the enantiomers of etomidate or the neurosteroids to a 60% difference between the enantiomers of isoflurane. It is argued that a *major* difference in anesthetic potency between a pair of enantiomers could only be explained by a protein binding site (see *Protein Theories of Anesthesia*); this appears to be the case for etomidate and the neurosteroids. Enantiomeric pairs of anesthetics have also been used to study anesthetic actions on ion channels. It is argued that if an anesthetic effect on an ion channel contributes to the anesthetic state, the effect on the ion channel should show the same enantioselectivity as is observed in whole animal anesthetic potency. Early studies showed that the (+)-isomer of isoflurane is 1.5–2 times more potent than the (-)-isomer in eliciting an anesthetic-activated potassium current, in potentiating GABA_A currents, and in inhibiting the current mediated by a neuronal nicotinic acetylcholine receptor.^{95,110} In contrast, the stereoisomers of isoflurane are equipotent in their effects on a voltage-activated potassium current and in their effects on lipid phase-transition temperature.¹¹⁰ Studies with the neurosteroids⁹³ and etomidate¹⁶⁰ show that these anesthetics exert enantioselective effects on

GABA_A currents that parallel the enantioselective effects observed for anesthetic potency.

The exceptions to the Meyer-Overton rule do not obviate the importance of the rule. They do, however, indicate that the properties of a solvent such as octanol describe some, but not all, of the properties of an anesthetic binding site. Compounds that deviate from the Meyer-Overton rule suggest that anesthetic target site(s) are also defined by other properties including size and shape.

In defining the molecular target(s) of anesthetic molecules one must be able to account both for the Meyer-Overton rule and for the well-defined exceptions to this rule. It has sometimes been suggested that a correct molecular mechanism of anesthesia should also be able to account for pressure reversal. *Pressure reversal* is a phenomenon whereby the concentration of a given anesthetic needed to produce anesthesia is greatly increased if the anesthetic is administered to an animal under hyperbaric conditions. The idea that pressure reversal is a useful tool for elucidating mechanisms of anesthesia is based on the assumption that pressure reverses the specific physicochemical actions of the anesthetic that are responsible for producing anesthesia; that is to say, pressure and anesthetics act on the same molecular targets. There is now evidence that pressure reverses anesthesia by producing excitation that physiologically counteracts anesthetic depression, rather than by acting as an anesthetic antagonist at the anesthetic site of action.¹⁶² Therefore, in the following discussion of molecular targets of anesthesia, pressure reversal will not be further discussed.

Lipid vs. Protein Targets

Anesthetics might interact with several possible molecular targets to produce their effects on the *function* of ion channels and other proteins. Anesthetics might dissolve in the *lipid* bilayer, causing physicochemical changes in membrane structure that alter the ability of embedded membrane proteins to undergo conformational changes important for their function. Alternatively, anesthetics could bind directly to *proteins* (either ion channel proteins or modulatory proteins), thus either (1) interfering with binding of a ligand (e.g., a neurotransmitter, a substrate, a second messenger molecule) or (2) altering the ability of the protein to undergo conformational changes important for its function. The following section summarizes the arguments for and against lipid theories and protein theories of anesthesia.

Lipid Theories of Anesthesia

The elucidation of the Meyer-Overton rule suggested that anesthetics interact with a hydrophobic target. To investigators in the early part of the 20th century, the most logical hydrophobic target was a lipid. In its simplest incarnation, the lipid theory of anesthesia postulates that anesthetics dissolve in the lipid bilayers of biological membranes and produce anesthesia when they reach a critical concentration in the membrane. Consistent with this hypothesis, the membrane/gas partition coefficients of anesthetic gases in pure lipid bilayers correlate strongly with anesthetic potency.¹⁶³ This simple theory can account for anesthetics that obey the Meyer-Overton rule, but cannot account for anesthetics that deviate from this rule. For example, the cutoff effect cannot be explained by this theory since compounds above the cutoff can achieve membrane concentrations equal to those of compounds below the cutoff.¹⁶⁴ Similarly, enantioselectivity cannot be explained by this theory. Most importantly, this simplest version of the lipid theory does not explain how the presence of the anesthetic in the membrane is translated into an effect on the function of the embedded proteins.

Membrane Perturbation

More sophisticated versions of the lipid theory require that the anesthetic molecules dissolved in the lipid bilayer cause a change or perturbation in one or more physical properties of the membrane. According to this theory, anesthesia is a function of both the concentration of anesthetic in the membrane and the effectiveness of that anesthetic as a perturbant. This potentially could explain deviations from the Meyer-Overton rule, since nonanesthetics could achieve high concentrations in the membrane, but might not be effective perturbants. In examining this theory it is important to explicitly define the perturbation caused by an anesthetic. One can then test the relevance of a specific perturbation to the mechanism of anesthesia by measuring the perturbation caused by various compounds (anesthetics and nonanesthetics) and correlating perturbation with anesthetic potency. The specific perturbations of membrane structure that have been proposed to be causally related to the anesthetic state are briefly explored in the following section.

Membrane Expansion. Anesthetics dissolved in membranes do increase membrane volume. This occurs both because the anesthetic molecules occupy space and, in principle, because they produce changes in lipid packing and/or protein folding. The *critical volume hypothesis* is an attempt to correlate changes in membrane volume with anesthesia. This hypothesis predicts that anesthesia occurs when anesthetic dissolved in the membrane produces a critical change in membrane volume. Changes in membrane volume could compress ion channels and thus alter their function. Alternatively, increases in membrane thickness could alter neuronal excitability by changing the potential gradient across the plasma membrane.¹⁶⁵ Several studies have shown that anesthetics can produce changes in membrane volume.¹⁶⁶ However, the amount of expansion caused by clinical concentrations of anesthetics is probably very small. One study of erythrocyte membranes showed that halothane (0.27 mM = 1.0 MAC) expanded the membranes by only 0.1%.¹⁶⁷ Another study of erythrocyte membranes showed that both anesthetics and nonanesthetics (long-chain *n*-alkanols above the anesthetic cutoff) produced similar degrees of membrane expansion.¹⁶⁸ While clinical concentrations of anesthetics clearly produce membrane expansion, the small magnitude of anesthetic-induced membrane expansion, coupled with the inability of this theory to account for the cutoff effect, makes it unlikely that membrane expansion is the correct mechanism of anesthesia. A recent study by Cantor revisits this topic.¹⁶⁹ Based on thermodynamic modeling, he argues that anesthetics in biologic membranes preferentially distribute to the interface between lipid and aqueous phases. This distribution results in increased lateral pressure, which could alter the function of membrane-embedded ion channels. His calculations also suggest that nonimmobilizers should not show the same interfacial distribution. There is some experimental evidence showing that anesthetics, but not nonimmobilizers, do preferentially distribute to the lipid/aqueous interface in a membrane.¹⁷⁰ The relationship between these recent observations and anesthetic effects on protein function remains to be determined.

Membrane Disordering. Studies using nuclear magnetic resonance (NMR) spectroscopy¹⁷¹ and electron spin resonance (ESR) spectroscopy¹⁷² have shown that a variety of anesthetics can disorder the packing of phospholipids in lipid bilayers and in biological membranes. The decrease in membrane order (often referred to as an increase in membrane fluidity) can, in principle, alter the function of ion channels embedded in the lipid bilayer. The ability of anesthetics to fluidize lipid bilayers does show a modest correlation with anesthetic potency.¹⁷³ Membrane disordering can also account for the cutoff effect. Studies on synaptic membranes have shown that anesthetic alkanols (octanol, decanol, dodecanol) fluidize membranes, whereas nonanesthetic alkanols have either no effect on fluidity (tetradecanol) or a rigidifying effect (hexadecanol, octadecanol) on the membranes.¹⁷⁴ Unfortunately, the degree of fluidization produced by clinical concentrations of anesthetics is quite small.¹⁷³ While it is unclear how much fluidization would be required to affect ion channel function, anesthetics produce changes in membrane fluidity that can be mimicked by changes in temperature of less than 1°C. Clearly, a 1°C increase in temperature does not cause anesthesia, or even increase anesthetic potency. It is highly unlikely that changes in the fluidity of bulk membrane lipid are responsible for general anesthesia.

Lipid Phase Transitions. Another lipid perturbation that has been proposed to account for general anesthesia is a change in lipid phase-transition behavior. In its original version this theory proposed that anesthetics promote a transition of the lipids in neuronal membranes between a solid (gel) phase and a liquid-crystalline phase. Indeed, in pure lipid systems clinical concentrations of anesthetics do decrease the temperature at which such a transition occurs.¹⁷⁵ A second version of this theory, the *lateral phase-separation theory*, proposed that anesthetics *prevent* phase transitions between the liquid-crystalline and the gel phase.¹⁷⁶ According to this theory, liquid-crystalline to gel phase transition is required for normal ion channel function; inhibition of this phase transition causes anesthesia. There is little evidence to support the phase-transition theories. Anesthetic-induced phase changes have not been observed in biologic membranes, lipid phase transitions are not known to be required for normal ion channel function, and the changes in phase-transition temperature observed in pure lipid systems are less than 1°C.

Protein Theories of Anesthesia

The Meyer-Overton rule could also be explained by the direct interaction of anesthetics with hydrophobic sites on proteins. There are three types of hydrophobic sites on proteins with which anesthetics might interact:

1. Hydrophobic amino acids comprise the core of water-soluble proteins. Anesthetics could bind in hydrophobic pockets that are fortuitously present in the protein core.
2. Hydrophobic amino acids also form the lining of binding sites for hydrophobic ligands. For example, there are hydrophobic pockets in which fatty acids tightly bind on proteins such as albumin and the low-molecular-weight fatty acid-binding proteins. Anesthetics could compete with endogenous ligands for binding to such sites on either water-soluble or membrane proteins.
3. Hydrophobic amino acids are major constituents of the α -helices which form the membrane-spanning regions of membrane proteins; hydrophobic amino acid side chains form the protein surface that faces the membrane lipid. Anesthetic molecules could interact with the hydrophobic surface of these membrane proteins, disrupting normal lipid-protein interactions and possibly directly affecting protein conformation. This last possibility would involve the interaction of many anesthetic molecules with each membrane protein molecule and would probably be a nonselective interaction between anesthetic molecules and *all* membrane proteins.

Direct interactions of anesthetic molecules with proteins would not only satisfy the Meyer-Overton rule, but would also provide the simplest explanation for compounds that deviate from this rule. Any protein binding site is likely to be defined by properties such as size and shape in addition to its solvent properties. Limitations in size

and shape could reduce the binding affinity of compounds beyond the cutoff, thus explaining their lack of anesthetic effect. Enantioselectivity is also most easily explained by a direct binding of anesthetic molecules to defined sites on proteins; a protein binding site of defined dimensions could readily distinguish between enantiomers on the basis of their different shape. Protein binding sites for anesthetics could also explain the convulsant effects of some polyhalogenated alkanes. Different compounds binding (in slightly different ways) to the same binding pocket can produce different effects on protein conformation and hence on protein function. For example, there are three kinds of compounds that can bind at the benzodiazepine binding site on the GABA_A channel: *agonists*, which potentiate GABA effects and produce sedation and anxiolysis; *inverse-agonists*, which promote channel closure and produce convulsant effects; and *antagonists*, which produce no effect on their own but can competitively block the effects of agonists and inverse-agonists. By analogy, polyhalogenated alkanes could be inverse-agonists, binding at the same protein sites at which halogenated alkane anesthetics are agonists. The evidence for direct interactions between anesthetics and proteins is briefly reviewed in the following section.

Evidence for Anesthetic Binding to Proteins

One of the initial approaches to probing anesthetic interactions with proteins was to observe the effects of anesthetics on the function of a protein and to try to make inferences about binding from the functional behavior. It is entirely reasonable to assume that direct anesthetic–protein interactions are responsible for functional effects of anesthetics on purified water-soluble proteins, since no lipid or membrane is present in the preparations studied. Firefly luciferase is a water-soluble, light-emitting protein, which is inhibited by a wide variety of anesthetic molecules. Numerous studies have extensively characterized anesthetic inhibition of firefly luciferase activity, and have revealed the following^{177,178}:

1. Anesthetics inhibit firefly luciferase activity at concentrations very similar to those required to produce clinical anesthesia.
2. The potency of anesthetics as inhibitors of firefly luciferase activity correlates strongly with their potency as anesthetics, in keeping with the Meyer-Overton rule.
3. Halothane inhibition of luciferase activity is competitive with respect to the substrate D-luciferin.
4. Inhibition of firefly luciferase activity shows a cutoff in anesthetic potency for both *n*-alkanes and *n*-alkanols.

Based on these studies it can be inferred that a wide variety of anesthetics can bind in the luciferin-binding pocket of firefly luciferase. The fact that anesthetic inhibition of luciferase activity is consistent with the Meyer-Overton rule, occurs at clinical anesthetic concentrations, and explains the cutoff effect suggests that the luciferin-binding pocket may have physical and chemical characteristics similar to those of a putative anesthetic binding site in the CNS.

More direct approaches to studying anesthetic binding to proteins have included NMR spectroscopy and photoaffinity labeling. Based on early studies by Wishnia and Pinder, it was suspected that anesthetics could bind to several fatty acid-binding proteins, including b-lactoglobulin and bovine serum albumin (BSA).^{179,180} ¹⁹F-NMR spectroscopic studies confirmed¹⁸¹ this, and demonstrated that isoflurane binds to approximately three saturable binding sites on BSA. Isoflurane binding is eliminated by co-incubation with oleic acid, suggesting that isoflurane binds to the fatty acid-binding sites on albumin. Other anesthetics, including halothane, methoxyflurane, sevoflurane, and octanol, compete with isoflurane for binding to BSA.¹⁸² The studies with BSA provide direct evidence that a variety of anesthetics can compete for binding to the same site on a protein. Using this BSA model, it was subsequently shown that anesthetic binding sites could be identified and characterized using a photoaffinity labeling technique. The anesthetic halothane contains a carbon–bromine bond. This bond can be broken by ultraviolet light generating a free radical. That free radical allows the anesthetic to permanently (covalently) label the anesthetic binding site. Eckenhoff and colleagues used ¹⁴C-labeled halothane to photoaffinity-label anesthetic binding sites on BSA,¹⁸³ and obtained results virtually identical to those obtained using NMR spectroscopy. Eckenhoff subsequently has identified the specific amino acids that are photoaffinity-labeled by [¹⁴C]halothane.¹⁸⁴ NMR and photoaffinity-labeling techniques have also been applied to several other proteins. For example, saturable binding of halothane to the luciferin-binding site on firefly luciferase has been directly confirmed using NMR and photoaffinity-labeling techniques.¹⁸⁵ Both NMR and photoaffinity-labeling techniques are also being applied to membrane proteins. At the current time these techniques can only be applied to purified proteins available in relatively large quantity. The muscle-type nicotinic acetylcholine receptor is one of the few membrane proteins that can be purified in large quantity. Eckenhoff has used photoaffinity labeling to show that halothane binds to this protein. The pattern of photoaffinity labeling is complex, suggesting multiple binding sites.¹⁸⁶ Most recently, Miller and colleagues have developed a general anesthetic that is an analog of octanol and functions as a photoaffinity label. This compound, 3-diazirinyloctanol, also binds to specific sites on the nicotinic acetylcholine receptor.¹⁸⁷

Although NMR and photoaffinity techniques can provide extensive information about anesthetic binding sites on proteins, they cannot reveal the details of the three-dimensional structure of these sites. X-Ray diffraction crystallography can provide this kind of three-dimensional detail and has been used to study anesthetic interactions with a small number of proteins. To date, it has been difficult to crystallize membrane proteins; thus, these studies have been limited to water-soluble proteins. In 1965, Schoenborn and colleagues first used X-ray diffraction techniques to examine the interactions of several anesthetics with crystalline myoglobin.^{188,189} These studies demonstrated that at a partial pressure of 2.5 atm (xenon MAC = 1 atm), a single molecule of xenon binds to a specific pocket in the hydrophobic core of the myoglobin molecule. The anesthetics cyclopropane and dichloromethane also bind in this pocket, but larger anesthetics do not. It should be noted that xenon occupies a small empty space in the hydrophobic core of myoglobin and that even dichloromethane is a tight fit in this space. These data provided a clear demonstration that anesthetic molecules can bind in the hydrophobic core of a water-soluble protein and that the size of the hydrophobic binding pocket can account for a cutoff in the size of anesthetic molecules that can bind in that pocket. However, myoglobin cannot bind most anesthetic molecules (because of their size) and is therefore not a good model for the actual anesthetic binding site(s) in the central nervous system.

X-Ray diffraction has also been used to demonstrate that a single molecule of halothane binds in a hydrophobic pocket deep within the enzyme adenylate kinase.¹⁹⁰ Halothane binding was localized to the binding site for the adenine moiety of AMP (adenine monophosphate), a substrate for adenylate kinase. Consistent with this finding, halothane was found to inhibit adenylate kinase in a manner that is competitive with respect to AMP. Unfortunately, halothane binding to adenylate kinase only occurs at concentrations well beyond the clinically useful range. Recently, firefly luciferase has been crystallized in the presence and absence of the anesthetic bromoform. X-Ray diffraction studies of these crystals showed that the anesthetic does bind in the luciferin-binding pocket, as had been inferred from functional studies. Interestingly, two molecules of bromoform bind in the luciferin pocket—one that is likely to compete directly with luciferin for binding and one that is not.¹⁹¹ The binding data with firefly luciferase and adenylate kinase are of particular interest because they demonstrate that anesthetics can bind to endogenous ligand binding sites and there can be a strong correlation between anesthetic binding to a protein site and anesthetic inhibition of protein function.

A recent approach to studying anesthetic interactions with proteins has been to employ site-directed mutagenesis of known anesthetic targets, coupled with molecular modeling to make predictions about the location and structure of anesthetic binding sites. For example, Adron Harris and colleagues have used this approach to predict the location and structure of the alcohol binding site on GABA_A and glycine receptors.¹⁹² A related approach has been to develop model proteins to define the structural requirements for an anesthetic binding site. Using this approach, Johansson has shown that a four- α -helix bundle with a hydrophobic core can bind volatile anesthetics at concentrations (K_D) similar to those required to produce anesthesia.¹⁹³

Summary

There is unequivocal evidence from studies using water-soluble proteins that anesthetics can bind to hydrophobic pockets on proteins. Functional and binding studies with firefly luciferase demonstrate that anesthetics can bind to a protein site at clinically relevant concentrations in a manner that can account for the Meyer-Overton rule and deviations from it. Evidence that direct anesthetic–protein binding interactions may be responsible for anesthetic effects on ion channels in the CNS remains indirect; stereoselectivity currently offers the strongest indirect argument.

Overall, current evidence strongly indicates protein rather than lipid as the molecular target for anesthetic action. While it seems likely that the long-standing controversy between lipid and protein theories of anesthesia is behind us, this leaves numerous unanswered questions about the details of anesthetic–protein interactions. Important questions that remain to be answered include:

1. What is the stoichiometry of anesthetic binding to a protein? (*i.e.*, Do many anesthetic molecules interact with a single protein molecule or only a few?)
2. Do anesthetics compete with endogenous ligands for binding to hydrophobic pockets on protein targets or do they bind to fortuitous cavities in the protein?
3. Do all anesthetics bind to the same pocket on a protein or are there multiple hydrophobic pockets for different anesthetics?
4. How many proteins have hydrophobic pockets in which anesthetics can bind at clinically used concentrations?

HOW ARE THE EFFECTS OF ANESTHETICS ON MOLECULAR TARGETS LINKED TO ANESTHESIA IN THE INTACT ORGANISM?

In previous sections it has been shown that anesthetics affect the function of a number of ion channels and signaling proteins, probably *via* direct anesthetic–protein interactions. It is unclear which, if any, of these effects of anesthetics on protein function are necessary and/or sufficient to produce anesthesia in an intact organism. A number of approaches have been employed to try to link anesthetic effects observed at a molecular level to anesthesia in intact animals. These approaches and their pitfalls are briefly explored in the following section.

Pharmacologic Approaches

An experimental paradigm frequently used to study anesthetic mechanisms is to administer a drug thought to act specifically at a putative anesthetic target (e.g., a receptor agonist or antagonist, an ion channel activator or antagonist), then determine whether the drug has either increased or decreased the animal's sensitivity to a given anesthetic. The underlying assumption is that if a change in anesthetic sensitivity is observed, then the anesthetic is likely to act *via* an action on the specific target of the administered drug. This is a largely flawed strategy that has nonetheless produced a huge literature. The drugs used to modulate anesthetic sensitivity usually have their own direct effects on central nervous system excitability and thus *indirectly* affect anesthetic requirements. For example, while α_2 -adrenergic agonists decrease halothane MAC,¹⁹⁴ they are profound CNS depressants in their own right and produce anesthesia by mechanisms distinct from those used by volatile anesthetics. Thus, the "MAC-sparing" effects of α_2 -agonists provide little insight into how halothane works. A more useful pharmacologic strategy would be to identify drugs that have no effect on CNS excitability but prevent the effects of given anesthetics. Currently, however, there are no such anesthetic antagonists. Development of specific antagonists for anesthetic agents would provide a major tool for linking anesthetic effects at the molecular level to anesthesia in the intact organism, and might also be of significant clinical utility.

An alternative pharmacologic approach is to develop "litmus tests" for the relevance of anesthetic effects observed *in vitro*. One such test takes advantage of compounds that are nonanesthetic despite the predictions of the Meyer-Overton rule. It is argued that "a site affected by these nonanesthetic compounds is unlikely to be relevant to the production of anesthesia."¹⁵³ A similar argument uses stereoselectivity as the discriminator and argues that a site that does not show the same stereoselectivity as that observed for whole animal anesthesia is unlikely to be relevant to the production of anesthesia.¹⁹⁵ Although these tests may be useful, they are very dependent on the assumption that anesthesia is produced *via* drug action at a *single* site. For example, a nonanesthetic might depress CNS excitability *via* its actions on an important anesthetic target site while simultaneously producing counterbalancing excitatory effects at a second site. In this case the "litmus test" would incorrectly eliminate the anesthetic site as irrelevant to whole animal anesthesia. This example is quite plausible given the convulsant effects of many of the nonanesthetic polyhalogenated hydrocarbons.

Summary

Pharmacologic approaches to studying anesthetic mechanism are plagued by issues of pharmacologic and physiologic nonselectivity. Development of selective anesthetic antagonists offers one clear pharmacologic path to link molecular effects of anesthetics to anesthetic action in the intact organism.

Genetic Approaches

An alternative approach to studying the relationship between anesthetic effects observed *in vitro* and whole animal anesthesia is to alter the structure of putative anesthetic targets and determine how this affects whole animal anesthetic sensitivity. Genetic techniques provide the most reliable and versatile methods for changing the structure of putative anesthetic targets. There are genetically determined differences in the sensitivity of individual humans and animals to anesthetics. Selective breeding on the basis of sensitivity to anesthetics can be used to develop strains of animals that differ in their anesthetic sensitivity. In principle, identification of the genetic loci responsible for inter-strain differences in anesthetic sensitivity should provide insight into the molecular targets of anesthetics. Koblin and colleagues have successfully used this strategy to breed two strains of mice (HI and LO) that differ in their sensitivity to N₂O by almost 1.0 atm.¹⁹⁶ A similar strategy has been used to breed mice that have differential sensitivity to the hypnotic effects of the benzodiazepine, diazepam. The two strains of mice (DR and DS) show some modest, but consistent, differences in their sensitivity to volatile anesthetics.¹⁹⁷

Although the development of the HI/LO and DS/DR strains of mice demonstrates that there is a genetic basis for anesthetic sensitivity, there are several reasons why it is unlikely that this approach will result in identification of genetic loci responsible for anesthetic sensitivity:

1. As with the pharmacologic approach, it is unclear whether the various strains of mice differ in their level of CNS excitability rather than in their response to specific anesthetic agents. This is illustrated by the fact that HI mice have been shown to be more sensitive to a variety of convulsants (including picrotoxin, strychnine, and fluorothyl) than are LO mice,¹⁹⁸ suggesting that HI mice may simply have greater CNS excitability than LO mice.
2. The differences in anesthetic sensitivity between these strains are likely to be polygenic, making it difficult to map the responsible genetic loci. This point is illustrated by cross-breeding studies that were performed between HI and LO mice.¹⁹⁹ If a single gene were responsible for N₂O sensitivity, cross-breeding HI and LO should produce a Mendelian distribution of offspring with HI, LO, and intermediate sensitivity to N₂O. The experimental result showed that all animals had intermediate sensitivity, indicating that N₂O sensitivity is determined by multiple genes.
3. The strains have been developed from a nonuniform genetic background, increasing the complexity of localizing the genes responsible for differential anesthetic sensitivity.
4. Mice and other mammals have a relatively long gestation period, making it difficult to screen large numbers of animals and breed over multiple generations.

Genes responsible for polygenic traits such as anesthetic sensitivity can, in principle, be more easily identified in simpler species, such as the microscopic worm *Caenorhabditis elegans*. This is because of the short breeding time of *C. elegans*, the ability to examine large numbers of worms, the extensive genetic information available (the *C. elegans* genome has now been completely sequenced), and the large number of genetic tools available for studies in *C. elegans*. Studies of anesthetic sensitivity in lower organisms are, however, complicated by the difficulty of assigning appropriate anesthetic end points (see [What Is Anesthesia?](#)). Crowder and colleagues have identified behavioral end points in *C. elegans* (mating, coordinated movement, chemotaxis) that are inhibited by volatile anesthetic concentrations similar to human MAC values.²⁰⁰ Using these behavioral end points and quantitative population genetic techniques, Crowder has identified one major locus and five minor loci responsible for variable sensitivity to halothane.²⁰¹ None of these loci affects behavior in the absence of halothane, suggesting that these loci code for targets and/or downstream effectors of halothane in *C. elegans*. Sequencing and identification of these loci is one way in which novel volatile anesthetic targets are likely to be identified.

Anesthetic effects in simple organisms such as *C. elegans* or *Drosophila melanogaster* (the fruit fly) can also be studied using other genetic techniques. For example, a large number of known single gene mutations have been characterized in these species. Crowder has screened many of the behavioral mutants of *C. elegans* for sensitivity to isoflurane and identified the syntaxin gene and several related genes (synaptobrevin, SNAP-25) as potentially important in the anesthetic response. The products of these genes are proteins involved in the process of docking and release of synaptic vesicles. Various mutations in the syntaxin gene produce a 33-fold range of sensitivities to isoflurane.⁵⁶ These data indicate that volatile anesthetics may interfere with neurotransmitter release, suggesting a presynaptic mechanism of anesthesia.

One can also administer mutagenic agents to *C. elegans* or *D. melanogaster* and screen the resulting organisms for volatile anesthetic sensitivity. This potentially increases the likelihood of finding novel genes encoding anesthetic sensitivity. Nash and colleagues have used this approach in fruit flies. As an anesthetic end point, flies were considered to be anesthetized when they fell from their perches in a vertically oriented cylinder.²⁰² Using this end point, four halothane-resistant strains were identified. Two of these strains had abnormal behavior in the absence of anesthetics, but the other two (Har63 and Har56) were phenotypically indistinguishable from normal fruit flies. Interestingly, Har56 and Har63 produced resistance to some volatile anesthetics but not others. For example, Har63 flies were resistant to halothane, enflurane, and isoflurane, but showed increased sensitivity to diethyl ether.²⁰³ The anesthetic response of the mutant flies was also dependent on the anesthetic end point used. When Har63 flies were assayed for their response to a noxious stimulus (a focused beam of light), they were found to be resistant to enflurane, isoflurane, and desflurane, but had *increased* sensitivity to halothane and diethyl ether.²⁰³

Morgan and Sedensky have mutagenized *C. elegans* and screened for anesthetic sensitivity using immobility as an anesthetic end point. The anesthetic concentrations required to produce immobility in *C. elegans* are significantly higher than those required to produce anesthesia in higher animals, but the rank-order potency of various inhalational anesthetics is consistent with the Meyer-Overton rule. When worms were chemically mutagenized and screened for halothane sensitivity, two hypersensitive strains, unc-79 and unc-80, were identified.¹ These strains had increased sensitivity to anesthetics with olive oil/gas partition coefficients greater than that of halothane (chloroform, methoxyflurane, thiomethoxyflurane), but not to less lipophilic agents (enflurane, isoflurane, diethyl ether).²⁰⁴ In a subsequent study, two additional kinds of mutations were identified by screening for alterations in sensitivity to enflurane, isoflurane, and diethyl ether.²⁰⁵ One class of mutant worms showed increased sensitivity to isoflurane and enflurane, but not to halothane or diethyl ether. A second class of mutant worms showed increased sensitivity to all inhalation anesthetics tested. In total, Morgan and Sedensky have now identified eight genes that affect sensitivity to volatile anesthetics. They have sequenced and identified two of these genes. The first, unc-1, has been identified as a homolog of stomatin, an integral membrane protein thought to regulate an associated ion channel.²⁰⁶ The second gene, referred to as GAS-1, encodes a mitochondrial protein involved in the respiratory chain.²⁰⁷ The manner in which these proteins mediate or modulate the immobilizing effects of anesthetics is not understood.

The studies in *Drosophila* and *C. elegans* make two important points. First, the fact that mutations have been isolated that alter sensitivity to some, but not all, anesthetics argues that the mutations are not simply affecting CNS excitability. Second, the mutations isolated from these two species provide evidence against the unitary theory of anesthesia: Mutations that differentially affect sensitivity to various anesthetic agents suggest that different anesthetics may act at different targets.

Mutations that differentially affect anesthetic sensitivity depending on the anesthetic end point used suggest that the various components of the anesthetic state may be caused by anesthetic actions at different targets.

Summary

Overall, genetic studies in lower organisms provide a powerful tool for determining which genes and gene products are important in producing anesthesia in an intact organism. It should be remembered that the anesthetic end points used in lower organisms are always subject to question, and it remains possible that the anesthetic targets identified in these animals are unrelated to targets responsible for anesthesia in higher organisms.

A final genetic technique useful in studying anesthetic mechanisms is the use of transgenic or gene “knockout” technology. This approach can be used to produce animals lacking or overexpressing a putative anesthetic target. Limbird and colleagues have successfully used this approach to introduce a nonfunctional α_{2a} receptor in mice; these mice lost the hypnotic response to dexmedetomidine,²⁰⁸ showing that the anesthetic effects of α_2 -agonists are mediated by the α_{2a} receptor. In studies aimed at defining the role of GABA_A receptor subunits in producing anesthesia, mice have been generated that lack the α_6 and β_3 subunits. Knockout of the α_6 receptor had no effect on sensitivity to barbiturates or volatile anesthetics.²⁰⁹ Interestingly, mice lacking the β_3 subunit had normal sensitivity to barbiturates, enflurane, and halothane using righting reflex as an end point, but were less sensitive than strain-matched controls to halothane and enflurane when tail-clamp response was used as the anesthetic end point. The β_3 knockout mice also showed significantly shorter sleep times in response to etomidate and midazolam (but not pentobarbital) than did strain-matched controls.²¹⁰ It is likely that transgenic and knockout techniques will increasingly be used to test the role of anesthetic targets identified *in vitro* to anesthesia in the intact organism.

CONCLUSIONS

In this chapter evidence has been reviewed concerning the anatomic, physiologic, and molecular loci of anesthetic action. It is clear that anesthetic actions cannot be localized to a specific anatomic site in the central nervous system; indeed, there is some suggestion that different components of the anesthetic state may be mediated by actions at disparate anatomic sites. The actions of anesthetics also cannot be localized to a specific physiologic process. While there is consensus that anesthetics preferentially affect synaptic function as opposed to action potential propagation, the effects of anesthetics are dependent on the agent and synapse studied and can affect presynaptic and/or postsynaptic function. At a molecular level, anesthetics show some selectivity, but still affect the function of multiple ion channels and signaling proteins. Although it is likely that these effects are mediated *via* direct protein–anesthetic interactions, it appears that there are numerous proteins that can directly interact with anesthetics. All of these data suggest that the unitary theory of anesthesia is incorrect and that there are at least several molecular mechanisms of anesthesia.

In keeping with the idea that anesthesia can be produced in a variety of ways, Pancrazio and Lynch have suggested that different anesthetic targets may mediate different components of the anesthetic state.²¹¹ As illustrated in Figure 7-8, they suggest that the analgesic effects of opiates, α_2 -agonists, and volatile anesthetics are mediated *via* inhibition of calcium currents and/or activation of potassium currents. Sedation and amnesia, they propose, are mediated by potentiation or activation of GABA_A receptors. In this model, anesthetic states can also be produced by totally independent mechanisms such as the inhibition of glutamate receptors by ketamine. Although there may be many more important anesthetic targets than those suggested by Pancrazio and Lynch, their proposal illustrates the idea that different molecular targets may mediate the various components of the anesthetic state, and that volatile anesthetics are complete anesthetics because they can interact with several of these molecular targets.

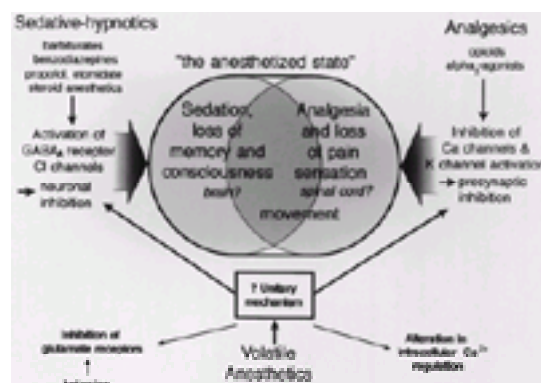

Figure 7-8. A multisite model for anesthesia. The model proposes that presynaptic inhibition (Ca^{2+} channel inhibition, K^+ channel activation) is responsible for analgesic effects, whereas postsynaptic GABA_A receptor activation is responsible for sedation and amnesia. As indicated by the overlapping circles, the behavioral effects of Ca^{2+} channel inhibition and GABA_A receptor activation are not mutually exclusive. The model suggests that some anesthetic agents predominantly affect Ca^{2+} and K^+ channels, other anesthetic agents predominantly affect GABA_A receptors, and volatile anesthetics affect both. As illustrated at the bottom of the model, inhibition of glutamate receptor function is an alternative pathway by which ketamine and perhaps the volatile anesthetics produce anesthesia. (Reproduced with permission from Pancrazio JJ, Lynch C: Snails, spiders, and stereospecificity—Is there a role for calcium channels in anesthetic mechanisms? *Anesthesiology* 81:3, 1994.)

Although the precise molecular interactions responsible for producing anesthesia have not been fully elucidated, it has become clear that anesthetics do act *via* selective effects on specific molecular targets. The technologic revolutions in molecular biology, genetics, and cell physiology make it likely that the next decade will provide the answers to the century-old pharmacologic puzzle of the molecular mechanism of anesthesia.

The myriad of electrical and electronic devices in the modern operating room greatly improve patient care and safety. However, these devices also subject both the patient and operating room personnel to increased risks. To reduce the risk of electrical shock, most operating rooms have electrical systems that incorporate special safety features. It is incumbent upon the anesthesiologist to have a thorough understanding of the basic principles of electricity and an appreciation of the concepts of electrical safety applicable to the operating room environment.

PRINCIPLES OF ELECTRICITY

A basic principle of electricity is known as *Ohm's law*, which is represented by the equation:

$$E = I \times R$$

where E is electromotive force (in volts), I is current (in amperes), and R is resistance (in ohms). Ohm's law forms the basis for the physiologic equation $BP = CO \times SVR$; that is, blood pressure (BP) is equal to the cardiac output (CO) times the systemic vascular resistance (SVR). In this case, the blood pressure of the vascular system is analogous to voltage, the cardiac output to current, and systemic vascular resistance to the forces opposing the flow of electrons. Electrical power is measured in watts. Wattage (W) is the product of the voltage (E) and the current (I), as defined by the formula:

$$W = E \times I$$

The amount of electrical work done is measured in watts per unit of time. The watt-second (a joule, J) is a common designation for electrical energy expended in doing work. The energy produced by a defibrillator is measured in watt-seconds (or joules), and the kilowatt-hour is frequently used to measure larger quantities of electrical energy. For example, electrical utility companies charge their customers on the basis of kilowatt-hours of electricity consumed.

Wattage can be thought of as a measure not only of work done but also of heat produced in any electrical circuit. Substituting Ohm's law in the formula

$$\begin{aligned} W &= E \times I \\ W &= (I \times R) \times I \\ W &= I^2 \times R \end{aligned}$$

Thus, wattage is equal to the square of the current I^2 (amperage) times the resistance R . Using these formulas, it is possible to calculate the number of amperes and the resistance of a given device if the wattage and the voltage are known. For example, a 60-watt light bulb operating on a household 120-volt circuit would require 0.5 amperes of current for operation. Rearranging the formula so that

$$I = W/E$$

we have

$$\begin{aligned} I &= (60 \text{ watts}) / (120 \text{ volts}) \\ I &= 0.5 \text{ ampere} \end{aligned}$$

Using this in Ohm's law

$$R = E/I$$

the resistance can be calculated to be 240 ohms:

$$\begin{aligned} R &= (120 \text{ volts}) / (0.5 \text{ ampere}) \\ R &= 240 \text{ ohms} \end{aligned}$$

It is obvious from the previous discussion that 1 volt of electromotive force (EMF) flowing through a 1-ohm resistance will generate 1 ampere of current. Similarly, 1 ampere of current induced by 1 volt of electromotive force will generate 1 watt of power.

Direct and Alternating Currents

Any substance that permits the flow of electrons is called a *conductor*. Current is characterized by electrons flowing through a conductor. If the electron flow is always in the same direction, it is referred to as *direct current* (DC). However, if the electron flow reverses direction at a regular interval, it is termed *alternating current* (AC). Either of these types of current can be pulsed or continuous in nature.¹

The previous discussion of Ohm's law is accurate when applied to DC circuits. However, when dealing with AC circuits, the situation is more complex because the flow of the current is opposed by a more complicated form of resistance, known as *impedance*.

Impedance

Impedance, designated by the letter Z , is defined as the sum of the forces that oppose electron movement in an AC circuit. Impedance consists of resistance (ohms) but also takes capacitance and inductance into account. In actuality, when referring to AC circuits, Ohm's law is defined as

$$E = I \times Z$$

An *insulator* is a substance that opposes the flow of electrons. Therefore, an insulator has a high impedance to electron flow, whereas a conductor has a low impedance to electron flow.

In AC circuits the capacitance and inductance can be important factors in determining the total impedance. Both capacitance and inductance are influenced by the frequency (cycles per second or hertz, Hz) at which the AC current reverses direction. The impedance is directly proportional to the frequency (f) times the inductance (IND):

$$Z \propto (f \times \text{IND})$$

and the impedance is inversely proportional to the product of the frequency (f) and the capacitance (CAP):

$$Z \propto 1 / (f \times \text{CAP})$$

As the AC current increases in frequency, the net effect of both capacitance and inductance increases. However, because impedance and capacitance are inversely related, total impedance decreases as the product of the frequency and the capacitance increases. Thus, as frequency increases, impedance falls and more current is allowed to pass.²

Capacitance

A *capacitor* consists of any two parallel conductors that are separated by an insulator (Fig. 8-1). A capacitor has the ability to store charge. *Capacitance* is the measure of that substance's ability to store charge. In a DC circuit the capacitor plates are charged by a voltage source (*i.e.*, a battery) and there is only a momentary current flow. The circuit is not completed and no further current can flow unless a resistance is connected between the two plates and the capacitor is discharged.³

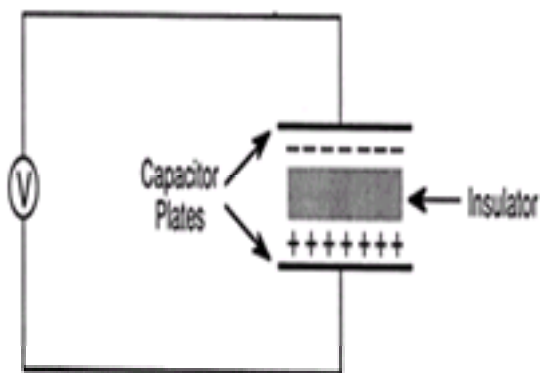

Figure 8-1. A capacitor consists of two parallel conductors separated by an insulator. The capacitor is capable of storing charge supplied by a voltage source.

In contrast to DC circuits, a capacitor in an AC circuit permits current flow even when the circuit is not completed by a resistance. This is due to the nature of AC circuits, in which the current flow is constantly being reversed. Because current flow results from the movement of electrons, the capacitor plates are alternately charged—first positive and then negative with every reversal of the AC current direction—resulting in an effective current flow as far as the remainder of the circuit is concerned, even though the circuit is not completed.⁴

Because the effect of capacitance on impedance varies directly with the AC frequency (Hz), the greater the AC frequency, the lower the impedance. Therefore, high-frequency currents (0.5–2 million Hz), such as those used by electrosurgical units (ESUs), will cause a marked decrease in impedance. For example, a 20-million-ohm impedance in a 60-Hz AC circuit will be reduced to just a few hundred ohms when the frequency is increased to 1 million Hz.⁵

Electrical devices use capacitors for various beneficial purposes. There is, however, a phenomenon known as *stray capacitance*—capacitance that was not designed into the system but is incidental to the construction of the equipment.⁶ All AC-operated equipment produces stray capacitance. An ordinary power cord, for example, consisting of two insulated wires running next to each other will generate significant capacitance simply by being plugged into a 120-volt circuit, even though the piece of equipment is not turned on. Another example of stray capacitance is found in electric motors. The circuit wiring in electric motors generates stray capacitance to the metal housing of the motor.⁷ The clinical importance of capacitance will be emphasized later in the chapter.

Inductance

Whenever electrons flow in a wire, a magnetic field is induced around the wire. If the wire is coiled repeatedly around an iron core, as in a transformer, the magnetic field can be very strong. *Inductance* is a property of AC circuits in which an opposing EMF can be electromagnetically generated in the circuit. The net effect of inductance is to increase impedance. Because the effect of inductance on impedance is also dependent on AC frequency, increases in frequency will increase the total impedance. Therefore, the total impedance of a coil will be much greater than its simple resistance.⁴

ELECTRICAL SHOCK HAZARDS

Alternating and Direct Currents

Whenever an individual contacts an external source of electricity, an electrical shock is possible. An electrical current can stimulate skeletal muscle cells to contract, and thus can be used therapeutically in devices such as pacemakers or defibrillators. However, casual contact with an electrical current, whether AC or DC, can lead to injury or death. Although it takes approximately three times as much DC as AC to cause ventricular fibrillation,³ this by no means renders DC harmless. Devices such as an automobile battery or a DC defibrillator can be sources of direct current shocks.

In the United States, utility companies supply electrical energy in the form of alternating currents of 120 volts at a frequency of 60 Hz.* The 60 Hz refers to the number of times in 1 second that the current reverses its direction of flow.⁸ Both the voltage and current waveforms form a sinusoidal pattern (Fig. 8-2).

Figure 8-2. Sine wave flow of electrons in a 60-Hz alternating current.

To have the completed circuit necessary for current flow, a closed loop must exist and a voltage source must drive the current through the impedance. If current is to flow in the electrical circuit, there has to be a *voltage differential*, or a drop in the driving pressure across the impedance. According to Ohm's law, if the resistance is held constant, then the greater the current flow, the larger the voltage drop must be.⁹

The power company attempts to maintain the line voltage constant at 120 volts. Therefore, by Ohm's law the current flow is inversely proportional to the impedance. A typical power cord consists of two conductors. One designated as "hot" carries the current to the impedance; the other is neutral, and it returns the current to the source. The potential difference between the two is effectively 120 volts (Fig. 8-3). The amount of current flowing through a given device is frequently referred to as the "load." The load of the circuit is dependent on the impedance. A very high impedance circuit allows only a small current to flow and thus has a small load. A very low impedance circuit will draw a large current and is said to be a large load. A "short circuit" occurs when there is a zero impedance load with a very high current flow.¹⁰

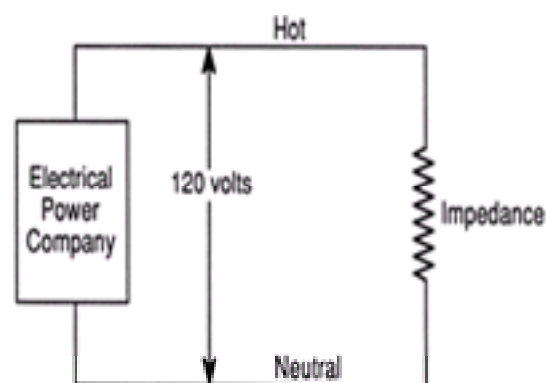

Figure 8-3. A typical AC circuit where there is a potential difference of 120 volts between the hot and neutral sides of the circuit. The current flows through a resistance, which in AC circuits is more accurately referred to as impedance, and then returns to the electrical power company.

Source of Shocks

To practice electrical safety it is important for the anesthesiologist to understand the basic principles of electricity and be aware of how electrical accidents can occur. Electrical accidents or shocks occur when a person becomes part of or completes an electrical circuit. To receive a shock, one must contact the electrical circuit at two points, and there must be a voltage source that causes the current to flow through an individual (Fig. 8-4).

Figure 8-4. An individual can complete an electric circuit and receive a shock by coming in contact with the hot side of the circuit (point A). This is because he or she is standing on the ground (point B) and the contact point A and the ground point B provide the two contact points necessary for a completed circuit. The severity of the shock that the individual receives is dependent upon his or her skin resistance.

When an individual contacts a source of electricity, damage occurs in one of two ways. First, the electrical current can disrupt the normal electrical function of cells. Depending on its magnitude, the current can contract muscles, alter brain function, paralyze respiration, or disrupt normal heart function, leading to ventricular fibrillation. The second mechanism involves the dissipation of electrical energy throughout the body's tissues. An electrical current passing through any resistance raises the temperature of that substance. If enough thermal energy is released, the temperature will rise sufficiently to produce a burn. Accidents involving household currents usually do not result in severe burns. However, in accidents involving very high voltages (*i.e.*, power transmission lines), severe burns are common.

The severity of an electrical shock is determined by the amount of current (number of amperes) and the duration of the current flow. For the purposes of this discussion, electrical shocks are divided into two categories. *Macroshock* refers to large amounts of current flowing through a person, which can cause harm or death. *Microshock* refers to very small amounts of current and applies only to the electrically susceptible patient. This is an individual who has an external conduit that is in direct contact with the heart. This can be a pacing wire or a saline-filled catheter such as a central venous or pulmonary artery catheter. In the case of the electrically susceptible patient, even minute amounts of current (microshock) may cause ventricular fibrillation.

Table 8-1 shows the effects typically produced by various currents following a 1-second contact with a 60-Hz current. When an individual contacts a 120-volt household current, the severity of the shock will depend on his or her skin resistance, the duration of the contact, and the current density. Skin resistance can vary from a few thousand to 1 million ohms. If a person with a skin resistance of 1000 ohms contacts a 120-volt circuit, he or she would receive 120 milliamperes (mA) of current, which would probably be lethal. However, if that same person's skin resistance is 100,000 ohms, the current flow would be 1.2 mA, which would barely be perceptible.

| Current | Effect |
|------------------------|--|
| MACROSHOCK | |
| 1 mA (0.001 A) | Threshold of perception |
| 5 mA (0.005 A) | Accepted as maximum harmless current intensity |
| 10–20 mA (0.01–0.02 A) | “Let-go” current before sustained muscle contraction |
| 50 mA (0.05 A) | Pain, possible fainting, mechanical injury; heart and respiratory functions continue |
| 100–300 mA (0.1–0.3 A) | Ventricular fibrillation will start, but respiratory center remains intact |
| 6000 mA (6 A) | Sustained myocardial contraction, followed by normal heart rhythm; temporary respiratory paralysis; burns if current density is high |
| MICROSHOCK | |
| 100 μ A (0.1 mA) | Ventricular fibrillation |
| 10 μ A (0.01 mA) | Recommended maximum 60 Hz leakage current |

A = amperes; mA = milliamperes; μ A = microamperes.

Table 8-1. EFFECTS OF 60-HZ CURRENT ON AN AVERAGE HUMAN FOR A 1-SECOND CONTACT

$$I = E/R = (120 \text{ volts}) / (1000 \text{ ohms}) = 120 \text{ mA}$$

$$I = E/R = (120 \text{ volts}) / (100,000 \text{ ohms}) = 1.2 \text{ mA}$$

The longer an individual is in contact with the electrical source, the more dire the consequences because more energy will be released and more tissue damaged. Also, there will be a greater chance of ventricular fibrillation from excitation of the heart during the vulnerable period of the electrocardiogram (ECG) cycle.

Current density is a way of expressing the amount of current that is applied per unit area of tissue. The diffusion of current in the body tends to be in all directions. The greater the current or the smaller the area to which it is applied, the higher the current density. In relation to the heart, a current of 100 mA (100,000 μ A) is generally required to produce ventricular fibrillation when applied to the surface of the body. However, only 100 μ A (0.1 mA) is required to produce ventricular fibrillation when that minute current is applied directly to the myocardium through an instrument having a very small contact area, such as a pacing wire electrode. In this case, the current density is 1000-fold greater when applied directly to the heart; therefore, only 1/1000 of the energy is required to cause ventricular fibrillation. In this case, the electrically susceptible patient can be electrocuted with currents well below 1 mA, which is the threshold of perception for humans. The frequency at which the current reverses is also an important factor in determining the amount of current an individual can safely contact. Utility companies in the United States produce electricity at a frequency of 60 Hz. They use 60 Hz because higher frequencies cause greater power loss through transmission lines and lower frequencies cause a detectable flicker from light sources.¹¹ The “let-go” current is defined as that current above which sustained muscular contraction occurs and at which an individual would be unable to let go of an energized wire. The let-go current for a 60-Hz AC power is 10–20 mA,^{10,12,13} whereas at a frequency of 1 million Hz, up to 3 amperes (3000 mA) is generally considered safe.³ It should be noted that very high frequency currents do not excite contractile tissue; consequently, they do not cause cardiac arrhythmias.

It can be seen that Ohm’s law governs the flow of electricity. For a completed circuit to exist, there must be a closed loop with a driving pressure to force a current through a resistance. Just as in the cardiovascular system there must be a blood pressure to drive the cardiac output through the peripheral resistance. [Figure 8-5](#) illustrates that a hot wire carrying a 120-volt pressure through the resistance of a 60-watt light bulb produces a current flow of 0.5 ampere. The voltage in the neutral wire is approximately 0 volts, while the current in the neutral wire remains at 0.5 ampere. This correlates with our cardiovascular analogy, where a mean blood pressure decrease of 80 mm Hg between the aortic root and the right atrium forces a cardiac output of 6 L \cdot min⁻¹ through a systemic vascular resistance of 13.3 resistance units. However, the flow (in this case, the cardiac output, or in the case of the electrical model, the current) is still the same everywhere in the circuit. That is, the cardiac output on the arterial side is the same as the cardiac output on the venous side.

Figure 8-5. A 60-watt light bulb has an internal resistance of 240 ohms and draws 0.5 ampere of current. The voltage drop in the circuit is from 120 in the hot wire to 0 in the neutral wire, but the current is 0.5 ampere in both the hot and neutral wires.

Grounding

To fully understand electrical shock hazards and their prevention, one must have a thorough knowledge of the concepts of grounding. These concepts of grounding probably constitute the most confusing aspects of electrical safety because the same term is used to describe several different principles. In electrical terminology, grounding is applied to two separate concepts. The first is the grounding of electrical *power*, and the second is the grounding of electrical *equipment*. Thus, the concepts that (1) power can be grounded or ungrounded and that (2) power can supply electrical devices that are themselves grounded or ungrounded are not mutually exclusive. It is vital to understand this point as the basis of electrical safety ([Table 8-2](#)). Whereas electrical *power* is grounded in the home, it is usually ungrounded in the operating room. In the home, electrical *equipment* may be grounded or ungrounded, but it should always be grounded in the operating room.

| | Power | Equipment |
|----------------|-------|-----------|
| Home | + | ± |
| Operating room | - | + |

+ , grounded; - , ungrounded; ± , may or may not be grounded.

Table 8-2. DIFFERENCES BETWEEN POWER AND EQUIPMENT GROUNDING IN THE HOME AND THE OPERATING ROOM

ELECTRICAL POWER: GROUNDED

Electrical utilities universally provide power that is grounded (by convention, the earth–ground potential is zero, and all voltages represent a difference between potentials). That is, one of the wires supplying the power to a home is intentionally connected to the earth. The utility companies do this as a safety measure to prevent electrical charges from building up in their wiring during electrical storms. This also prevents the very high voltages used in transmitting power by the utility from entering the home in the event of an equipment failure in their high-voltage system.³

The power enters the typical home via two wires. These two wires are attached to the main fuse or the circuit breaker box at the service entrance. The “hot” wire supplies power to the “hot” distribution strip. The neutral wire is connected to the neutral distribution strip and to a service entrance ground (*i.e.*, a pipe buried in the earth) (Fig. 8-6). From the fuse box, three wires leave to supply the electrical outlets in the house. In the United States, the “hot” wire is color-coded black and carries a voltage 120 volts above ground potential. The second wire is the neutral wire color-coded white; the third wire is the ground wire, which is either color-coded green or is uninsulated (bare wire). The ground and the neutral wires are attached at the same point in the circuit breaker box and then further connected to a cold-water pipe (Fig. 8-7 and Fig. 8-8). Thus, this grounded power system is also referred to as a neutral grounded power system. The black wire is not connected to the ground, as this would create a short circuit. The black wire is attached to the “hot” (*i.e.*, 120 volts above ground) distribution strip upon which the circuit breakers or fuses are located. From here, numerous branch circuits supply electrical power to the outlets in the house. Each branch circuit is protected by a circuit breaker or fuse that limits current to a specific maximum amperage. Most electrical circuits in the house are 15- or 20-ampere circuits. These typically supply power to the electrical outlets and lights in the house. Several higher amperage circuits are also provided for devices such as an electric stove or an electric clothes dryer. These devices are also powered by 240-volt circuits, which can draw from 30 to 50 amperes of current. The circuit breaker or fuse will interrupt the flow of current on the hot side of the line in the event of a short circuit or if the demand placed on that circuit is too high. For example, a 15-ampere branch circuit will be capable of supporting 1800 watts of power.

Figure 8-6. In a neutral grounded power system, the electric company supplies two lines to the typical home. The neutral is connected to ground by the power company and again connected to a service entrance ground when it enters the fuse box. Both the neutral and ground wires are connected together in the fuse box at the neutral bus bar, which is also attached to the service entrance ground.

Figure 8-7. Inside a fuse box with the circuit breakers removed. The arrowheads indicate the hot wires energizing the strips where the circuit breakers are located. The arrows point to the neutral bus bar where the neutral and ground wires are connected.

Figure 8-8. The arrowhead indicates the ground wire from the fuse box attached to a cold-water pipe.

$$W = E \times I$$

$$W = 120 \text{ volts} \times 15 \text{ amperes}$$

$$W = 1800 \text{ watts}$$

Therefore, if two 1500-watt hair dryers were simultaneously plugged into one outlet, the load would be too great for a 15-ampere circuit, and the circuit breaker would open (trip) or the fuse would melt. This is done to prevent the supply wires in the circuit from melting and starting a fire. The amperage of the circuit breaker on the branch circuit is determined by the thickness of the wire that it supplies. If a 20-ampere breaker is used with wire rated for only 15 amperes, the wire could melt and start a fire before the circuit breaker would trip. It is important to note that a 15-ampere circuit breaker does not protect an individual from lethal shocks. The 15 amperes of current that would trip the circuit breaker far exceeds the 100–200 mA that will produce ventricular fibrillation.

The wires that leave the circuit breaker supply the electrical outlets and lighting for the rest of the house. In older homes the electrical cable consists of two wires, a hot and a neutral, which supply power to the electrical outlets (Fig. 8-9). In newer homes, a third wire has been added to the electrical cable (Fig. 8-10). This third wire is either green or uninsulated (bare) and serves as a ground wire for the power receptacle (Fig. 8-11). On one end, the ground wire is attached to the electrical outlet (Fig. 8-12); on the other, it is connected to the neutral distribution strip in the circuit breaker box along with the neutral (white) wires (Fig. 8-13).

Figure 8-9. An older style electrical outlet consisting of just two wires (a hot and a neutral). There is no ground wire.

Figure 8-10. Modern electrical cable in which a third, or ground, wire has been added.

Figure 8-11. Modern electrical outlet in which the ground wire is present. The arrowhead points to the part of the receptacle where the ground wire connects.

Figure 8-12. Detail of modern electrical power receptacle. The arrow points to the ground wire, which is attached to the grounding screw on the power receptacle.

Figure 8-13. The ground wires from the power outlet are run to the neutral bus bar, where they are connected with the neutral wires (arrowheads).

It should be realized that in both the old and new situations, the power is grounded. That is, a 120-volt potential exists between the hot (black) and the neutral (white) wire and between the hot wire and ground. In this case, the ground is the earth (Fig. 8-14). In modern home construction, there is still a 120-volt potential difference between the hot (black) and the neutral (white) wire as well as a 120-volt difference between the equipment ground wire (which is the third wire), and between the hot wire and earth (Fig. 8-15).

Figure 8-14. Diagram of a house with older style wiring that does not contain a ground wire. A 120-volt potential difference exists between the hot and the neutral wire as well as between the hot wire and earth.

Figure 8-15. Diagram of a house with modern wiring in which the third, or ground, wire has been added. The 120-volt potential difference exists between the hot and neutral wires, the hot and the ground wires, and the hot wire and the earth.

A 60-watt light bulb can be used as an example to further illustrate this point. Normally, the hot and neutral wires are connected to the two wires of the light bulb socket, and throwing the switch will illuminate the bulb (Fig. 8-16). Similarly, if the hot wire is connected to one side of the bulb socket and the other wire from the light bulb is connected to the equipment ground wire, the bulb will still illuminate. If there is no equipment ground wire, the bulb will still light if the second wire is connected to any grounded metallic object such as a water pipe or a faucet. This illustrates the fact that the 120-volt potential difference exists not only between the hot and the neutral wires but also between the hot wire and any grounded object. Thus, in a grounded power system, the current will flow between the hot wire and any conductor with an earth ground.

Figure 8-16. A simple light bulb circuit in which the hot and neutral wires are connected with the corresponding wires from the light bulb fixture.

As previously stated, current flow requires a closed loop with a source of voltage. For an individual to receive an electric shock, he or she must contact the loop at two points. Because we may be standing on ground or be in contact with an object that is referenced to ground, only one additional contact point is necessary to complete the circuit and thus receive an electrical shock. This is an unfortunate and inherently dangerous consequence of grounded power systems. Modern wiring systems have added the third wire, the equipment ground wire, as a safety measure to reduce the severity of a potential electrical shock. This is accomplished by providing an alternate, low-resistance pathway through which the current can flow to ground.

Over time the insulation covering wires may deteriorate. It is then possible for a bare, hot wire to contact the metal case or frame of an electrical device. The case would then become energized and constitute a shock hazard to someone coming in contact with it. Figure 8-17 illustrates a typical short circuit, where the individual has come in contact with the hot case of an instrument. This illustrates the type of wiring found in older homes. There is no ground wire in the electrical outlet, nor is the electrical apparatus equipped with a ground wire. Here, the individual completes the circuit and receives a severe shock. Figure 8-18 illustrates a similar example, except that now the equipment ground wire is part of the electrical distribution system. In this example, the equipment ground wire provides a pathway of low impedance through which the current can travel; therefore, most of the current would travel through the ground wire. In this case, the person may get a shock, but it is unlikely to be fatal.

Figure 8-17. When a faulty piece of equipment without an equipment ground wire is plugged into an electrical outlet not containing a ground wire, the case of the instrument will become hot. An individual touching the hot case (point A) will receive a shock because he or she is standing on the earth (point B) and completes the circuit. The current (dashed line) will flow from the instrument through the individual touching the hot case.

Figure 8-18. When a faulty piece of equipment containing an equipment ground wire is properly connected to an electrical outlet with a grounding connection, the current (dashed line) will preferentially flow down the low-resistance ground wire. An individual touching the case (point A) while standing on the ground (point B) will still complete the circuit; however, only a small part of the current will go through the individual.

The electrical power supplied to homes is always grounded. A 120-volt potential always exists between the hot conductor and ground or earth. The third or equipment ground wire used in modern electrical wiring systems does not normally have current flowing through it. In the event of a short circuit, an electrical device with a

three-prong plug (*i.e.*, a ground wire connected to its case) will conduct the majority of the short circuited or “fault” current through the ground wire and away from the individual. This provides a significant safety benefit to someone accidentally contacting the defective device. If a large enough fault current exists, the ground wire also will provide a means to complete the short circuit back to the circuit breaker or fuse, and this will either melt the fuse or trip the circuit breaker. Thus, in a grounded power system, it is possible to have either grounded or ungrounded equipment, depending upon when the wiring was installed and whether the electrical device is equipped with a three-prong plug containing a ground wire. Obviously, attempts to bypass the safety system of the equipment ground should be avoided. Devices such as a “cheater plug” (Fig. 8-19) should never be used because they defeat the safety feature of the equipment ground wire.

Figure 8-19. Right: A “cheater plug” that converts a three-prong power cord to a two-prong cord. Left: The wire attached to the cheater plug is rarely connected to the screw in the middle of the outlet. This totally defeats the purpose of the equipment ground wire.

ELECTRICAL POWER: UNGROUNDED

Numerous electronic devices, together with power cords and puddles of saline solutions on the floor, make the operating room an electrically hazardous environment for both patients and personnel. Bruner *et al*¹⁴ found that 40% of electrical accidents in hospitals occurred in the operating room. The complexity of electrical equipment in the modern operating room demands that electrical safety be a factor of paramount importance. To provide an extra measure of safety from gross electrical shock (macroshock), the power supplied to most operating rooms is ungrounded. In this ungrounded power system, the current is isolated from ground potential. The 120-volt potential difference exists only between the two wires of the isolated power system, but no circuit exists between the ground and either of the isolated power lines.

Supplying ungrounded power to the operating room requires the use of an *isolation transformer* (Fig. 8-20). This device uses electromagnetic induction to induce a current in the un-grounded or secondary winding of the transformer from energy supplied to the primary winding. There is no direct electrical connection between the power supplied by the utility company on the primary side and the power induced by the transformer on the ungrounded or secondary side. Thus, the power supplied to the operating room is isolated from ground (Fig. 8-21). Because the 120-volt potential exists only between the two wires of the isolated circuit, neither wire is hot or neutral with reference to ground. In this case, they are simply referred to as line 1 and line 2 (Fig. 8-22). Using the example of the light bulb, if one connects the two wires of the bulb socket to the two wires of the isolated power system, the light will illuminate. However, if one connects one of the wires to one side of the isolated power and the other wire to ground, the light will not illuminate. If the wires of the isolated power system are connected, the short circuit will trip the circuit breaker. In comparing the two systems, the standard grounded power has a direct connection to ground, whereas the isolated system imposes a very high impedance to any current flow to ground. The added safety of this system can be seen in Figure 8-23. In this case, a person has come in contact with one side of the isolated power system (point A). Because standing on ground (point B) does not constitute a part of the isolated circuit, the individual does not complete the loop and will not receive a shock. This is because the ground is part of the primary circuit (*solid lines*), and the person is contacting only one side of the isolated secondary circuit (*cross-hatched lines*). The person does not complete either circuit (*i.e.*, have two contact points); therefore, this situation does not pose an electric shock hazard. Of course, if the person contacts both lines of the isolated power system (an unlikely event), he or she would receive a shock.

Figure 8-20. (A) Isolated power panel showing circuit breakers, LIM, and isolation transformer (arrow). (B) Detail of an isolation transformer with the attached warning lights. The arrow points to ground wire connection on the primary side of the transformer. Note that no similar connection exists on the secondary side of the transformer.

Figure 8-21. In the operating room, the isolation transformer converts the grounded power on the primary side to an ungrounded power system on the secondary side of the transformer. A 120-volt potential difference exists between line 1 and line 2. There is no direct connection from the power on the secondary side to ground. The equipment ground wire, however, is still present.

Figure 8-22. Detail of the inside of a circuit breaker box in an isolated power system. The bottom arrow points to ground wires meeting at the common ground terminal. Arrows 1 and 2 indicate lines 1 and 2 from the isolated power circuit breaker. Neither line 1 nor line 2 is connected to the same terminals as the ground wires. This is in marked contrast to [Figure 8-13](#), where the neutral and ground wires are attached at the same point.

Figure 8-23. A safety feature of the isolated power system is illustrated. An individual contacting one side of the isolated power system (point A) and standing on the ground (point B) will not receive a shock. In this instance, the individual is not contacting the circuit at two points and thus is not completing the circuit. Point A (cross-hatched lines) is part of the isolated power system, and point B is part of the primary or grounded side of the circuit. (solid lines).

If a faulty electrical appliance with an intact equipment ground wire is plugged into a standard household outlet, and the home wiring has a properly connected ground wire, then the amount of electrical current that will flow through the individual is considerably less than what will flow through the low-resistance ground wire. Here, an individual would be fairly well protected from a serious shock. However, if that ground wire were broken, the individual might receive a lethal shock. No shock would occur if the same faulty piece of equipment were plugged into the isolated power system, even if the equipment ground wire were broken. Thus, the isolated power system provides a significant amount of protection from macroshock. Another feature of the isolated power system is that the faulty piece of equipment, even though it may be partially short-circuited, will not usually trip the circuit breaker. This is an important feature because the faulty piece of equipment may be part of a life-support system for a patient. It is important to note that even though the power is isolated from ground, the case or frame of all electrical equipment is still connected to an equipment ground. The third wire (equipment ground wire) is necessary for a total electrical safety program.

[Figure 8-24](#) illustrates a scenario involving a faulty piece of equipment connected to the isolated power system. This does not represent a hazard; it merely converts the isolated power back to a grounded power system as exists outside the operating room. In fact, a *second* fault is necessary to create a hazard.

Figure 8-24. A faulty piece of equipment plugged into the isolated power system does not present a shock hazard. It merely converts the isolated power system into a grounded power system. The figure insert illustrates that the isolated power system is now identical to the grounded power system. The dashed line indicates current flow in the ground wire.

The previous discussion assumes that the isolated power system is perfectly isolated from ground. Actually, perfect isolation is impossible to achieve. All AC-operated power systems and electrical devices manifest some degree of capacitance. As previously discussed, electrical power cords, wires, and electrical motors exhibit capacitive coupling to the ground wire and metal conduits, and “leak” small amounts of current to ground ([Fig. 8-25](#)). This so-called *leakage current* partially ungrounds the isolated power system. This does not usually amount to more than a few milliamperes in an operating room. So an individual coming in contact with one side of the isolated power system would receive only a very small shock (1–2 mA). Although this amount of current would be perceptible, it would not be dangerous.

Figure 8-25. The capacitance that exists in AC power lines and AC-operated equipment results in small “leakage currents” that partially degrade the isolated power system.

THE LINE ISOLATION MONITOR

The line isolation monitor (LIM) is a device that continuously monitors the integrity of an isolated power system. If a faulty piece of equipment is connected to the isolated power system, this will, in effect, change the system back to a conventional grounded system. Also, the faulty piece of equipment will continue to function normally. Therefore, it is essential that a warning system be in place to alert the personnel that the power is no longer ungrounded. The LIM continuously monitors the isolated power to ensure that it is indeed isolated from ground, and the device has a meter that displays a continuous indication of the integrity of the system ([Fig. 8-26](#)). The LIM is actually measuring the impedance to ground of each side of the isolated power system. As previously discussed, with perfect isolation, impedance would be infinitely high and there would be no current flow in the event of a first fault situation ($Z = E/I$; if $I = 0$, then $Z = \infty$). Because all AC wiring and all AC-operated electrical devices have some capacitance, small leakage currents are present that partially degrade the isolation of the system. The meter of the LIM will indicate (in milliamperes) the total amount of leakage in the system resulting from capacitance, electrical wiring, and any devices plugged into the isolated power system.

Figure 8-26. The meter of the line isolation monitor is calibrated in milliamperes. If the isolation of the power system is degraded such that >12 mA (5 mA in newer systems) of current could flow, the hazard light will illuminate and a warning buzzer will sound. Note the button for testing the hazard warning system. (A) Older line isolation monitor that will trigger an alarm at 2 mA. (B) Newer line isolation monitor that will trigger an alarm at 5 mA.

The reading on the LIM meter does not mean that current is actually flowing; rather, it indicates how much current would flow in the event of a first fault. The LIM is set to alarm at 2 or 5 mA, depending on the age and brand of the system. Once this preset limit is exceeded, visual and audible alarms are triggered to indicate that the isolation from ground has been degraded beyond a predetermined limit (Fig. 8-27). This does not necessarily mean that there is a hazardous situation, but rather that the system is no longer totally isolated from ground. It would require a second fault to create a dangerous situation.

Figure 8-27. When a faulty piece of equipment is plugged into the isolated power system, it will markedly decrease the impedance from line 1 or line 2 to ground. This will be detected by the LIM, which will sound an alarm.

For example, if the LIM were set to alarm at 2 mA, using Ohm's law, the impedance for either side of the isolated power system would be 60,000 ohms:

$$Z = E/I$$

$$Z = (120 \text{ volts})/(0.002 \text{ amperes})$$

$$Z = 60,000 \text{ ohms}$$

Therefore, if either side of the isolated power system had less than 60,000 ohms impedance to ground, the LIM would trigger an alarm. This might occur in two situations. In the first, a faulty piece of equipment is plugged into the isolated power system. In this case, a true fault to ground exists from one line to ground. Now the system would be converted to the equivalent of a grounded power system. This faulty piece of equipment should be removed and serviced as soon as possible. However, this piece of equipment could still be used safely if it were essential for the care of the patient. It should be remembered, however, that continuing to use this faulty piece of equipment would create the potential for a serious electrical shock. This would occur if a second faulty piece of equipment were simultaneously connected to the isolated power system.

The second situation involves connecting many perfectly normal pieces of equipment to the isolated power system. Although each piece of equipment has only a small amount of leakage current, if the total leakage exceeds 2 mA, the LIM will trigger an alarm. Assume that in the same operating room there are 30 electrical devices, each having 100 μ A of leakage current. The total leakage current ($30 \times 100 \mu\text{A}$) would be 3 mA. The impedance to ground would still be 40,000 ohms ($120/0.003$). The LIM alarm would sound because the 2-mA set point was violated. However, the system is still safe and represents a state significantly different from that in the first situation. For this reason, the newer LIMs are set to alarm at 5 mA instead of 2 mA.

The newest LIMs are referred to as third-generation monitors. The first-generation monitor, or static LIM, was unable to detect balanced faults (*i.e.*, a situation in which there are equal faults to ground from both line 1 and line 2). The second-generation, or dynamic LIM, did not have this problem but could interfere with physiologic monitoring. Both of these monitors would trigger an alarm at 2 mA, which led to annoying "false" alarms. The third-generation LIM corrects the problems of its predecessors and has the alarm threshold set at 5 mA.¹⁵ Proper functioning of the LIM is dependent on having both intact equipment ground wires as well as its own connection to ground. First- and second-generation LIMs could not detect the loss of the LIM ground connection. The third-generation LIM can detect this loss of ground to the monitor. In this case the LIM alarm would sound and the red hazard light would illuminate, but the LIM meter would read zero. This condition will alert the staff that the LIM needs to be repaired. However, the LIM still cannot detect broken equipment ground wires. An example of the third-generation LIM is the *Iso-Gard* made by the Square D Company (Monroe, NC).

The equipment ground wire is again an important part of the safety system. If this wire is broken, a faulty piece of equipment that is plugged into an outlet would operate normally, but the LIM would not alarm. A second fault could therefore cause a shock, without any alarm from the LIM. Also, in the event of a second fault, the equipment ground wire provides a low-resistance path to ground for most of the fault current (Fig. 8-24). The LIM will only be able to register leakage currents from pieces of equipment that are connected to the isolated power system and have intact ground wires.

If the line isolation monitor alarm is triggered, the first thing to do is to check the gauge to determine if it is a true fault. The other possibility is that too many pieces of electrical equipment have been plugged in and the 2-mA limit has been exceeded. If the gauge is between 2 and 5 mA, it is probable that too much electrical equipment has been plugged in. If the gauge reads >15 mA, most likely there is a faulty piece of equipment present in the operating room. The next step is to identify the faulty equipment, which is done by unplugging each piece of equipment until the alarm ceases. If the faulty piece of equipment is not of a life-support nature, it should be removed from the operating room. If it is a vital piece of life-support equipment, it can be safely used. However, it must be remembered that the protection of the isolated power system and the line isolation monitor is no longer operative. Therefore, if possible, no other electrical equipment should be connected during the remainder of the case, or until the faulty piece of equipment can be safely removed.

GROUND FAULT CIRCUIT INTERRUPTER

The ground fault circuit interrupter (GFCI) is another popular device used to prevent individuals from receiving an electrical shock in a grounded power system. Electrical codes for most new construction require that a GFCI circuit be present in potentially hazardous (*e.g.*, wet) areas such as bathrooms, kitchens, or outdoor electrical outlets. The GFCI may be installed as an individual power outlet (Fig. 8-28) or may be a special circuit breaker to which all the individual protected outlets are connected at a single point. The special GFCI circuit breaker is located in the main fuse/circuit breaker box and can be distinguished by its red test button (Fig. 8-29). As Figure 8-5 demonstrates, the current flowing in both the hot and neutral wires is usually equal. The GFCI monitors both sides of the circuit for the equality of current flow; if a difference is detected, the power is immediately interrupted. If an individual should contact a faulty piece of equipment such that current flowed through the individual, an imbalance between the two sides of the circuit would be created, which would be detected by the GFCI. Because the GFCI can detect very small current differences (in the range of 5 mA), the GFCI will open the circuit in a few milliseconds, thereby interrupting the current flow before a significant shock occurs. Thus, the GFCI provides a high level of protection at a very modest cost.

Figure 8-28. A ground fault circuit interrupter (GFCI) electrical outlet with integrated test and reset buttons.

Figure 8-29. Special GFCI circuit breaker. The arrowhead points to the distinguishing red test button.

The disadvantage of using a GFCI in the operating room is that it interrupts the power without warning. A defective piece of equipment could no longer be used, which might be a problem if it were of a life-support nature, whereas if the same faulty piece of equipment were plugged into an isolated power system, the LIM would alarm, but the equipment could still be used.

MICROSHOCK

As previously discussed, macroshock involves relatively large amounts of current applied to the surface of the body. The current is conducted through all the tissues in proportion to their conductivity and area in a plane perpendicular to the current. Consequently, the “density” of the current (amperes per meter squared) that reaches the heart is considerably less than what is applied to the body surface. However, an electrically susceptible patient (*i.e.*, one who has a direct, external connection to the heart) may be at risk from very small currents; this is called *microshock*.¹⁶ The catheter orifice or electrical wire with a very small surface area in contact with the heart produces a relatively large current density at the heart.¹⁷ Stated another way, even very small amounts of current applied directly to the myocardium will cause ventricular fibrillation. Microshock is a particularly difficult problem because of the insidious nature of the hazard.

In the electrically susceptible patient ventricular fibrillation can be produced by a current that is below the threshold of human perception. The exact amount of current necessary to cause ventricular fibrillation in this type of patient is unknown. Whalen *et al*.¹⁸ were able to produce fibrillation with 20 μA of current applied directly to the myocardium of dogs. Raftery *et al*.¹⁹ produced fibrillation with 80 μA of current in some patients. Hull²⁰ used data obtained by Watson *et al*.²¹ to show that 50% of patients would fibrillate at currents of 200 μA . Because 1000 μA (1 mA) is generally regarded as the threshold of human perception with 60-Hz AC, the electrically susceptible patient can be electrocuted with one tenth the normally perceptible currents. This is not only of academic interest but also of practical concern because many cases of ventricular fibrillation from microshock have been reported.^{22,23,24,25,26 and 27}

The stray capacitance that is part of any AC-powered electrical instrument may result in significant amounts of charge buildup on the case of the instrument. If an individual simultaneously touches the case of an instrument where this has occurred and the electrically susceptible patient, he or she may unknowingly cause a discharge to the patient that results in ventricular fibrillation. Once again, the equipment ground wire constitutes the major source of protection against microshock for the electrically susceptible patient. In this case, the equipment ground wire provides a low-resistance path by which most of the leakage current is dissipated instead of stored as a charge.

[Figure 8-30](#) illustrates a situation involving a patient with a saline-filled catheter in the heart with a resistance of ~ 500 ohms. The ground wire with a resistance of 1 ohm is connected to the instrument case. A leakage current of 100 μA will divide according to the relative resistances of the two paths. In this case, 99.8 μA will flow through the equipment ground wire, and only 0.2 μA will flow through the fluid-filled catheter. This extremely small current does not endanger the patient. If, however, the equipment ground wire were broken, the electrically susceptible patient would be at great risk because all 100 μA of leakage current could flow through the catheter and cause ventricular fibrillation ([Fig. 8-31](#)).

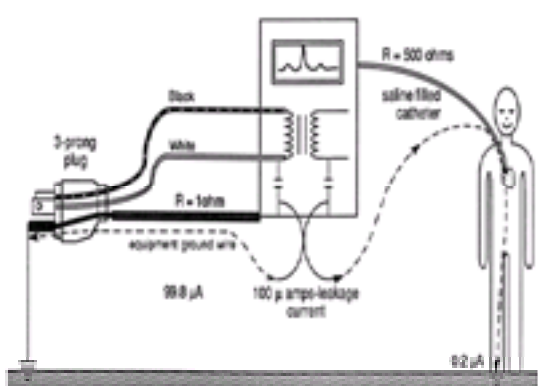

Figure 8-30. The electrically susceptible patient is protected from microshock by the presence of an intact equipment ground wire. The equipment ground wire provides a low-impedance path in which the majority of the leakage current (dashed lines) can flow.

Figure 8-31. A broken equipment ground wire results in a significant hazard to the electrically susceptible patient. In this case, the entire leakage current can be conducted to the heart and may result in ventricular fibrillation.

Modern patient monitors incorporate another mechanism to reduce the risk of microshock for electrically susceptible patients. This mechanism involves electrically isolating all direct patient connections from the power supply of the monitor by placing a very high impedance between the patient and any device. This limits the amount of internal leakage through the patient connection to a very small value. Currently the standard is $<10 \mu\text{A}$. For instance, the output of an ECG monitor's power supply is electrically isolated from the patient by placing a very high impedance between the monitor and the patient's ECG leads.^{6,28} Isolation techniques are designed to inhibit hazardous electrical pathways between the patient and the monitor while allowing the passage of the physiologic signal.

An intact equipment ground wire is probably the most important factor in preventing microshock. There are, however, other things that the anesthesiologist can do to reduce the incidence of microshock. One should never simultaneously touch an electrical device and a saline-filled central catheter or external pacing wires. Whenever one is handling a central catheter or pacing wires, it is best to insulate oneself by wearing rubber gloves. Also, one should never let any external current source, such as a nerve stimulator, come into contact with the catheter or wires. Finally, one should be alert to potential sources of energy that can be transmitted to the patient. Even stray radiofrequency current from the ESU can (with the right conditions) be a source of microshock.²⁹

It must be remembered that the LIM is not designed to provide protection from microshock. The microampere currents involved in microshock are far below the LIM threshold of protection. In addition, the LIM does not register the leakage of individual monitors, but rather indicates the status of the total system. The LIM reading indicates the total amount of leakage current resulting from the entire capacitance of the system. This is the amount of current that would flow to ground in the event of a first-fault situation.

The essence of electrical safety is a thorough understanding of all the principles of grounding. According to Bruner, "Grounding is neither safe nor unsafe. Its significance is dependent on what is grounded and in what context."⁹ The objective of electrical safety is to make it difficult for electrical current to pass through people. For this reason, both the patient and the anesthesiologist should be isolated from ground as much as possible. That is, their resistance to current flow should be as high as is technologically feasible. In the inherently unsafe electrical environment of an operating room, several measures can be taken to help protect against contacting hazardous current flows. First, the grounded power provided by the utility company can be converted to ungrounded power by means of an isolation transformer. The LIM will continuously monitor the status of this isolation from ground, and warn that the isolation of the power (from ground) has been lost in the event that a defective piece of equipment is plugged into one of the isolated circuit outlets. In addition, the shock that an individual could receive from a faulty piece of equipment is determined by the capacitance of the system and is limited to a few milliamperes. Second, all equipment plugged into the isolated power system has an equipment ground wire that is attached to the case of the instrument. This equipment ground wire provides an alternative low-resistance pathway enabling potentially dangerous currents to flow to ground. Thus, the patient and the anesthesiologist should be as insulated from ground as possible and all electrical equipment should be grounded.

The equipment ground wire serves three functions. First, it provides a low-resistance path for fault currents to reduce the risk of macroshock. Second, it dissipates leakage currents that are potentially harmful to the electrically susceptible patient. Third, it provides information to the LIM on the status of the ungrounded power system. If the equipment ground wire is broken, a significant factor in the prevention of electrical shock is lost. Additionally, the isolated power system will appear safer than it actually is, because the LIM is unable to detect broken equipment ground wires.

Because power cord plugs and receptacles are subjected to greater abuse in the hospital than in the home, the Underwriters Laboratories (Melville, NY) has issued a strict specification for special "hospital grade" plugs and receptacles (Fig. 8-32). The plugs and receptacles that conform to this specification are marked by a green dot.³⁰ The hospital-grade plug is one that can be visually inspected or easily disassembled to ensure the integrity of the ground wire connection. Molded opaque plugs are not acceptable. Edwards reported that of 3000 non-hospital-grade receptacles installed in a new hospital building, 1800 (60%) were defective after 3 years.³¹ When 2000 of the non-hospital-grade receptacles were replaced with ones of hospital grade, no failures occurred after 18 months of use.

Figure 8-32. (A) A hospital-grade plug that can be visually inspected. The arrow points to the equipment ground wire whose integrity can be readily verified. (B) A hospital-grade plug that can be easily disassembled for inspection. Note that the prong for the ground wire (arrow) is longer than the hot or neutral prong, so that it is the first to enter the receptacle. (C) The arrow points to the green dot denoting a hospital-grade power outlet.

ELECTROSURGERY

On that fateful October day in 1926 when Dr. Harvey W. Cushing first used an electrosurgical machine invented by Professor William T. Bovie to resect a brain tumor, the course of modern surgery and anesthesia was forever altered.³² The ubiquitous use of electrosurgery attests to the success of Professor Bovie's invention. However, this technology was not adopted without a cost. The widespread use of electrocautery has, at the very least, hastened the elimination of explosive anesthetic agents from the operating room. In addition, as every anesthesiologist is aware, few things in the operating room are immune to interference from the "Bovie." The high-frequency electrical energy generated by the electrosurgery unit (ESU) interferes with everything from the ECG signal to cardiac output computers, pulse oximeters, and even implanted cardiac pacemakers.³³

The ESU operates by generating very high frequency currents (radiofrequency range) of anywhere from 500,000 to 1 million Hz. Heat is generated whenever a current passes through a resistance. The amount of heat (H) produced is proportional to the square of the current and inversely proportional to the area through which the current passes ($H = I^2/A$).³⁴ By concentrating the energy at the tip of the "Bovie pencil," the surgeon can produce either a cut or a coagulation at any given spot. This very high frequency current behaves differently from the standard 60-Hz AC current and can pass directly across the precordium without causing ventricular fibrillation.³⁴ This is because high-frequency currents have a low tissue penetration and do not excite contractile cells.

The large amount of energy generated by the ESU can pose other problems to the operator and the patient. Dr. Cushing became aware of one such problem. He wrote, "Once the operator received a shock which passed through a metal retractor to his arm and out by a wire from his headlight, which was unpleasant to say the least."³⁵ The ESU cannot be safely operated unless the energy is properly routed from the ESU through the patient and back to the unit. Ideally, the current generated by the active electrode is concentrated at the ESU tip constituting a very small surface area. This energy has a high current density and is able to generate enough heat to produce a therapeutic cut or coagulation. The energy then passes through the patient to a dispersive electrode of large surface area that returns the energy safely to the ESU (Fig. 8-33).

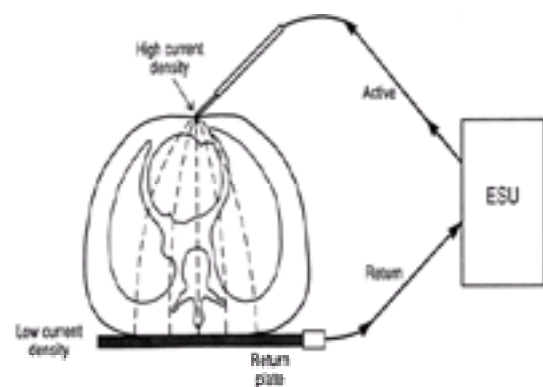

Figure 8-33. A properly applied ESU return plate. The current density at the return plate is low, resulting in no danger to the patient.

One unfortunate quirk in terminology concerns the return (dispersive) plate of the ESU. This plate, often incorrectly referred to as a “ground plate,” is actually a dispersive electrode of large surface area that safely returns the generated energy to the ESU via a low current density pathway. When inquiring whether the dispersive electrode has been attached to the patient, operating room personnel frequently ask, “Is the patient grounded?” Because the aim of electrical safety is to isolate the patient from ground, this expression is worse than erroneous; it can lead to confusion. Because the area of the return plate is large, the current density is low; therefore, no harmful heat is generated and no tissue destruction occurs. In a properly functioning system, the only tissue effect is at the site of the active electrode that is held by the surgeon.

Problems can arise if the electrosurgical return plate is improperly applied to the patient or if the cord connecting the return plate to the ESU is damaged or broken. In these instances, the high-frequency current generated by the ESU will seek an alternate return pathway. Anything attached to the patient, such as ECG leads or a temperature probe, can provide this alternate return pathway. The current density at the ECG pad will be considerably higher than normal because its surface area is much less than that of the ESU return plate. This may result in a serious burn at this alternate return site. Similarly, a burn may occur at the site of the ESU return plate if it is not properly applied to the patient or if it becomes partially dislodged during the operation (Fig. 8-34). That this is not merely a theoretical possibility is evidenced by the numerous case reports involving patients who have received ESU burns.^{36,37,38,39,40 and 41}

Figure 8-34. An improperly applied ESU return plate. Poor contact with the return plate results in a high current density and a possible burn to the patient.

The original ESUs were manufactured with the power supply connected directly to ground by the equipment ground wire. These devices made it extremely easy for ESU current to return by alternate pathways. The ESU would continue to operate normally even without the return plate connected to the patient. In most modern ESUs the power supply is isolated from ground to protect the patient from burns. It was hoped that by isolating the return pathway from ground, the only route for current flow would be via the return electrode. Theoretically, this would eliminate alternate return pathways and greatly reduce the incidence of burns.⁵ However, Mitchell found two situations in which the current could return via alternate pathways, even with the isolated ESU circuit.⁴² If the return plate were left either on top of an uninsulated ESU cabinet or in contact with the bottom of the operating room table, then the ESU could operate fairly normally and the current would return via alternate pathways. It will be recalled that the impedance is inversely proportional to the capacitance times the current frequency. The ESU operates at 500,000 to >11,000,000 Hz, which greatly enhances the effect of capacitive coupling and causes a marked reduction in impedance. Therefore, even with isolated ESUs, the decrease in impedance allows the current to return to the ESU by alternate pathways. In addition, the isolated ESU does not protect the patient from burns if the return electrode does not make proper contact with the patient. Although the isolated ESU does provide additional patient safety, it is by no means foolproof protection against the patient receiving a burn.

Preventing patient burns from the ESU is the responsibility of all professional staff in the operating room. Not only the circulating nurse, but also the surgeon and the anesthesiologist must be aware of proper techniques and be vigilant to potential problems. The most important factor is the proper application of the return plate. It is essential that the return plate have the appropriate amount of electrolyte gel and an intact return wire. Reusable return plates must be properly cleaned after each use, and disposable plates must be checked to ensure that the electrolyte has not dried out during storage. In addition, it is prudent to place the return plate as close as possible to the site of the operation. Electrocardiographic pads should be placed as far from the site of the operation as is feasible. Operating room personnel must be alert to the possibility that pools of flammable “prep” solutions such as ether and acetone can ignite when the ESU is used. If the ESU must be used on a patient with a demand pacemaker, the return electrode should be located below the thorax, and preparations for treating potential arrhythmias should be available, including a magnet to convert the pacemaker to a fixed rate, a defibrillator, and an external pacemaker. The ESU has also caused other problems in patients with pacemakers, including reprogramming and microshock.^{43,44} If the surgeon requests higher than normal power settings on the ESU, this should alert both the circulating nurse and the anesthesiologist to a potential problem. The return plate and cable must be immediately inspected to ensure that it is functioning and properly positioned. If this does not correct the problem, the return plate should be replaced. If the problem remains, the entire ESU should be taken out of service. Finally, an ESU that is dropped or damaged must be removed immediately from the operating room and thoroughly tested by a qualified biomedical engineer. Following these simple safety steps will prevent most patient burns from the ESU.

The previous discussion concerned only *unipolar* ESUs. There is a second type of ESU, in which the current passes only between the two blades of a pair of forceps. This type of device is referred to as a *bipolar* ESU. Because the active and return electrodes are the two blades of the forceps, it is not necessary to attach another dispersive electrode to the patient, unless a unipolar ESU is also being used. The bipolar ESU generates considerably less power than the unipolar and is mainly used for ophthalmic and neurologic surgery.²

In 1980 Mirowski *et al*⁴⁵ reported the first human implantation of a device to treat intractable ventricular tachyarrhythmias. This device, known as the automatic implantable cardioverter-defibrillator (AICD), is capable of sensing ventricular tachycardia (VT) and ventricular fibrillation (VF) and then automatically defibrillating the patient. Since 1980 thousands of patients have received AICD implants.^{46,47} Because some of these patients may now present for noncardiac surgery, it is important that the anesthesiologist be aware of potential problems.⁴⁸ The use of a unipolar ESU may cause electrical interference that could be interpreted by the AICD as a ventricular tachyarrhythmia. This would trigger a defibrillation pulse to be delivered to the patient and would likely cause an actual episode of VT or VF. The patient with an AICD is also at risk for VF during electroconvulsive therapy.⁴⁸ In both cases, the AICD should be disabled by placing a magnet over the device. Although most AICDs can be disabled with a magnet, some require a special device or specific magnet to shut it off. Therefore, it is best to consult with someone experienced with the device before starting surgery. The device can be reactivated by reversing the process. Also, an external defibrillator and a noninvasive pacemaker must be in the operating room whenever a patient with an AICD is anesthetized.

Electrical safety in the operating room is a matter of combining common sense with some basic principles of electricity. Once operating room personnel understand the importance of safe electrical practice, they are able to develop a heightened awareness to potential problems. All electrical equipment must undergo routine maintenance, service, and inspection to ensure that it conforms to designated electrical safety standards. Records of these test results must be kept for future inspection because human error can easily compound electrical hazards. Starmer *et al*⁴⁹ cited one case concerning a newly constructed laboratory where the ground wire was not attached to a receptacle. In another study Albisser *et al*⁵⁰ found a 14% (198/1424) incidence of improperly or incorrectly wired outlets. Furthermore, potentially hazardous situations should be recognized and corrected before they become a problem. For instance, electrical power cords are frequently placed on the floor where they can be crushed by various carts or the anesthesia machine. These cords could be located overhead or placed in an area of low traffic flow.

Multiple-plug extension boxes should not be left on the floor where they can come in contact with electrolyte solutions. These could easily be mounted on a cart or the anesthesia machine. Pieces of equipment that have been damaged or have obvious defects in the power cord must not be used until they have been properly repaired. If everyone is aware of what constitutes a potential hazard, dangerous situations can be prevented with minimal effort.

Sparks generated by the ESU may provide the ignition source for a fire with resulting burns to the patient and operating room personnel. This is a particular risk when the ESU is used in an oxygen-enriched environment as may be present in the patient's airway or in close proximity to the patient's face. Most plastics such as tracheal tubes and components of the anesthetic breathing system that would not burn in room air will ignite in the presence of oxygen and/or nitrous oxide. Tenting of the drapes to allow dispersion of any accumulated oxygen and/or its dilution by room air or use of a circle anesthesia breathing system with minimal to no leak of gases around the anesthesia mask will decrease the risk of ignition from a spark generated by a nearby ESU.

Conductive Flooring

Conductive flooring was mandated for operating rooms where flammable anesthetic agents were being administered. The conductive floor was specified to have a resistance of between 25,000 and 1 million ohms. This would minimize the buildup of static charges that could cause a flammable anesthetic agent to ignite. The standards have been changed to eliminate the necessity for conductive flooring in anesthetizing areas where flammable agents are no longer used.

ENVIRONMENTAL HAZARDS

There are a number of potential hazards in the operating room that are of concern to the anesthesiologist. There is the potential for electrical shock not only to the patient, but also to operating room personnel. In addition, cables and power cords to electrical equipment and monitoring devices can become hazardous. Finally, all operating room personnel should have a plan of what to do in the event of a power failure.

In today's operating room, there are literally dozens of pieces of electrical equipment. It is not uncommon to have numerous power cords lying on the floor, where they are vulnerable to damage. If the insulation on the power cable becomes damaged, it is fairly easy for the hot wire to come in contact with a piece of metal equipment. If the operating room did not have isolated power, that piece of equipment would become energized and a potential electrical shock hazard.⁵¹ Having isolated power minimizes the risk to the patient and operating room personnel. Clearly, getting electrical power cords off the floor is desirable. This can be accomplished by having electrical outlets in the ceiling or by having ceiling-mounted articulated arms that contain electrical outlets. Also, the use of multi-outlet extension boxes that sit on the floor can be hazardous. These can be contaminated with fluids, which could easily trip the circuit breaker. In one case, it apparently tripped the main circuit breaker for the entire operating room, resulting in a loss of all electrical power except for the overhead lights.⁵²

Modern monitoring devices have many safety features incorporated into them. Virtually all of them have isolated the patient input from the power supply of the device. This was an important feature that was lacking from the original ECG monitors. In the early days, patients could actually become part of the electrical circuit of the monitor. There have been relatively few problems with patients and monitoring devices since the advent of isolated inputs. However, between 1985 and 1994, the Food and Drug Administration (FDA) received approximately 24 reports where infants and children had received an electrical shock including five children who died by electrocution.^{53,54} These electrical accidents occurred because the electrode lead wires from either an ECG monitor or an apnea monitor were plugged directly into a 120-volt electrical outlet instead of the appropriate patient cable. In 1997, the FDA issued a new performance standard for electrode lead wires and patient cables. The new standard requires that the exposed male connector pins from the electrode lead wires must be eliminated. Therefore, the lead wires must have female connections and the connector pins must be housed in a protected patient cable (Fig. 8-35). This effectively eliminates the possibility of the patient being connected directly to an alternating current source since there are no exposed connector pins on the lead wires.

Figure 8-35. The current standard for patient lead wires (*left*) requires a female connector. The patient cable (*right*) has shielded connector pins that the lead wires plug into.

All health care facilities are required to have a source of emergency power. This generally consists of one or more electrical generators. These generators are configured to start up automatically and provide power to the facility within a few seconds after detecting the loss of power from the utility company. The facility is required to test these generators on a regular basis. However, not all health care facilities test them under actual load. There are numerous anecdotal reports of generators not functioning properly during an actual power failure. If the generators are not tested under actual load, it is possible that many years will pass before a real power outage puts a severe demand on the generator. If the facility has several generators and one of them fails, the increased demand on the others may be enough to cause them to fail in rapid succession.

Other situations may also cause unexpected power outages. In our facility, a construction crew was remodeling an existing operating room. They accidentally caused a short circuit in the power supply when they were working on an electrical panel. This caused the ground fault circuit interrupter (GFCI) in the basement to trip, thus shutting off power to a whole section of the operating room. Consequently, several operating rooms were suddenly without power at crucial junctures in surgery. The operating room personnel were waiting for the emergency generators to come on. Obviously, this was not going to happen because there was no interruption of power from the electrical utility. It took approximately 20–30 minutes until the source of the problem could be identified and corrected.

It is vitally important that each operating room have a contingency plan for a power failure. In most cases, the emergency generator will take over, but that is not always going to happen. There should be a supply of battery-operated light sources available in each operating room. A laryngoscope can serve as a readily available source of light that allows one to find flashlights and other pieces of equipment. The operating room's overhead lights should also be connected to some sort of battery-operated lighting system. A supply of battery-operated monitoring devices and pneumatically powered ventilators and anesthesia machines would enable life-support functions to continue. The cost of these contingencies is relatively small but the benefits can be incomparably great in an emergency.

ELECTROMAGNETIC INTERFERENCE (EMI)

Rapid advances in technology have led to an explosion in the number of wireless communication devices in the marketplace. These devices include cellular telephones, cordless telephones, walkie-talkies, and even wireless Internet access devices. All of these devices have something in common: they emit electromagnetic interference (EMI). This most commonly manifests itself when traveling on airplanes. Most airlines require that these devices be turned off when the plane is taking off or landing or, in some cases, during the entire flight. There is concern that the EMI emitted by these devices may interfere with the plane's navigation and communication equipment.

In recent years, the number of people who own these devices has increased exponentially. Indeed, in some hospitals, they form a vital link in the regular or emergency communication system. It is not uncommon for physicians, nurses, paramedics, and other personnel to have their own cellular telephones. In addition, patients and visitors may also have cellular telephones and other types of communication devices. Hospital maintenance and security personnel frequently have walkie-talkie-type radios and some hospitals have even instituted an in-house cellular telephone network that augments or replaces the paging system. There has been concern that the EMI emitted by these devices may interfere with implanted pacemakers or various types of monitoring devices in critical care areas.

Several studies have been done to find out if cellular telephones cause problems with cardiac pacemakers. One study by Hayes *et al* looked at 980 patients with five different types of cellular telephones.⁵⁵ They conducted more than 5000 tests and found that in more than 20% of the cases they could detect some interference from the cellular telephone. Patients were symptomatic in 7.2% of the cases, and clinically significant interference occurred in 6.6% of the cases. When the telephone was held in the normal position over the ear, clinically significant interference was not detected. In fact, the interference that caused clinical symptoms occurred only if the

telephone was directly over the pacemaker. Other studies have demonstrated changes such as erroneous sensing and pacer inhibition.^{56,57} Again, these occurred only when the telephone was close to the pacemaker. The changes were temporary, and the pacemaker reverted to normal when the cellular telephone was moved to a safe distance. Currently, the FDA guidelines are that the cellular telephones be kept at least 6 inches from the pacemaker. Therefore, the cellular telephone should not be carried in the shirt pocket, which is adjacent to the pacemaker.

Automatic implantable cardioverter-defibrillators (AICDs) comprise another group of devices of concern to biomedical engineers. Fetter *et al* conducted a study of 41 patients who had AICDs.⁵⁸ They had a 0% incidence of oversensing and concluded that the cellular telephones did not interfere with the AICDs that they tested. They did, however, recommend keeping the cellular telephone at least 6 inches from the device.

Electromagnetic interference extends well beyond that of cellular telephones. Walkie-talkies, which are frequently used by hospital maintenance and security personnel, paging systems, police radios, and even televisions all emit EMI, which could potentially interfere with medical devices of any nature. Although there are many anecdotal reports, the scientific data on this problem are scanty. Reports of interference include ventilator and infusion pumps that have been shut down or reprogrammed, interference with ECG monitors, and even an electronic wheelchair that was accidentally started because of EMI. It is a difficult problem to study because there are many different types of devices that emit EMI and a vast array of medical equipment that has the potential to interact with these devices. Even though a device may seem "safe" in the medical environment, if two or three cellular telephones or walkie-talkies are brought together in the same area at the same time, there may be unanticipated problems or interference.

Any time a cellular telephone is turned on, it is actually communicating with the cellular network, even though a call is not in progress. Therefore, the potential to interfere with devices exists. The Emergency Care Research Institute (ECRI) reported in the October 1999 issue of *Health Devices* that walkie-talkies were far more likely to cause problems with medical devices than cellular telephones.⁵⁹ This is because they operate on a lower frequency than cellular telephones and have a higher power output. The ECRI recommends that cellular telephones be maintained at a distance of 1 meter from medical devices while walkie-talkies be kept at a distance of 6–8 meters.

Many hospitals have made restrictive policies on the use of cellular telephones, particularly in critical care areas.⁶⁰ These policies are supported by little scientific documentation and are nearly impossible to enforce. The ubiquitous presence of cellular telephones carried by hospital personnel and visitors makes enforcing a ban virtually impossible. Even when people try to comply with the ban, failure is nearly inevitable because the general public is usually unaware that a cellular telephone in the standby mode is still communicating with the tower and generating EMI.

The real solution is to "harden" devices against electromagnetic interference. This is difficult to do because of the many different frequencies on which these devices operate. Education of medical personnel is essential. When working in an operating room or critical care area, all personnel must be alert to the fact that electronic devices and pacemakers can be interfered with by EMI. Creating a restrictive policy would certainly irritate personnel and visitors, and in some cases, may actually compromise emergency communications.⁶¹

CONSTRUCTION OF NEW OPERATING ROOMS

A final area of electrical safety that concerns the anesthesiologist is the design of new operating room facilities or the remodeling of older ones. Frequently, an anesthesiologist is asked to consult with hospital administrators and architects in designing new or remodeling older operating rooms. In the past a strict electrical code was enforced because of the use of flammable anesthetic agents. This code included a requirement for isolated power systems and LIMs. The National Fire Protection Association (NFPA) revised its standard for health care facilities in 1984 (NFPA 99-1984). These standards do not require isolated power systems or LIMs in areas designated for use of nonflammable anesthetic agents only.^{62,63} Although not mandatory, NFPA standards are usually adopted by local authorities when revising their electrical codes.

This change in the standard creates a dilemma. The NFPA 99—Standard for Health Care Facilities, 1990 Edition, mandates that "wet location patient care areas be provided with special protection against electrical shock." Section 3-4.1.2.6 further states that "this special protection shall be provided by a power distribution system that inherently limits the possible ground fault current due to a first fault to a low value, without interrupting the power supply; or by a power distribution system in which the power supply is interrupted if the ground fault current does, in fact, exceed a value of 6 milliamperes."

The decision of whether to install isolated power hinges on two factors. The first is whether or not the operating room is considered a wet location, and, if so, whether an interruptible power supply is tolerable. Where power interruption is tolerable, a GFCI is permitted as the protective means. However, the Standard also states that "the use of an isolated power system (IPS) shall be permitted as a protective means capable of limiting ground fault current without power interruption."

Most people who have worked in an operating room would attest to its being a wet location. The presence of blood, body fluids, and saline solutions spilled on the floor all contribute to making this a wet environment. The cytology suite serves as a good example.

Once the premise that the operating room is a wet location is accepted, it must be determined whether a GFCI can provide the means of protection. The argument against using GFCIs in the operating room is illustrated by the following example. Assume that during an open heart procedure the cardiopulmonary bypass pump and the patient monitors are plugged into outlets on the same branch circuit. Also assume that during bypass, the circulating nurse now plugs in a faulty headlight. If there is a GFCI protecting the circuit, the fault will be detected and the GFCI will interrupt all power to the pump and the monitors. This undoubtedly would cause a great deal of confusion and consternation among the operating room personnel, and may place the patient at risk for injury. The pump would have to be manually operated while the problem was being resolved. In addition, the GFCI could not be reset (and power restored) until the headlight was identified as the cause of the fault and unplugged from the outlet. However, if the operating room were protected with an isolated power system and LIM, the same scenario would cause the LIM to alarm, but the pump and patient monitors would continue to operate normally. There would be no interruption of power, and the problem could be resolved without risk to the patient.

It should be realized that a GFCI is an active system. That is, a potentially hazardous current is already flowing and must be actively interrupted, whereas the isolated power system (with LIM) is designed to be safe during a first-fault situation. Thus, it is a passive system because no mechanical action is required to activate the protection.⁶⁴

It is likely that hospital administrators may want to eliminate isolated power systems in new operating room construction as a cost-saving measure. Others,^{64,65} and ⁶⁶ however, have advocated the retention of isolated power systems. Not to do this would be a short-sighted, foolhardy measure. This is especially true because the cost of adding isolated power is estimated to be 1% of the cost of constructing an operating room.⁶⁴ Although not perfect,⁶⁷ the isolated power system and LIM do provide both the patient and operating room personnel with a significant amount of protection in an electrically hazardous environment. The value of the isolated power system is illustrated in a report by Day in 1994.⁶⁸ He reported four instances of electrical shock to operating room personnel in a 1-year period. The operating suite had been renovated and the isolated power system removed, and it was not until the operating room personnel received a shock that a problem was discovered.

Anesthesiologists need to be aware of this cost-saving attitude and strongly encourage that new operating rooms be constructed with isolated power systems. The relatively small cost savings that the alternative would represent do not justify the elimination of such a useful safety system, and the use of GFCIs is not practical in the operating room environment.

Electrical safety should be the concern of everyone in the operating room. Accidents can be prevented only if proper installation and maintenance of the appropriate safety equipment in the operating room have occurred and the operating room personnel understand the concepts of electrical safety and are vigilant in their efforts to detect new hazards.⁶⁹

* The 120 volts of EMF and 1 ampere of current are the effective voltage and amperage in an AC circuit. This is also referred to as "RMS" (root-mean-square). It takes 1.414 amperes of peak amperage in the sinusoidal curve to give an effective amperage of 1 ampere. Similarly, it takes 170 volts (120×1.414) at the peak of the AC curve to get an effective voltage of 120 volts.⁸

As a consequence of underlying diseases and of therapeutic manipulations, surgical patients may develop potentially harmful disorders of acid–base equilibrium, intravascular and extravascular volume, and serum electrolytes. Precise perioperative management of acid–base status, fluids, and electrolytes may limit surgical morbidity and mortality.

ACID–BASE INTERPRETATION AND TREATMENT

Treatment of acid–base disturbances may be required preoperatively or during the course of anesthesia to limit the complications of metabolic alkalosis, metabolic acidosis, respiratory alkalosis, or respiratory acidosis. Following is a review of the pathogenesis, major complications, physiologic compensatory mechanisms, and treatment of the four simple acid–base disorders.

Overview of Acid–Base Equilibrium

The conventional approach to describing acid–base equilibrium is the *Henderson-Hasselbach* equation:

$$pH = 6.1 + \log \frac{[HCO_3^-]}{0.03 \times PaCO_2} \quad (9-1)$$

where 6.1 is the pK_a of carbonic acid and 0.03 is the solubility coefficient in blood of carbon dioxide (CO_2). Conventional acid–base terminology defines acid–base disturbances as *metabolic* (those in which the bicarbonate concentration ($[HCO_3^-]$) is primarily increased or decreased) and *respiratory* (those in which $PaCO_2$ is primarily increased or decreased).

The term used to define the acidity or alkalinity of solutions or blood, pH, is the negative logarithm of the hydrogen ion concentration ($[H^+]$). An alternative to the Henderson-Hasselbach equation is the simpler Henderson equation:

$$[H^+] = \frac{24 \times PaCO_2}{[HCO_3^-]} \quad (9-2)$$

This equation clearly expresses the relationship between the three major variables measured or calculated in blood gas samples. Conversion of pH to $[H^+]$ can be accomplished by knowing that the $[H^+]$ is $40 \text{ mmol} \cdot \text{l}^{-1}$ at a pH of 7.4; that an increase in pH of 0.10 pH units reduces $[H^+]$ to 0.8 times the starting $[H^+]$ concentration; that a decrease in pH of 0.10 pH units increases the $[H^+]$ by a factor of 1.25; and that small changes (*i.e.*, <0.05 pH units) produce approximately a $1.0 \text{ mmol} \cdot \text{l}^{-1}$ increase in $[H^+]$ for each 0.01 decrease in pH or a decrease in $[H^+]$ of $1.0 \text{ mmol} \cdot \text{l}^{-1}$ per 0.01 increase in pH.

An alternative approach to acid–base interpretation, proposed by Stewart¹ and reviewed by Eicker,² distinguishes between the independent variables and dependent variables that define pH. From this perspective, the independent variables are $PaCO_2$, the strong (*i.e.*, highly dissociated) ion difference (SID), and the concentration of proteins, which usually are not strong ions. The strong ions, important because they are present in large concentrations, include sodium (Na^+), potassium (K^+), chloride (Cl^-), and lactate. The SID, calculated as $(Na^+ + K^+ - Cl^-)$, under normal circumstances is approximately $42 \text{ mEq} \cdot \text{l}^{-1}$. By using a series of equations, the acid–base status can be accurately described using these concepts. However, this review does not utilize the Stewart approach because there is little evidence that the clinical interpretation or treatment of common acid–base disturbances is handicapped by the simpler constructs of the conventional Henderson-Hasselbach or Henderson equations.

Metabolic Alkalosis

Metabolic alkalosis, usually characterized by an alkalemic pH (>7.45) and hyperbicarbonatemia ($>27.0 \text{ mEq} \cdot \text{l}^{-1}$), occurs frequently in hospitalized patients. In critically ill patients, severe metabolic alkalosis is associated with increased mortality.³ Factors that generate metabolic alkalosis include, among others, nasogastric suction and diuretic administration (Table 9-1).⁴ The maintenance of metabolic alkalosis is dependent upon a continued stimulus, such as renal hypoperfusion, hypokalemia, or hypochloremia, for the reabsorption of ($[HCO_3^-]$) from the distal renal tubules. Potassium depletion generates metabolic alkalosis in part by increasing the exit of bicarbonate from proximal tubular cells into the circulation.⁵ Chloride depletion, even in the absence of volume depletion, may impair bicarbonate secretion by decreasing delivery of chloride to the collecting duct and by inducing potassium depletion.⁶

| Generation | Example | Maintenance |
|---|--|---|
| I. Loss of acid from extracellular space | | |
| A. Loss of gastric fluid | Vomiting; nasogastric drainage | ↓ effective arterial volume (EAV) |
| B. Loss of acid into urine; continued Na^+ delivery to the distal tubule in presence of hypokalemia | 1. Primary aldosteronism 2. Diuretic administration | 1. K^+ depletion = aldosterone excess 2. ↓ EAV = K^+ depletion |
| II. Excessive HCO_3^- loads | | |
| A. Absolute | $NaHCO_3$ administration | ↓ EAV |
| B. Relative | Lactate, acetate, citrate administration | ↓ EAV |
| C. Relative | Alkali administration to patients with renal failure | Renal failure |
| III. Post-hypertensive state | Absorp correction of chronic hypertension | ↓ EAV |

Table 9-1. GENERATION AND MAINTENANCE OF METABOLIC ALKALOSIS

Metabolic alkalosis exerts multiple physiologic effects. Metabolic alkalosis is associated with a decrease in serum potassium and in ionized calcium.⁷ Hypokalemia and alkalemia may precipitate primary ventricular dysrhythmias and may potentiate the toxicity of digoxin. Metabolic alkalosis may also generate compensatory hypoventilation (hypercarbia), sometimes of considerable magnitude (Table 9-2).⁸ To the extent that PaCO₂ is increased, PaO₂ will be reciprocally decreased but is easily corrected by oxygen administration. Alkalemia also increases bronchial tone and, through a combination of increased bronchial tone and decreased ventilatory effort, may help to produce atelectasis. A leftward shift in the oxyhemoglobin dissociation curve may reduce the availability of oxygen to tissues, as may alkalemia-induced decreased cardiac output.

Metabolic alkalosis

1. PaCO₂ increases approximately 0.5 to 0.6 mm Hg for each 1.0 mEq · l⁻¹ increase in [HCO₃⁻]
2. The last two digits of the pH should equal the [HCO₃⁻] + 15

Metabolic acidosis

1. PaCO₂ = [HCO₃⁻] × 1.5 + 8.
2. The last two digits of the pH equal [HCO₃⁻] + 15.

Table 9-2. RULES OF THUMB FOR RESPIRATORY COMPENSATION IN RESPONSE TO METABOLIC ALKALOSIS AND METABOLIC ACIDOSIS

In the absence of arterial blood gases, serum electrolytes and a history of major risk factors, such as vomiting, nasogastric suction, or chronic diuretic use, can suggest metabolic alkalosis. Because the vast majority of CO₂ carried in the blood is carried as bicarbonate, the measurement of total CO₂ (usually abbreviated on electrolyte reports as CO₂) should be about 1.0 mEq · l⁻¹ greater than ([HCO₃⁻]) calculated on simultaneously obtained arterial blood gases. Therefore, a normal calculated ([HCO₃⁻]) on an arterial blood gas sample should be about 24 mEq and a normal “CO₂” on the serum electrolytes should be approximately 25. If either measurement exceeds normal by >4.0 mEq · l⁻¹, either the patient has a primary metabolic alkalosis or has conserved bicarbonate in response to chronic hypercarbia. Recognition of hyperbicarbonatemia on the preoperative serum electrolytes justifies arterial blood gas analysis and should alert the anesthesiologist to the possibility that the patient is hypovolemic or hypokalemic.

Confirmation of metabolic alkalosis should serve as a warning to avoid adding iatrogenic respiratory alkalosis to metabolic alkalosis, since that may produce cardiovascular depression, dysrhythmias, and the other complications of severe alkalemia. Table 9-3 is an example of the effects of hyperventilation added to chronic metabolic alkalosis secondary to diuretic administration. The expected effects on pH and ([HCO₃⁻]) of acutely and chronically decreasing or increasing PaCO₂ are illustrated in Table 9-4.

| | Normal | Chronic Diuretic Administration | Intraoperative Hyperventilation |
|---|--------|---------------------------------|---------------------------------|
| BLOOD GASES | | | |
| pH | 7.40 | 7.47 | 7.62 |
| PaCO ₂ (mm Hg) | 40 | 45 | 30 |
| [HCO ₃ ⁻] (mEq · l ⁻¹) | 24 | 32 | 29 |
| ELECTROLYTES | | | |
| “CO ₂ ” (mEq · l ⁻¹) | 25 | 33 | 30 |

Note: Respiratory alkalosis, produced by an inappropriately high minute ventilation, has been added to the previously compensated metabolic alkalosis induced by chronic diuretic administration.

Table 9-3. METABOLIC ALKALOSIS PLUS HYPERVENTILATION

- Decreased PaCO₂**
1. pH increases 0.10 for every 10 mm Hg decrease in PaCO₂.
 2. [HCO₃⁻] decreases 2 mEq · l⁻¹ for every 10 mm Hg decrease in PaCO₂.
 3. pH will nearly normalize if hypocarbia is sustained.
 4. [HCO₃⁻] will decrease 5 to 6 mEq · l⁻¹ for each chronic 10 mm Hg ↓ in PaCO₂.
- Increased PaCO₂**
1. pH will decrease 0.05 for every acute PaCO₂ increase of 10 mm Hg.
 2. [HCO₃⁻] will increase 1.0 mEq · l⁻¹ for every PaCO₂ increase of 10 mm Hg.
 3. pH will return toward normal if hypercarbia is sustained.
 4. [HCO₃⁻] will increase 4 mEq · l⁻¹ for each chronic 10 mm Hg ↑ PaCO₂.

* Note: Hospitalized patients rarely develop chronic compensation for hypocarbia because of stimuli that enhance distal tubular reabsorption of sodium.

Table 9-4. RULES OF THUMB FOR [HCO₃⁻] AND pH CHANGES IN RESPONSE TO ACUTE AND CHRONIC CHANGES IN PaCO₂

In general, treatment of metabolic alkalosis can be divided into etiologic and nonetiologic therapy. Etiologic therapy consists of measures such as expansion of intravascular volume to increase renal perfusion or the administration of potassium to reverse hypokalemia. For a patient with metabolic alkalosis, 0.9% saline might be preferable to lactated Ringer's solution for intraoperative fluid administration, because lactate provides additional substrate for generation of bicarbonate and administration of 0.9% saline tends to increase serum [Cl⁻] and decrease serum ([HCO₃⁻]).⁹ Theoretically, hypoproteinemia can cause a mild metabolic alkalosis.^{10,11} and ¹² However, ([HCO₃⁻]) elevations secondary to hypoproteinemia are unlikely to be clinically important. Nonetiologic therapy includes the administration of [H⁺] (in the form of ammonium chloride, arginine hydrochloride, or 0.1 N hydrochloric acid), the administration of acetazolamide (a carbonic anhydrase inhibitor that causes renal bicarbonate wasting), or acid dialysis.¹³ Of these, in an acute situation associated with high risk secondary to metabolic alkalosis, 0.1 N hydrochloric acid most rapidly corrects metabolic alkalosis. However, dilute hydrochloric acid must be given into a central vein; peripheral infusion will cause severe tissue damage.

Metabolic Acidosis

Metabolic acidosis, usually characterized by an acidemic pH (<7.35) and hypobicarbonatemia (<21 mEq · l⁻¹), occurs as a consequence of the buffering by bicarbonate of endogenous or exogenous acid loads or as a consequence of abnormal external loss of bicarbonate. Extracellular volume contains 350 mmol of bicarbonate buffer. Glomerular filtration of plasma volume necessitates reabsorption of 4500 mmol of bicarbonate daily, of which 85% is reabsorbed in the proximal tubule, 10% in the thick ascending limb, and the remainder is titrated by proton secretion in the collecting duct.¹⁴ Approximately 70 mmol of acid metabolites are produced, buffered, and

excreted daily; these include about 25 mmol of sulfuric acid from amino acid metabolism, 40 mmol of organic acids, plus phosphoric and other acids.¹⁴

Two types of metabolic acidosis may be distinguished, based upon whether the calculated anion gap is normal or increased (Table 9-5).¹⁵ The anion gap ($\text{Na}^+ - [\text{Cl}^-] + ([\text{HCO}_3^-])$) is normal ($<13 \text{ mEq} \cdot \text{l}^{-1}$) in situations, such as diarrhea, biliary drainage, and renal tubular acidosis, in which bicarbonate is lost externally. Metabolic acidosis associated with a high anion gap ($>13 \text{ mEq} \cdot \text{l}^{-1}$) is attributed to excess production of lactic acid or ketoacids, increased retention of waste products (such as sulfate and phosphate) that are inadequately excreted in uremic states, and ingestion of toxic quantities of substances such as aspirin, ethylene glycol, and methanol.

| Elevated Anion Gap | Normal Anion Gap |
|--------------------|----------------------------------|
| Three Diseases | |
| 1. Uremia | 1. Renal tubular acidosis |
| 2. Ketoacidosis | 2. Diarrhea |
| 3. Lactic acidosis | 3. Carbonic anhydrase inhibition |
| Toxins | 4. Ureteral diversions |
| 1. Methanol | 5. Early renal failure |
| 2. Ethylene glycol | 6. Hydronephrosis |
| 3. Salicylates | 7. HCl administration |
| 4. Paraldehyde | 8. Saline administration |

Table 9-5. DIFFERENTIAL DIAGNOSIS OF METABOLIC ACIDOSIS

The term *anion gap* refers to the fact that we commonly measure more of the cationic than of the anionic components in the serum. The commonly measured cation concentration $[\text{Na}^+]$ usually exceeds by approximately 9.0 to $13.0 \text{ mEq} \cdot \text{l}^{-1}$ the total concentration of the anions, $[\text{Cl}^-] + ([\text{HCO}_3^-])$. The anion gap remains normal in hyperchloremic acidosis, such as that associated with renal or gastrointestinal loss of bicarbonate or with perioperative infusion of $15 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$ of 0.9% saline.¹⁶ In contrast, lactic acidosis or ketoacidosis increases the anion gap because bicarbonate ions are used to buffer hydrogen ions from the excess production of metabolic acids, while serum $([\text{HCO}_3^-])$ is displaced by the associated anion.

If pH is sufficiently reduced, myocardial contractility may be reduced,¹⁷ pulmonary vascular resistance may increase,¹⁸ systemic vascular resistance may decrease,¹⁹ and there may be an impaired response of the cardiovascular system to endogenous or exogenous catecholamines.²⁰ It is particularly important to note that compensatory hyperventilation normally occurs in response to metabolic acidosis.²¹ Failure of a patient to appropriately hyperventilate in response to metabolic acidosis is physiologically equivalent to respiratory acidosis and represents a severe disturbance. If a patient with metabolic acidosis requires mechanical ventilation, every attempt should be made to maintain an appropriate level of ventilatory compensation until the primary process can be corrected (see Table 9-2). Table 9-6 illustrates failure to maintain compensatory hyperventilation.

| | | Spontaneous Ventilation | Mechanical Ventilation |
|-------------|---|-------------------------|------------------------|
| Arterial | pH | 7.29 | 7.13 |
| Blood gases | Paco ₂ (mm Hg) | 29 | 49 |
| | [HCO ₃ ⁻] (mEq · l ⁻¹) | 14 | 16 |

Note: In the presence of metabolic acidosis, an otherwise innocuous increase in Paco₂ may create a life-threatening decrease in pH.

Table 9-6. FAILURE TO MAINTAIN APPROPRIATE VENTILATORY COMPENSATION FOR METABOLIC ACIDOSIS

The anesthetic implications of metabolic acidosis are proportional to the severity of the underlying process. Although a patient with hyperchloremic metabolic acidosis may be relatively healthy, those with lactic acidosis, ketoacidosis, uremia, or toxic ingestions will be chronically or acutely ill. Occasionally, on physical examination, metabolic acidosis may be suspected because a patient exhibits obvious hyperpnea. The serum electrolytes will demonstrate a decreased “CO₂.” Arterial blood gases are indicated if a metabolic acidosis is suspected. Perioperative assessment of the patient should determine whether the patient has ongoing evidence of hypovolemia or hypoperfusion, whether renal function is abnormal, and whether there is pulmonary pathology likely to interfere with intraoperative gas exchange. If shock is the etiology, direct arterial pressure monitoring and, occasionally, pulmonary arterial catheterization may be indicated. Intraoperatively, one should be concerned about the possibility of exaggerated hypotensive responses to drugs and positive pressure ventilation. As noted earlier, sudden cessation of ventilatory compensation for the metabolic acidosis may be devastating. The previous degree of compensatory hyperventilation should be maintained during anesthesia, capnography employed to monitor end-tidal CO₂, and arterial blood gases obtained to document the adequacy of intraoperative ventilation and pH maintenance. Consideration also should be given to the composition of intravenous fluids. Assuming that Paco₂ remains constant, balanced salt solutions containing bicarbonate or bicarbonate substrate (e.g., lactate) will generally increase pH and solutions containing high concentrations of chloride (e.g., 0.9% saline) will generally decrease pH.^{9,16}

The treatment of metabolic acidosis consists of the treatment of the primary pathophysiologic process (hypoperfusion, hypoxia), and if pH is severely decreased, administration of (NaHCO₃⁻). A commonly employed calculation of an initial dose of NaHCO₃ is:

$$\text{NaHCO}_3 \text{ (mEq} \cdot \text{l}^{-1}\text{)} = \frac{\text{Wt (kg)} \times 0.3 \times (24 \text{ mEq} \cdot \text{l}^{-1} - \text{actual HCO}_3^-)}{2} \quad (9-3)$$

where 0.3 is the assumed distribution space for bicarbonate and $24 \text{ mEq} \cdot \text{l}^{-1}$ is the normal value for $([\text{HCO}_3^-])$ on arterial blood gas determination. The calculation markedly underestimates dosage in severe metabolic acidosis.

If $([\text{HCO}_3^-])$ is infused, arterial blood gases should be measured again after approximately five minutes. In infants and children, an appropriate initial dose is 1.0 to $2.0 \text{ mEq} \cdot \text{kg}^{-1}$ of body weight. Hyperventilation, though an important compensatory response to metabolic acidosis, is not definitive therapy for metabolic acidosis.

One continuing controversy is the use of NaHCO₃ to treat acidemia induced by lactic acidosis. Although the best treatment is restoration of adequate tissue oxygenation, the conventional approach, if pH is <7.25 , has been to administer NaHCO₃. However, few data support that strategy. In experimental animals, administration of NaHCO₃ transiently increases mean arterial blood pressure while increasing pH²²; however, intracellular pH does not improve. Moreover, there is no substantial difference between NaHCO₃, Carbicarb (a combination of sodium carbonate and NaHCO₃), and equimolar sodium chloride.²² This suggests that the primary effect on hemodynamics may be due to the administration of a hypertonic salt solution.

In critically ill patients with lactic acidosis, there were no important differences between the effects of 0.9 M NaHCO₃ and 0.9 M sodium chloride.²³ The effects on cardiac output and arterial pressure were similar, despite increases in pH, $([\text{HCO}_3^-])$, and Paco₂ after receiving sodium bicarbonate. Importantly, NaHCO₃ did not improve the cardiovascular response to catecholamines and actually reduced plasma ionized calcium.²³ Several studies have demonstrated that bicarbonate therapy is

safe in critically ill patients and in perioperative patients.^{24,25} and ²⁶ Although many clinicians continue to administer NaHCO_3 to patients with persistent lactic acidosis and ongoing deterioration,²⁷ no study has demonstrated improved outcome. In addition, neither Carbicarb²⁶ nor dichloroacetate²⁸ improved clinical outcome. The buffer THAM (tris-hydroxymethyl aminomethane) is effective at reducing $[\text{H}^+]$ and does not generate CO_2 as a byproduct of buffering²⁹; however, there is no generally accepted indication for THAM.

Respiratory Alkalosis

Respiratory alkalosis, usually characterized by an alkalemic pH (>7.45) and always characterized by hypocarbia ($\text{PaCO}_2 \leq 35$ mm Hg), describes an increase in minute ventilation to a level greater than that required to excrete the metabolic production of CO_2 . Because respiratory alkalosis may be a sign of pain, anxiety, hypoxemia, central nervous system disease, or systemic sepsis, the development of spontaneous respiratory alkalosis in a previously normocarbic patient requires prompt evaluation.

Respiratory alkalosis, like metabolic alkalosis, may produce hypokalemia, hypocalcemia, cardiac dysrhythmias, bronchoconstriction, and hypotension, and may potentiate the toxicity of digoxin. In addition, acute changes in PaCO_2 alter cerebral blood flow, normally approximately $50 \text{ ml} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$ at a PaCO_2 of 40 mm Hg. Doubling minute ventilation reduces PaCO_2 to 20 mm Hg and halves cerebral blood flow. Conversely, if minute ventilation is halved, PaCO_2 will double and cerebral blood flow will also double. If minute ventilation and PaCO_2 are maintained at abnormally high or low levels for 8 to 24 hours, cerebral blood flow will return toward previous levels, associated with a return of cerebrospinal fluid ($[\text{HCO}_3^-]$) toward normal.^{30,31} Subsequent changes in PaCO_2 , after accommodation of the cerebrospinal fluid ($[\text{HCO}_3^-]$) and pH levels to chronic hypocapnia or hypercapnia, will again acutely change cerebral blood flow.

Preoperative recognition of chronic hyperventilation necessitates maintenance intraoperatively of a similar PaCO_2 . Acute hyperventilation may be useful in neurosurgical procedures to reduce brain bulk and to control intracranial pressure (ICP) during emergent surgery for patients with acute closed head trauma. In those situations, intraoperative monitoring of arterial blood gases, correlated with capnography, will document adequate reduction of PaCO_2 . Acute profound hypocapnia (<20 mm Hg) may produce EEG evidence of cerebral ischemia.

Respiratory Acidosis

Respiratory acidosis, usually characterized by a low pH (<7.35) and always characterized by hypercarbia ($\text{PaCO}_2 \geq 45$ mm Hg), occurs when minute ventilation is insufficient to eliminate CO_2 production without an increased capillary–alveolar CO_2 gradient. Respiratory acidosis may be either acute, without compensation by renal ($[\text{HCO}_3^-]$) retention, or chronic, with ($[\text{HCO}_3^-]$) retention offsetting the decrease in pH (Table 9-4). Respiratory acidosis occurs because of a decrease in minute alveolar ventilation (\dot{V}_A), an increase in production of carbon dioxide (\dot{V}_{CO_2}) or both, from the equation:

$$\text{PaCO}_2 = K \frac{\dot{V}_{\text{CO}_2}}{\dot{V}_A} \quad (9-4)$$

where K is a constant. (Of course, rebreathing of exhaled, carbon dioxide–containing gas may also increase PaCO_2 .) A reduction in \dot{V}_A may be due to an overall decrease in minute ventilation (\dot{V}_E) or to an increase in the amount of wasted ventilation (\dot{V}_D), according to the equation:

$$\dot{V}_A = \dot{V}_E - \dot{V}_D \quad (9-5)$$

Decreases in \dot{V}_E may occur because of central ventilatory depression by drugs or central nervous system injury, because of increased work of breathing, or because of airway obstruction or neuromuscular dysfunction. Increases in \dot{V}_D occur with chronic obstructive pulmonary disease, pulmonary embolism, and most acute forms of respiratory failure. \dot{V}_{CO_2} may be increased by sepsis, high-glucose parenteral feeding, or fever.

Patients with chronic hypercarbia due to intrinsic pulmonary disease require careful preoperative evaluation. The ventilatory restriction imposed by upper abdominal or thoracic surgery may be a particular risk to patients who chronically are unable to excrete \dot{V}_{CO_2} at a normal PaCO_2 . Administration of narcotics and sedatives, even in small doses, may cause hazardous ventilatory depression. Preoperative evaluation should consider direct arterial pressure monitoring and frequent intraoperative blood gas determinations, as well as postoperative pain management. Intraoperatively, a patient with chronic hypercapnia should be ventilated to maintain a normal pH. An abrupt increase in minute ventilation may result in profound alkalemia, and the associated complications, since the chronic elevation in ($[\text{HCO}_3^-]$) will persist as PaCO_2 is abruptly reduced (analogous to the addition of hyperventilation to metabolic alkalosis described in Table 9-3). Postoperatively, prophylactic ventilatory support may be required for selected patients with chronic hypercarbia. Epidural opioid administration represents one potential alternative that may provide adequate postoperative analgesia without undue depression of ventilatory drive.

The treatment of respiratory acidosis depends upon whether the process is acute or chronic. Acute respiratory acidosis may require mechanical ventilation unless a simple etiologic factor (e.g., opioid overdose or residual muscular blockade) can be treated quickly. Bicarbonate administration is rarely indicated unless severe metabolic acidosis is also present or unless mechanical ventilation is ineffective in reducing acute hypercarbia. In contrast, chronic respiratory acidosis is rarely managed with ventilation. Rather, efforts are made to improve pulmonary function to permit more effective elimination of carbon dioxide.

PRACTICAL APPROACH TO ACID–BASE INTERPRETATION

Rapid interpretation of a patient's acid–base status involves the integration of three sets of data: arterial blood gases, electrolytes, and history. The following stepwise approach facilitates interpretation (Table 9-7).

-
1. Is the pH life-threatening, requiring immediate intervention?
 2. Is the pH acidemic or alkalemic?
 3. Could the entire arterial blood gas picture represent only an acute increase or decrease in PaCO_2 ?
 4. If the answer to question #3 is "No," is there evidence of a chronic respiratory disturbance or of an acute metabolic disturbance?
 5. Are appropriate compensatory changes present?
 6. Is an anion gap present?
 7. Do the clinical data fit the acid–base picture?
-

Table 9-7. SEQUENTIAL APPROACH TO ACID–BASE INTERPRETATION

Usually, most of the acid–base picture can be assessed before initiating therapy; however, some data require immediate attention. Respiratory acidosis with a pH <7.1 suggests the need for tracheal intubation and ventilatory support while a metabolic acidosis with a similar pH suggests the need for appropriate etiologic intervention and, perhaps, alkalinizing therapy. Life-threatening alkalemia, rarely encountered, is often the consequence of the addition of inappropriate hyperventilation to underlying metabolic alkalosis.

The next problem is to define the primary acid–base disturbance. Is the patient acidemic (pH <7.35) or alkalemic (pH >7.45)? The pH status will usually indicate the primary process: that is, acidosis produces acidemia; alkalosis produces alkalemia. (Note that the suffix “-osis” indicates a primary process that, if unopposed, will produce the corresponding pH change. The suffix “-emia” refers to the pH. A compensatory process is not considered an “-osis.”) Of course, a patient may have mixed

“-oses,” that is, more than one primary process.

Next, one asks whether or not the entire arterial blood gas picture is consistent with a simple acute respiratory alkalosis or acidosis. [Table 9-4](#) lists the rules of pH change associated with acute hyperventilation and the secondary ($[\text{HCO}_3^-]$) changes. For example, a patient with an acute drop in PaCO_2 to 30 mm Hg would have a pH increase of 0.10 units to a pH of 7.50 and a calculated ($[\text{HCO}_3^-]$) of 22. An acute increase in PaCO_2 ([Table 9-4](#)) results in an acute increase in ($[\text{HCO}_3^-]$) of about 1 mmol for every increase of 10 mm Hg in PaCO_2 due to intracellular buffering of hydrogen ions and transcellular exchange of chloride for bicarbonate.¹⁴

If the changes in PaCO_2 , pH and ($[\text{HCO}_3^-]$) are not consistent with a simple acute respiratory disturbance, a chronic respiratory problem (≥ 24 hours) should be considered. The rules for a chronic respiratory disturbance are also listed in [Table 9-4](#). Note that the pH becomes nearly normal as the body compensates. For example, if a patient chronically hypoventilates to a PaCO_2 of 60 mm Hg (*i.e.*, increases PaCO_2 by 20 mm Hg), the ($[\text{HCO}_3^-]$) level should increase by 8 mEq \cdot l⁻¹; the arterial blood gases should show a PaCO_2 of 60 mm Hg, a pH of 7.35, and a ($[\text{HCO}_3^-]$) of 32 mEq \cdot l⁻¹. An episode of acute hypoventilation of this magnitude would have yielded a pH of 7.30 with a ($[\text{HCO}_3^-]$) of 26 mEq \cdot l⁻¹. The history will often provide clues as to whether the respiratory changes are acute or chronic. If neither an acute respiratory change nor a chronic compensatory change can describe the entire blood gas picture, then one must assume that a primary metabolic disturbance is also present.

[Table 9-2](#) characterizes the usual compensatory responses that should occur in response to metabolic disturbances. Note that respiratory compensation for metabolic disturbances occurs more rapidly than metabolic compensation for respiratory disturbances. Several general rules describe compensation. First, overcompensation is rare. Second, inadequate or excessive compensation suggests an additional primary disturbance. Third, a metabolic acidosis associated with an increased anion gap is never compensatory. Finally, the rules-of-thumb only approximate the logarithmic relationship between pH and $[\text{H}^+]$. The more the pH deviates from 7.40, the less accurate the rules become.

The next question, whether an anion gap is present, should be assessed even if the arterial blood gases appear straightforward. The simultaneous occurrence of metabolic alkalosis and metabolic acidosis (as a consequence of pathophysiology producing a high anion gap) may result in an unremarkable pH and ($[\text{HCO}_3^-]$); the combined abnormality may only be appreciated by examining the anion gap.³² Metabolic acidoses associated with a high anion gap require specific treatments, thus necessitating a correct diagnosis. This is particularly important in managing hyperchloremic metabolic acidosis after administration of large volumes of 0.9% saline perioperatively or even in critically ill patients.³³ In these circumstances, no anion gap would be expected and no specific treatment of metabolic acidosis would be required.^{9,34}

The final question is whether the clinical data are consistent with the arterial blood gas data. Failure to consider clinical status also may lead to serious errors in blood gas interpretation.

Examples

The foregoing has summarized an approach that simplifies interpretation. The following two hypothetical cases will be approached using the algorithm and rules just discussed.

Example 1

A 65-year-old female has undergone 12 hours of an expected 16-hour radical neck dissection and flap construction. The estimated blood loss is 1000 ml. She has received three units of packed red blood cells and 9 l of 0.9% saline. Her blood pressure and heart rate have remained stable while anesthetized with 0.5% to 1.0% isoflurane in 70:30 nitrous oxide and oxygen. Urinary output is adequate. Arterial blood gas levels are shown in [Table 9-8](#).

| | | |
|----------------------|--------------------|---------------------------------|
| Arterial blood gases | pH | 7.38 |
| | PaCO_2 | 32 mm Hg |
| | $[\text{HCO}_3^-]$ | 17 mEq \cdot l ⁻¹ |
| Electrolytes | Na^+ | 140 mEq \cdot l ⁻¹ |
| | Cl^- | 112 mEq \cdot l ⁻¹ |
| | CO_2 | 18 mEq \cdot l ⁻¹ |
| | Anion Gap | 10 mEq \cdot l ⁻¹ |

Table 9-8. HYPOBICARBONATEMIA AND HYPERCHLOREMIC ACIDOSIS DURING PROLONGED SURGERY

The step-by-step interpretation is as follows:

1. The pH is not life-threatening.
2. The pH is <7.40 but is not frankly acidemic.
3. The arterial blood gases cannot be adequately explained by acute hypocarbia. The predicted pH would be 7.48 and the predicted ($[\text{HCO}_3^-]$) would be 22 mEq \cdot l⁻¹ ([Table 9-4](#)).
4. A metabolic acidosis appears to be present.
5. The question of compensation is not pertinent during general anesthesia, given that PaCO_2 is established by mechanical ventilation. However, if this represented spontaneous hypocarbia, it would suggest slight overcompensation ([Table 9-2](#)) and should prompt a search for a reason for primary respiratory alkalosis.
6. During prolonged anesthesia and surgery, one might assume the presence of lactic acidosis and provide additional fluid therapy or otherwise attempt to improve perfusion. However, serum electrolytes reveal ([Table 9-8](#)) a normal anion gap, indicating that the metabolic acidosis is probably the result of dilution of the extracellular volume with a high-chloride fluid.^{9,16} A random urine sample could help confirm this etiology of hyperchloremic acidosis ([Table 9-9](#)).¹⁴ Hyperchloremic acidosis secondary to infusion of high-chloride fluid requires no treatment.

| | Urinary Solutes | | | |
|-----------------------------------|-----------------|---------------|--------------|---------------|
| | NH_4^+ | Cl^- | A^- | Na^+ |
| GI tract HCO_3^- loss | ↑ | ↓ | ** | ↓ |
| Generated/ingested organic acids | ↑ | ** | ↑ | ↑ |
| HCl intake or equivalent* | ↓ | ↑ | ** | ↓ |
| Inadequate renal HCO_3^- | ↓ | ** | ** | ** |
| Renal HCO_3^- loss | ↓ | ** | ** | ** |

* NH_4Cl , chloride salts of amino acids or dilutional acidosis; ** designates normal; (a) NH_4^+ > 1 mmol/kg daily; (b) $\text{Fe} < 1$ mmol/kg daily; FE = fractional excretion of a solute; Urinary unmeasured anion concentration (sum of urinary K^+ , NH_4^+ , and Na^+ less Cl^-) estimates sum of urinary sulfate and organic anion concentrations. (Reproduced with permission from Gluck SL: Acid-base. Lancet 352:474, 1998.)

Table 9-9. EVALUATION OF HYPERCHLOREMIC ACIDOSIS

7. The arterial blood gases and serum electrolytes are compatible with the clinical picture.

Example 2

A 35-year-old male, three days after appendectomy, develops nausea with recurrent emesis persisting for 48 hours. An arterial blood gas reveals the results shown in the middle column of [Table 9-10](#).

| | | Normal | Metabolic Alkalosis | Metabolic Acidosis |
|--------------------|---|--------|---------------------|--------------------|
| Blood gases | pH | 7.40 | 7.50 | 7.40 |
| | Paco ₂ (mm Hg) | 40 | 46 | 40 |
| | [HCO ₃ ⁻] (mEq · l ⁻¹) | 24 | 35 | 24 |
| Serum electrolytes | Na ⁺ (mEq · l ⁻¹) | 140 | 140 | 140 |
| | Cl ⁻ (mEq · l ⁻¹) | 105 | 94 | 94 |
| | CO ₂ (mEq · l ⁻¹) | 25 | 36 | 25 |
| | Anion gap (mEq · l ⁻¹) | 30 | 30 | 21 |

Table 9-10. METABOLIC ALKALOSIS SECONDARY TO NAUSEA AND VOMITING WITH SUBSEQUENT LACTIC ACIDOSIS SECONDARY TO HYPOVOLEMIA

1. The pH of 7.50 requires no immediate intervention.
2. The pH is alkalemic, suggesting a primary alkalosis.
3. An acute PaCO₂ of 46 mm Hg would yield a pH of approximately 7.37; therefore, this is not simply an acute ventilatory disturbance.
4. The patient has a primary metabolic alkalosis, as suggested by the ([HCO₃⁻]) of 35 mEq · l⁻¹.
5. The limits of respiratory compensation for metabolic alkalosis are wide and difficult to predict for individual patients. The rules of thumb, summarized in [Table 9-2](#), suggest that ([HCO₃⁻]) + 15 should equal the last two digits of the pH and that the PaCO₂ should increase 5–6 mm Hg for every 10 mEq · l⁻¹ change in serum ([HCO₃⁻]), that is, pH = 7.50 and PaCO₂ = 46 mm Hg.
6. The anion gap is 12 mEq · l⁻¹.
7. The diagnosis of a primary metabolic alkalosis with compensatory hypoventilation is consistent with the history of recurrent vomiting. Consider how the arterial blood gases would change if vomiting were sufficiently severe to produce hypovolemic shock and lactic acidosis (third column, [Table 9-10](#)).

This sequence illustrates the important concept that the final pH, PaCO₂, and ([HCO₃⁻]) represent the result of all of the vectors operating on acid–base status. Complex, or “triple disturbances” can only be interpreted using a thorough, stepwise approach.

FLUID MANAGEMENT

Physiology

Body Fluid Compartments

Accurate replacement of fluid deficits necessitates an understanding of the distribution spaces of water, sodium, and colloid. Total body water (TBW), the distribution volume of sodium-free water, approximates 60% of total body weight. TBW includes intracellular volume (ICV), which constitutes 40% of total body weight, and extracellular volume (ECV), which constitutes 20% of body weight. Plasma volume (PV) equals about one fifth of ECV, the remainder of which is interstitial fluid (IF). Red cell volume, approximately 2 liters, is part of ICV.

The ECV contains most of total body sodium, with equal sodium concentrations ([Na⁺]) in the PV and IF. Plasma [Na⁺] is approximately 140 mEq · l⁻¹. The predominant intracellular cation, potassium, has an intracellular concentration ([K⁺]) approximating 150 mEq · l⁻¹. Albumin, the most important oncologically active constituent of ECV, is unequally distributed in PV (~4 g · dl⁻¹) and IF (~1 g · dl⁻¹). The IF concentration of albumin varies greatly among tissues. ECV is the distribution volume both for crystalloid solutions in which [Na⁺] is approximately 140 mEq · l⁻¹ and for colloid.

Distribution of Infused Fluids

Conventionally, clinical prediction of plasma volume expansion (PVE) after fluid infusion assumes that body fluid spaces are static. Kinetic analysis of PVE replaces the static assumption with a dynamic description. As an example of the static approach, assume that a 70-kg patient has suffered an acute blood loss of 2000 ml, approximately 40% of the predicted 5-l blood volume. The formula describing the effects of replacement with 5% dextrose in water (D5W), lactated Ringer's solution, or 5% or 25% human serum albumin is as follows:

$$\text{Expected PV increment} = \frac{\text{volume infused} \times \text{normal PV}}{\text{distribution volume}} \quad (9-6)$$

Rearranging the equation yields the following:

Volume infused

$$= \frac{\text{expected PV increment} \times \text{distribution volume}}{\text{normal PV}} \quad (9-7)$$

To restore blood volume using D5W:

$$28 \text{ l} = \frac{21 \times 42 \text{ l}}{31} \quad (9-8)$$

where 2 l is the desired PV increment, 42 l is the TBW in a 70-kg person, and 3 l is the normal estimated PV.

To restore blood volume using lactated Ringer's solution:

$$0.31 \text{ l} = \frac{21 \times 14 \text{ l}}{31} \quad (9-9)$$

where 14 l is the ECV in a 70-kg person.

If 5% albumin, which exerts colloid osmotic pressure similar to plasma, were infused, the infused volume initially would remain in the PV, perhaps attracting additional interstitial fluid intravascularly. Twenty-five percent human serum albumin, a concentrated colloid, expands PV by approximately 400 ml for each 100 ml infused.

However, in kinetic terms, these analyses are simplistic. Infused fluid does not simply equilibrate throughout an assumed distribution volume, but is added to a highly regulated system that maintains intravascular, interstitial, and intracellular volume within narrow limits. Excess fluid is excreted whereas hypovolemia initiates several

powerful compensatory mechanisms, including transcapillary refill and intense sodium and water conservation. The purpose of applying kinetic models to intravenous fluid therapy is to allow clinicians to predict more accurately the time course of volume changes produced by infusions of fluids of various compositions in patients with a variety of pathophysiologic abnormalities. Kinetic analysis permits estimation of peak volume expansion and rates of clearance of infused fluid and complements analysis of “pharmacodynamic” effects, such as changes in cardiac output or cardiac filling pressures.

Because infused fluid does not introduce a novel substance that can be measured, the effects of fluid infusion must be inferred from changes in variables such as albumin or hemoglobin concentration [Hb]. In addition, fluids usually are given not as rapid boluses but as infusions over longer time intervals, thereby producing more complicated decay curves than those in conventional pharmacokinetic analysis. To further complicate the comparison, fluid infusion acutely changes the volumes of distribution of infused fluid and may alter clearance mechanisms (*e.g.*, glomerular filtration and tubular reabsorption) as well as neuroendocrine factors such as antidiuretic hormone (ADH), atrial natriuretic peptide (ANP), and aldosterone.

A practical physiologic tracer should permit frequent measurements in order to define more completely the clearance curves. Svensen and Hahn³⁵ evaluated three endogenous tracers—blood water concentration, serum albumin concentration, and [Hb]—in volunteers who received infusions of acetated Ringer's solution, 6% dextran 70, or 7.5% saline. Although much less tedious than blood water calculations, [Hb] provided similar estimates of volumes of distribution and elimination rate constants.

Figure 9-1 illustrates the conceptual model used by Svenseén and Hahn.³⁵ The top of the figure illustrates a one-compartment model, while the bottom shows a two-compartment model. After infusing the test fluids, Svenseén and Hahn fitted the results to one-volume- and two-volume-of-fluid-space (VOFS) models. Each of the two VOFS models is based on physiologic and mathematical assumptions (Table 9-11).³⁶ The two-compartment VOFS model is most likely to be superior to the one-compartment model when urinary excretion in response to infusion is small.³⁷

Figure 9-1. Schematic drawing of the kinetic model used to calculate the size of the body fluid spaces expanded by intravenous infusions of fluid in humans. Data are fitted to a one-volume- or two-volume-of-fluid-space (VOFS) model. The assumptions underlying the one-compartment VOFS model (*top*) are as follows: (1) During fluid infusion, fluid enters an expandable space of volume v at a constant rate k_i ; (2) the expandable fluid space has a target volume V , which the body strives to maintain; (3) volume v changes by fluid being eliminated from the fluid space at a basal rate, k_b (perspiration and basal diuresis), and at a controlled rate. The controlled rate is proportional by a constant k_r to the relative deviation of v from the target volume V . The assumptions behind the two-compartment VOFS model (*bottom*) are similar: (1) During fluid infusion, fluid enters an expandable space of volume v_1 at a constant rate k_i ; (2) there is a secondary expandable fluid space of volume v_2 exchanging fluid with the primary fluid space; (3) volume v_1 changes through exchange with the secondary fluid space and as a result of fluid being eliminated from the primary fluid space at a basal rate, k_b (perspiration and basal diuresis), and at a controlled rate; (4) the primary and secondary fluid spaces have target volumes V_1 and V_2 which the system strives to maintain by acting on the controlled elimination mechanism, k_r , which is proportional to the relative deviation from the target volume of the primary fluid space, and by acting on the fluid exchange mechanism; (5) the net rate of fluid exchange between the two spaces is proportional to the difference in relative deviations from the target volumes by a constant k_e . (Reprinted with permission from Svenseén C, Hahn RG: Volume kinetics of Ringer solution, dextran 70, and hypertonic saline in male volunteers. *Anesthesiology* 87:204, 1997.)

| One-Compartment VOFS Assumptions | Two-Compartment VOFS Assumptions |
|--|---|
| 1. During fluid infusion, fluid enters an expandable space of volume v at a constant rate k_i . | 1. During fluid infusion, fluid enters an expandable space of volume v_1 at a constant rate k_i . |
| 2. The expandable fluid space has a target volume V , which the body strives to maintain. | 2. There is a secondary expandable fluid space of volume v_2 exchanging fluid with the primary fluid space. |
| 3. Volume v changes by fluid being eliminated from the fluid space at a basal rate, k_b (perspiration and basal diuresis), and at a controlled rate. The controlled rate is proportional by a constant k_r to the relative deviation of v from the target volume V . | 3. Volume v_1 changes through exchange with the secondary fluid space and as a result of fluid being eliminated from the primary fluid space at a basal rate, k_b (perspiration and basal diuresis), and at a controlled rate. |
| | 4. The primary and secondary fluid spaces have target volumes V_1 and V_2 , which the system strives to maintain by acting on the controlled elimination mechanism, k_r , which is proportional to the relative deviation from the target volume of the primary, and by acting on the fluid exchange mechanism. |
| | 5. The net rate of fluid exchange between the two spaces is proportional to the difference in relative deviations from the target volumes by a constant k_e . |

VOFS, volume-of-fluid-space.

Table 9-11. PHYSIOLOGIC AND MATHEMATICAL ASSUMPTIONS FOR ONE- AND TWO-VOLUME-OF-FLUID-SPACE MODELS

Figure 9-2 shows the mean plasma volume dilution curves obtained with the infusion of Ringer's solution or dextran 70. All dextran infusions were consistent with a one-VOFS model, suggesting that the colloid infusion remained in the PV. Hypertonic crystalloid, like isotonic crystalloid, is associated in individual instances with a mixture of one- and two-VOFS models.

Figure 9-2. Kinetic curves obtained after infusion in adult male volunteers of $25 \text{ ml} \cdot \text{kg}^{-1}$ of acetated Ringer's solution (Ringer) or $5 \text{ ml} \cdot \text{kg}^{-1}$ of dextran 70 over 30 min. Dilution of plasma volume is calculated from changes in hemoglobin (B-hemoglobin) concentration, blood water (B-water) concentration, and serum albumin (S-albumin) concentration. (Reprinted with permission from Svenseén C, Hahn RG: Volume kinetics of Ringer solution, dextran 70, and hypertonic saline in male volunteers. *Anesthesiology* 87:204, 1997.)

Using this approach, the effects of common physiologic and pharmacologic influences can be examined in experimental animals or humans. As an example, the influence of acute hypovolemia on PVE has been defined experimentally and clinically. In chronically instrumented, splenectomized, unanesthetized sheep, hemorrhage of 300 ml (~12% of blood volume), plasma transfilling consisted of approximately two-thirds of shed blood volume within 3 hours.³⁸ In fact, at 3 hours after the end of hemorrhage, PVE was similar to that in animals that had received $25 \text{ ml} \cdot \text{kg}^{-1}$ of 0.9% saline over 20 minutes beginning immediately after the termination of

hemorrhage. In conscious volunteers given $25 \text{ ml} \cdot \text{kg}^{-1}$ of acetated Ringer's solution over 30 minutes under conditions of normovolemia or after removal of 450 or 900 ml of blood, plasma dilution (closely related to volume expansion) 50 to 100 minutes after beginning the infusion was greatest after 900 ml of hemorrhage, less after 450 ml of hemorrhage, and least in the absence of hemorrhage.³⁹ Plasma transfilling appears to contribute substantially to the expansion of plasma volume by intravenous fluids given after hemorrhage, although these observations must be confirmed in anesthetized animals and humans.

Regulation of Extracellular Fluid Volume

Total body water content is regulated by the intake and output of water. Water intake includes ingested liquids plus an average of 750 ml ingested in solid food and 350 ml that is generated metabolically.⁴⁰ Insensible losses are normally 1 l per day and GI losses are 100 to 150 ml per day. Thirst, the primary mechanism of controlling water intake, is triggered by an increase in body fluid tonicity or by a decrease in extracellular volume.⁴¹

Reabsorption of filtered water and sodium is enhanced by changes mediated by the hormonal factors antidiuretic hormone (ADH), atrial natriuretic peptide (ANP), and aldosterone. Renal water handling has three important components: (1) delivery of tubular fluid to the diluting segments of the nephron; (2) separation of solute and water in the diluting segment; and (3) variable reabsorption of water in the collecting ducts.⁴¹ In the descending loop of Henle, water is reabsorbed while solute is retained to achieve a final osmolality of tubular fluid of $\sim 1200 \text{ mOsm} \cdot \text{kg}^{-1}$ (Fig. 9-3). This concentrated fluid is then diluted by the active reabsorption of electrolytes in the ascending limb of the loop of Henle and in the distal tubule, both of which are relatively impermeable to water.⁴¹ As fluid exits the distal tubule and enters the collecting duct, osmolality is $\sim 50 \text{ mOsm} \cdot \text{kg}^{-1}$. Within the collecting duct, water reabsorption is modulated by ADH (also called vasopressin). Vasopressin binds to V_2 receptors along the basolateral membrane of the collecting duct cells,⁴² then stimulates the synthesis and insertion of the aquaporin-2 water channel into the luminal membrane of collecting duct cells.^{42,43 and 44}

Figure 9-3. Renal filtration, reabsorption, and excretion of water. *Open arrows* represent water and *solid arrows* represent electrolytes. Water and electrolytes are filtered by the glomerulus. In the proximal tubule (1), water and electrolytes are absorbed isototically. In the descending loop of Henle (2), water is absorbed to achieve osmotic equilibrium with the interstitium while electrolytes are retained. The numbers (300, 600, 900, and 1200) between the descending and ascending limbs represent the osmolality of the interstitium in $\text{mOsm} \cdot \text{kg}^{-1}$. The delivery of solute and fluid to the distal nephron is a function of proximal tubular reabsorption; as proximal tubular reabsorption increases, delivery of solute to the medullary (3a) and cortical (3b) diluting sites decreases. In the diluting sites, electrolyte-free water is generated through selective reabsorption of electrolytes while water is retained in the tubular lumen, generating a dilute tubular fluid. In the absence of vasopressin, the collecting duct (4a) remains relatively impermeable to water and a dilute urine is excreted. When vasopressin acts on the collecting ducts (4b), water is reabsorbed from these vasopressin-responsive nephron segments, allowing the excretion of a concentrated urine. (Reprinted with permission from Fried LF, Palevsky PM: Hyponatremia and hypernatremia. In Saklayen MG (ed): The Medical Clinics of North America. Renal Disease, p 585. Philadelphia, WB Saunders, 1997.)

Plasma hypotonicity suppresses ADH release, resulting in excretion of dilute urine. Hypertonicity stimulates ADH secretion, which increases the permeability of the collecting duct to water and enhances water reabsorption. In response to changing plasma $[\text{Na}^+]$, changing secretion of ADH can vary urinary osmolality from 50 to $1200 \text{ mOsm} \cdot \text{kg}^{-1}$ and urinary volume from 0.4 to $20 \text{ l} \cdot \text{day}^{-1}$ (Fig. 9-4). Other factors that stimulate ADH secretion, though none as powerfully as plasma tonicity, include hypotension, hypovolemia, and nonosmotic stimuli such as nausea, pain, and medications, including opiates.⁴¹

Figure 9-4. *Top:* Relationship between plasma osmolality and plasma vasopressin (AVP; also referred to as ADH). *Bottom:* Relationship between plasma AVP and urinary osmolality. (Reprinted with permission from Ober KP: Endocrine crisis: Diabetes insipidus. Crit Care Clin 7:109, 1991.)

Two powerful hormonal systems regulate total body sodium. The natriuretic peptides—atrial natriuretic peptide (ANP), brain natriuretic peptide, and C-type natriuretic peptide—defend against sodium overload,⁴⁵ and the renin–angiotensin–aldosterone axis defends against sodium depletion and hypovolemia. ANP, released from the cardiac atria in response to increased atrial stretch, exerts vasodilatory effects and increases the renal excretion of sodium and water.^{46,47} ANP secretion is decreased during hypovolemia. Even in patients with chronic renal insufficiency, infusion of ANP in low, nonhypotensive doses increases sodium excretion and augments urinary losses of retained solutes.⁴⁸

Aldosterone is the final common pathway in a complex response to decreased effective arterial volume, whether decreased effective arterial volume is true or relative (edematous states or hypoalbuminemia). In this pathway, decreased stretch in the baroreceptors of the aortic arch and carotid body and stretch receptors in the great veins, pulmonary vasculature, and atria result in increased sympathetic tone. Increased sympathetic tone, in combination with decreased renal perfusion, leads to renin release and formation of angiotensin I from angiotensinogen.⁴⁹ Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II, which stimulates the adrenal cortex to synthesize and release aldosterone.⁵⁰ Acting primarily in the distal tubules, high concentrations of aldosterone cause sodium reabsorption⁵⁰ (Fig. 9-5) and may reduce urinary excretion of sodium nearly to zero. Intrarenal physical factors are also important in regulating sodium balance. Sodium loading decreases colloid osmotic pressure, thereby increasing the glomerular filtration rate (GFR), decreasing net sodium reabsorption, and increasing distal sodium delivery, which, in turn, suppresses renin secretion.⁵⁰

Figure 9-5. Mean urinary sodium excretion for given ranges of plasma renin activity and urinary aldosterone excretion in humans. Aldosterone exerts a regulatory effect on urinary sodium excretion even at low levels of secretory activity and relatively high levels of sodium excretion. (Reprinted with permission from Laragh JH: The endocrine control of blood volume, blood pressure and sodium balance: Atrial hormone and renin system interactions. *J Hypertens* 4(suppl 2):S143, 1986.)

Renal adaptation to hypovolemia (and decreased cardiac output) occurs through three primary mechanisms: a reduction in renal blood flow (RBF), a reduction in GFR, and increased tubular reabsorption of sodium and water.⁵¹ Renal perfusion during acute hypovolemia is determined by the balance between renal vasoconstrictive factors (the renal sympathetic nerves, angiotensin II, and catecholamines) and vasodilatory mechanisms (intrinsic renal autoregulation and the renal vasodilatory effects of prostaglandins).⁵² Although RBF autoregulates (remains constant over a wide range of perfusion pressures), autoregulation may be impaired or lost during severe, acute hypovolemia.⁵³ Renal sympathetic stimulation with secretion of α -adrenergic catecholamines and angiotensin II increases renal vascular resistance. Intrarenal vasodilator prostaglandins antagonize vasoconstrictor hormones and maintain RBF during hypovolemia. This protective effect is reduced by nonsteroidal anti-inflammatory drugs.⁵⁴

Fluid Replacement Therapy

Maintenance Requirements for Water, Sodium and Potassium

In healthy adults, sufficient water is required to balance gastrointestinal losses of $100\text{--}200\text{ ml} \cdot \text{day}^{-1}$, insensible losses of $500\text{--}1000\text{ ml} \cdot \text{day}^{-1}$ (half of which is respiratory and half cutaneous), and urinary losses of $1000\text{ ml} \cdot \text{day}^{-1}$. Two simple formulas are used interchangeably to estimate maintenance water requirements (Table 9-12). Urinary losses exceeding $1000\text{ ml} \cdot \text{day}^{-1}$ may represent an appropriate physiologic response to ECV expansion or an inability to conserve salt or water.

| Weight (kg) | $\text{ml} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ | $\text{ml} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ |
|-------------|--|--|
| 1-10 | 4 | 100 |
| 11-20 | 2 | 50 |
| 21-n | 1 | 20 |

Table 9-12. MAINTENANCE WATER REQUIREMENTS

Daily requirements for sodium and potassium are approximately $75\text{ mEq} \cdot \text{l}^{-1}$ and $40\text{ mEq} \cdot \text{l}^{-1}$, respectively, although wider ranges of sodium intake than potassium intake are physiologically tolerated because renal sodium conservation and excretion are more efficient than potassium conservation and excretion. Therefore, healthy, 70-kg adults require $2500\text{ ml} \cdot \text{day}^{-1}$ of water containing a $[\text{Na}^+]$ of $30\text{ mEq} \cdot \text{l}^{-1}$ and a $[\text{K}^+]$ of $15\text{--}20\text{ mEq} \cdot \text{l}^{-1}$. Intraoperatively, fluids containing sodium-free water (*i.e.*, $[\text{Na}^+] < 130\text{ mEq} \cdot \text{l}^{-1}$) are rarely used in adults because of the necessity for replacing isotonic losses and the risk of postoperative hyponatremia.

Dextrose

Traditionally, glucose-containing intravenous fluids have been given in an effort to prevent hypoglycemia and limit protein catabolism. However, owing to the hyperglycemic response associated with surgical stress, only infants and patients receiving insulin or drugs that interfere with glucose synthesis are at risk for hypoglycemia. Iatrogenic hyperglycemia can limit the effectiveness of fluid resuscitation by inducing an osmotic diuresis and, in animals, may aggravate ischemic neurologic injury.⁵⁵ Although associated with worse outcome in both ischemic⁵⁶ (Table 9-13) and traumatic⁵⁷ brain injury in humans, hyperglycemia may also constitute a hormonally mediated response to more severe injury.⁵⁸

| Outcome | Glu ≤ 120 mg-dl ⁻¹ | | Glu > 120 mg-dl ⁻¹ | | p |
|-----------------------------|---------------------------------------|------|------------------------------------|------|---------|
| | No | % | No | % | |

Table 9-13. INFLUENCE OF MEAN PLASMA GLUCOSE (DAYS 3 TO 7) ON 3-MONTH GLASGOW OUTCOME SCALE (GOS) SCORE IN SAH

Surgical Fluid Requirements

Water and Electrolyte Composition of Fluid Losses. Surgical patients require replacement of PV and ECV losses secondary to wound or burn edema, ascites, and gastrointestinal secretions. Wound and burn edema and ascitic fluid are protein-rich and contain electrolytes in concentrations similar to plasma. Although gastrointestinal secretions vary greatly in composition (Table 9-14), the composition of replacement fluid need not be closely matched if ECV is adequate and renal and cardiovascular function are normal. Substantial loss of gastrointestinal fluids requires more accurate replacement of electrolytes (*i.e.*, potassium, magnesium, phosphate). If cardiovascular or renal function is impaired, more precise replacement may require frequent assessment of serum electrolytes. Chronic gastric losses may produce hypochloremic metabolic alkalosis that can be corrected with 0.9% saline; chronic diarrhea may produce hyperchloremic metabolic acidosis that may be prevented or corrected by infusion of fluid containing bicarbonate or bicarbonate substrate (*e.g.*, lactate).

| Source | Volume (ml·day ⁻¹) | Na ⁺ (mEq·l ⁻¹) | K ⁺ (mEq·l ⁻¹) | Cl ⁻ (mEq·l ⁻¹) | HCO ₃ ⁻ (mEq·l ⁻¹) |
|------------|-----------------------------------|---|--|---|---|
| Gastric | 1500 | 40 | 10 | 130 | — |
| Intestinal | 3000 | 140 | 5 | 104 | 30 |
| Pancreatic | 400 | 140 | 5 | 75 | 115 |
| Biliary | 400 | 140 | 5 | 100 | 35 |

Table 9-14. AVERAGE VOLUMES AND ELECTROLYTE COMPOSITION OF GASTROINTESTINAL SECRETIONS

Fluid Shifts During Surgery. Replacement of intraoperative fluid losses must compensate for the acute reduction of functional ECV that accompanies trauma, hemorrhage, and tissue manipulation. For example, otherwise healthy subjects who received no intraoperative sodium while undergoing gastric or gallbladder surgery demonstrated a decline in ECV of nearly 2 liters and a 13% decline in GFR.⁵⁹ In contrast, patients who received lactated Ringer's solution maintained ECV and increased GFR by 10%. No data describe changes in PV, IF, and ICV during acute, unresuscitated shock in humans. Patients studied during the first 10 days after resuscitation from massive trauma demonstrated a 55% increase in IF volume (Fig. 9-6).⁶⁰ Because of the reduction of colloid osmotic pressure in traumatized patients, the ratio of IF to blood volume was increased, in some patients exceeding 5:1.⁶⁰ Based on static assumptions regarding the distribution volumes of infused fluids, such patients would require much larger volumes of crystalloids than healthy patients in order to achieve a specific amount of intravascular volume expansion. However, insufficient data are available to confirm that assessment.

Figure 9-6. In comparison with normal individuals, patients recently subjected to severe trauma (fluid and blood requirements exceeding an average of 21 liters on the day of admission) have a slight decrease in intracellular volume (as percentage of body weight) and an increase in extracellular volume and blood volume. (Data redrawn with permission from Böck JC, Barker BC, Clinton AG *et al*: Post-traumatic changes in, and effect of colloid osmotic pressure on the distribution of body water. *Ann Surg* 210:395, 1989.)

Based on these considerations, guidelines have been developed for replacement of fluid losses during surgical procedures. The simplest formula provides, in addition to maintenance fluids and replacement of estimated blood loss, $4 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$ for procedures involving minimal trauma, $6 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$ for those involving moderate trauma, and $8 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$ for those involving extreme trauma.

Mobilization of Expanded Interstitial Fluid

An important corollary of IF expansion is the mobilization and return of accumulated fluid to the ECV and the PV, colloquially termed “deresuscitation.” In most patients, mobilization occurs on approximately the third postoperative day. If the cardiovascular system and kidneys cannot effectively transport and excrete mobilized fluid, hypervolemia and pulmonary edema may occur.

Fluid Requirements During Labor and Cesarean Section

Labor is energy-intensive. Prolonged labor without caloric intake may lead to maternal and fetal hypoglycemia, ketosis, and lactic acidosis. In parturients randomized to receive no dextrose, 1% dextrose, or 5% dextrose, administration of dextrose-free solution resulted in umbilical artery hypoglycemia, 1% dextrose maintained euglycemia in both the mother and neonate, and 5% dextrose was associated with neonatal hypoglycemia.⁶¹ Based on these clinical studies, glucose should be given during labor in a dose of $1\text{--}2 \text{ g} \cdot \text{hr}^{-1}$ (equivalent to 100–200 ml of a 1% dextrose solution), should not exceed $6 \text{ g} \cdot \text{hr}^{-1}$, and should be considered especially in patients receiving regional anesthesia without epinephrine (which tends to increase serum glucose).

Aggressive preload augmentation before epidural anesthesia during labor is probably unnecessary because continuous infusion of low doses of local anesthetic agents produces gradual sympathectomy and vasodilation. Furthermore, rapid volume expansion may inhibit uterine activity and, in some high-risk parturients, may precipitate hypervolemia and pulmonary edema. However, preload augmentation and increased cardiac diastolic volume may enhance renal and placental perfusion by stimulating secretion of ANP.⁶²

In contrast to epidural anesthesia administered for labor, spinal anesthesia and, to a lesser extent, epidural anesthesia for cesarean section typically causes maternal hypotension. To prevent hypotension, large volumes of crystalloid solutions ($10\text{--}20 \text{ ml} \cdot \text{kg}^{-1}$) are conventionally infused before regional anesthesia. However, hypotension occurred in 55% of patients receiving crystalloid ($20 \text{ ml} \cdot \text{kg}^{-1}$) preloading, despite left uterine displacement, in comparison to 71% of patients not receiving preloading.⁶³ In contrast, preloading with 5% albumin solution in Ringer's lactate ($15 \text{ ml} \cdot \text{kg}^{-1}$) avoided hypotension in comparison to a 30% incidence in a crystalloid group preloaded with crystalloid⁶⁴; the clinical and biochemical status of the infants of mothers receiving albumin was superior. Because most clinical studies evaluated the relative efficacy of crystalloid or colloid solutions used for preloading in terms of blood pressure rather than cardiac output, systemic oxygen transport, or uteroplacental flow, further research defining the effects of preload on maternal and fetal outcome is required.

Colloids, Crystalloids, and Hypertonic Solutions

Physiology and Pharmacology

Osmotically active particles attract water across semipermeable membranes until equilibrium is attained. The *osmolarity* of a solution refers to the number of osmotically active particles per *liter* of solvent; *osmolality*, a measurement of the number of osmotically active particles per *kilogram*, can be estimated as follows:

$$\text{Osmolality} = ([\text{Na}^+] \times 2) + (\text{glucose}/18) + (\text{BUN}/2.3) \quad (9-10)$$

where osmolality is expressed in millimoles per kilogram ($\text{mmol} \cdot \text{kg}^{-1}$), $[\text{Na}^+]$ is expressed in milliequivalents per liter ($\text{mEq} \cdot \text{l}^{-1}$), serum glucose is expressed in milligrams per deciliter ($\text{mg} \cdot \text{dl}^{-1}$), and BUN is blood urea nitrogen expressed in $\text{mg} \cdot \text{dl}^{-1}$. Sugars, alcohols, and radiographic dyes increase measured osmolality, generating an increased “osmolal gap” between the measured and calculated values.

A hyperosmolar state occurs whenever the concentration of osmotically active particles is high. Both uremia (increased BUN) and hypernatremia (increased serum sodium) increase serum osmolality. However, because urea distributes throughout TBW, an increase in BUN does not cause *hypertonicity*. Sodium, largely restricted to the ECV, causes hypertonicity, that is, osmotically mediated redistribution of water from ICV to ECV. The term “tonicity” is also used colloquially to compare the osmotic

pressure of a parenteral solution to that of plasma.

Although osmotically active particles in blood represent only a small proportion of plasma proteins, those particles are essential in determining the equilibrium of fluid between the interstitial and plasma compartments of ECV. The reflection coefficient (s) describes the permeability of capillary membranes to individual solutes, with 0 representing free permeability and 1.0 representing complete impermeability. The reflection coefficient for albumin ranges from 0.6 to 0.9 in various capillary beds. Because capillary protein concentrations exceed interstitial concentrations, the osmotic pressure exerted by plasma proteins (termed *colloid osmotic pressure* or *oncotic pressure*) is higher than interstitial oncotic pressure and tends to preserve PV. The filtration rate of fluid from the capillaries into the interstitial space is the net result of a combination of forces, including the gradient from intravascular to interstitial colloid osmotic pressures and the hydrostatic gradient between intravascular and interstitial pressures. The net fluid filtration at any point within a systemic or pulmonary capillary is represented by Starling's law of capillary filtration, as expressed in the equation:

$$Q = kA[(P_c - P_i) + \sigma(\pi_i + \pi_c)] \quad (9-11)$$

where Q is fluid filtration, k is the capillary filtration coefficient (conductivity of water), A is the area of the capillary membrane, P_c is capillary hydrostatic pressure, P_i is interstitial hydrostatic pressure, s is the reflection coefficient for albumin, π_i is interstitial colloid osmotic pressure, and π_c is capillary colloid osmotic pressure.

The IF volume is determined by the relative rates of capillary filtration and lymphatic drainage. P_c , the most powerful factor promoting fluid filtration, is determined by capillary flow, arterial resistance, venous resistance, and venous pressure.⁶⁵ If capillary filtration increases, the rates of water and sodium filtration usually exceed protein filtration, resulting in preservation of π_c , dilution of π_i , and preservation of the oncotic pressure gradient, the most powerful factor opposing fluid filtration. When coupled with increased lymphatic drainage, preservation of the oncotic pressure gradient limits the accumulation of IF. If P_c increases at a time when lymphatic drainage is maximal, then IF accumulates, forming edema. In chronic edematous states, IF pressure is reduced by enhanced lymphatic drainage through dilated lymphatic vessels.⁶⁶ Increased fluid filtration also dilutes the proteoglycan matrix in the IF, increasing capillary permeability; dehydration of the interstitium reduces vascular permeability.⁶⁵

Clinical Implications of Choices Between Alternative Fluids

If membrane permeability is intact, colloids such as albumin or hydroxyethyl starch preferentially expand PV rather than IF volume. Concentrated colloid-containing solutions (e.g., 25% albumin) may exert sufficient oncotic pressure to translocate substantial volumes of IF into the PV. PV expansion unaccompanied by IF expansion offers apparent advantages: lower fluid requirements, less peripheral and pulmonary edema accumulation, and reduced concern about the cardiopulmonary consequences of later fluid mobilization.

However, exhaustive research has failed to establish the superiority of either colloid-containing or crystalloid-containing fluids (Table 9-15). Systematic reviews of available comparisons of colloid versus crystalloid⁶⁷ and albumin versus crystalloid⁶⁸ suggest increased mortality associated with colloid use. Other reviews suggest that crystalloid may be superior in multiply traumatized patients.^{69,70}

| Solution | Advantages | Disadvantages |
|-------------|--|---|
| Colloid | Smaller infused volume Prolonged increase in plasma volume Greater peripheral edema Less cerebral edema | Greater cost Coagulopathy (dextran > HES) Pulmonary edema (capillary leak states) Decreased GFR Osmotic diuresis (low molecular weight dextran) |
| Crystalloid | Lower cost Greater urinary flow Replaces interstitial fluid | Transient hemodynamic improvement Peripheral edema (protein dilution) Pulmonary edema (protein dilution plus high PAOP) |

HES = hydroxyethyl starch; GFR = glomerular filtration rate;
PAOP = pulmonary arterial occlusion pressure

Table 9-15. ADVANTAGES AND DISADVANTAGES OF COLLOID VS. CRYSTALLOID INTRAVENOUS FLUIDS

Much of the debate has centered on the relative risk of pulmonary edema. Crystalloid infusion can increase P_c and reduce π_c . Colloid can also produce increases, often of greater duration, in P_c . Moreover, in sepsis or the adult respiratory distress syndrome, increased microvascular permeability decreases the gradient between π_c and π_i . If the oncotic pressure gradient is decreased, minimal increases in hydrostatic pressure can produce clinically important pulmonary edema. After experimentally increasing microvascular permeability, Pearl *et al* found no differences between increases in extravascular lung water induced by colloid or crystalloid.⁷¹ In contrast, albumin therapy slowed extrapulmonary edema accumulation in sheep with sepsis produced by cecal ligation and puncture.⁷²

Hypoproteinemia in critically ill patients has been associated with the development of pulmonary edema⁷³ and with increased mortality,⁷⁴ although either crystalloid or colloid administration may precipitate pulmonary edema in patients who have heart failure. In surgical patients at risk for the development of pulmonary edema, pulmonary arterial catheterization may facilitate management. Pulmonary arterial occlusion pressure (PAOP) should be maintained at the lowest level compatible with adequate systemic perfusion. Theoretically, hemodynamic monitoring coupled with volume expansion with colloid (to preserve π_c) should minimize edema formation. However, Virgilio *et al* found no correlation in surgical patients between intrapulmonary shunt fraction (Q_s/Q_t) and the π_c -PAOP gradient.⁷⁵

Although hydroxyethyl starch, the most commonly used synthetic colloid, is less expensive than albumin, large doses produce laboratory evidence of coagulopathy.⁷⁶ Nevertheless, 6.0% hydroxyethyl starch, used in recommended volumes ($10\text{--}15 \text{ ml} \cdot \text{kg}^{-1}$), was not associated with clinically important coagulopathy in patients undergoing abdominal aneurysm repair,⁷⁷ major abdominal surgery,⁷⁸ or cardiac surgery.⁷⁹ Recently, a new hydroxyethyl starch formulation has been introduced that contains a different mix of molecular sizes and is dissolved in a base consisting of a balanced salt solution rather than 0.9% saline. Proposed advantages of the new formulation include less risk of inducing coagulopathy and of hyperchloremic metabolic acidosis.⁸⁰

Implications of Crystalloid and Colloid Infusions on Intracranial Pressure

Because the cerebral capillary membrane, the blood-brain barrier, is highly impermeable to protein, clinicians have assumed that administration of colloid-containing solutions should increase ICP less than crystalloid solutions. In anesthetized rabbits, plasmapheresis to reduce plasma osmolality by $13 \text{ mOsm} \cdot \text{kg}^{-1}$ (baseline value = $295 \text{ mOsm} \cdot \text{kg}^{-1}$) increased cortical water content and ICP; reducing colloid osmotic pressure from 20 to 7 mm Hg produced no significant change in either variable.⁸¹ Of course, because a reduction of $13 \text{ mOsm} \cdot \text{kg}^{-1}$ is equivalent to a reduction in osmotic pressure that is nearly 20-fold greater, the most important message of this report may simply be that much greater changes in osmotic pressure are possible as a consequence of changing serum sodium concentration than as a consequence of changing protein concentration. Similar independence of brain water and ICP from colloid osmotic pressure has been demonstrated with prolonged hypoalbuminemia⁸² and in animals after forebrain ischemia⁸³ and focal cryogenic injury.⁸⁴ In contrast, after fluid percussion brain injury, increasing colloid oncotic pressure with hetastarch reduced brain water in comparison to infusion of 0.9% saline (Fig. 9-7).⁸⁵

Figure 9-7. The percentage of water content (mean \pm SD; wet-dry method) of the percussed (*right*) hemisphere and in the contralateral (*left*) hemisphere in animals that underwent isovolemic exchange with whole blood, hetastarch, normal saline, or half-normal saline. Within each group, the water content of the percussed hemisphere was greater than the water content of the contralateral hemisphere. * $P < 0.05$ versus the corresponding hemisphere in the whole blood and hetastarch groups. (Reproduced with permission from Drummond JC, Patel PM, Cole DJ, Kelly PJ: The effect of the reduction of colloid oncotic pressure, with and without reduction of osmolality, on post-traumatic cerebral edema. *Anesthesiology* 88:993, 1998.)

Hypertonic Fluid Administration

An ideal alternative to conventional crystalloid and colloid fluids would be inexpensive, would produce minimal peripheral or pulmonary edema, would generate sustained hemodynamic effects, and would be effective even if administered in small volumes. Hypertonic, hypernatremic solutions appear to fulfill some of these criteria (Table 9-16).

| Solution | Advantages | Disadvantages |
|---|---|--|
| Hypertonic crystalloid | <ul style="list-style-type: none"> Inexpensive Promotes urinary flow Small initial volume Improved myocardial contractility Arterial dilation Reduces peripheral edema Lower intracranial pressure | <ul style="list-style-type: none"> Hypertonicity Subdural hemorrhage Transient effect |
| Hypertonic crystalloid plus Colloid (in comparison to Hypertonic crystalloid alone) | <ul style="list-style-type: none"> Sustained hemodynamic response Reduced subsequent volume requirements | <ul style="list-style-type: none"> Added expense Coagulopathy (dextran > HES) Oncotic diuresis Impaired crossmatch (dextran) Hypertonicity |

HES = hydroxyethyl starch.

Table 9-16. HYPERTONIC RESUSCITATION FLUIDS: ADVANTAGES AND DISADVANTAGES

Although for more than 75 years investigators have studied the physiologic effects of infusing hypertonic solutions,⁸⁶ the current enthusiasm was stimulated by the work of Velasco *et al*, who successfully used small volumes ($6.0 \text{ ml} \cdot \text{kg}^{-1}$) of 7.5% hypertonic saline (HS) as the sole resuscitative measure in dogs after severe hemorrhage.⁸⁷ The mechanism by which HS solutions improve hemodynamics is through PV expansion.⁸⁸ Experimental evidence *in vivo* suggests that resuscitation with HS/HES (7.2% NaCl + 10% HES) may improve microvascular perfusion by attenuating leukocyte-endothelial interactions.⁸⁹ Although hyperosmotic saline solutions (usually $250\text{--}300 \text{ mEq} \cdot \text{l}^{-1}$ sodium) have been used clinically for many years for burn resuscitation, studies in animals⁹⁰ and humans⁹¹ suggest limited value for that purpose.

Hypertonic solutions exert favorable effects on cerebral hemodynamics, in part because of the reciprocal relationship between plasma osmolality and brain water.⁸¹ ICP increases during resuscitation from hemorrhagic shock with lactated Ringer's solution but remains unchanged if 7.5% saline is infused in a sufficient volume to comparably improve systemic hemodynamics.⁹² In hemorrhaged rats subjected to mechanical brain injury, brain water content is lower in uninjured brain (but similar in injured brain) after resuscitation with a hyperosmotic solution.⁹³ In dogs with intracranial mass lesions, hypertonic solutions may also restore regional cerebral blood flow better than slightly hypotonic solutions.⁹² If fluid resuscitation continues after immediate stabilization, differences between fluids of varying tonicity become negligible.⁹⁴ Moreover, delayed increases in ICP have been reported after hypertonic resuscitation from hypovolemic shock accompanied by an intracranial mass lesion (Fig. 9-8).⁹⁵

Figure 9-8. Response of intracranial pressure after resuscitation from hemorrhage shock with 0.8% saline (SAL), hypertonic 7.2% saline (HS), 20% hydroxyethyl starch (HES), or hypertonic, hyperoncotic hydroxyethyl starch (HS/HES). Intracranial hypertension induced by inflation of a subdural balloon accompanied hemorrhage. BL = baseline; BI = balloon inflation; T0 = initiation of hemorrhage; T30 = end of hemorrhage and initiation of resuscitation; T35 = end of resuscitation; T65, T95, T125, and T155 = 30, 60, 90, and 120 minutes, respectively, after resuscitation. (Reproduced with permission from Prough DS, Whitley JM, Taylor CL *et al*: Rebound intracranial hypertension in dogs after resuscitation with hypertonic solutions from hemorrhagic shock accompanied by an intracranial mass lesion. *J Neurosurg Anesth* 11:102, 1999).

To address concerns about central nervous system dysfunction due to hypertonicity and hypernatremia associated with HS, Wisner and associates demonstrated, using high-energy phosphate nuclear magnetic resonance spectroscopy, a decreased intracellular pH after HS resuscitation compared with lactated Ringer's solution.⁹⁶ However, this decrease was not attributable to anaerobic glycolysis, but to concentration of intracellular hydrogen ions in dehydrated cells.⁹⁶ In humans resuscitated with HS, acute increases in serum sodium to $155\text{--}160 \text{ mEq} \cdot \text{l}^{-1}$ produced no apparent harm.^{97,98} Central pontine myelinolysis, which follows rapid correction of severe, chronic hyponatremia,⁹⁹ has not been observed in clinical trials of hypertonic resuscitation.

Unfortunately, systemic hemodynamic improvement produced by hypertonic resuscitation is short-lived. After initial improvement, both cerebral blood flow and cardiac output rapidly decline after single-dose resuscitation of hypovolemic dogs with either 0.8% or 7.2% saline.⁹² Strategies to prolong the therapeutic effects beyond 30–60 minutes include continued infusion of hypertonic saline, subsequent infusion of blood or conventional fluids, or addition of colloid to hypertonic resuscitation. In hemorrhaged animals, adding 6.0% dextran 70 to 7.5% saline increased the duration of hemodynamic improvement when compared with equal volumes of hypertonic saline, sodium bicarbonate, or sodium chloride/sodium acetate.¹⁰⁰ Vassar *et al* evaluated the effects of 250 ml of 7.5% sodium chloride with and without 6% and 12% dextran 70 for the prehospital resuscitation of hypotensive trauma patients.⁹⁷ Addition of dextran did not improve the blood pressure changes associated with administration of hypertonic saline alone. A small subgroup of patients with Glasgow Coma Scale scores <8 , but without severe anatomic injury seemed to benefit most

from hypertonic resuscitation.⁹⁷ Mattox *et al* reported improved survival in traumatized patients initially resuscitated with 7.5% saline and requiring surgery.⁹⁸

The least encouraging observations regarding hyperosmotic resuscitation involve models of uncontrolled hemorrhage,¹⁰¹ in which restoration of blood pressure increases bleeding and may adversely affect mortality.¹⁰¹ In urban trauma patients, Bickell *et al* have reported that immediate, prehospital resuscitation does not improve mortality in comparison to resuscitation initiated only after arrival at the hospital.¹⁰²

The clinical efficacy of hypertonic resuscitation in comparison to conventional fluids remains unclear because many preclinical studies have compared the effects of single boluses of experimental and control fluids. In contrast, clinical fluid resuscitation continues until no additional fluid is required. An attempt to simulate clinical resuscitation necessitates a choice among a variety of possible goals of resuscitation. Comparison of two or more resuscitation regimens that alter more than one variable may generate misleading conclusions. For example, because hypertonic fluids reduce systemic vascular resistance, systolic ventricular ejection may improve, leading to decreased PAOP; theoretically, therefore, more fluid would be necessary to restore a filling pressure similar to that produced by a colloid solution.

More physiologically sophisticated goals, also based on invasive monitoring, have been proposed. Oxygen delivery ($\dot{D}O_2$), a theoretically attractive end point for resuscitation, combines in a single term cardiac index (CI) and arterial oxygen content (PaO_2) according to the equation:

$$\dot{D}O_2 = CI \times CaO_2 \times 10 \quad (9-12)$$

where the factor 10 corrects $PaCO_2$, usually measured in $ml\ O_2 \cdot dl^{-1}$, to $ml \cdot l^{-1}$. However, because non-blood-containing fluid resuscitation both increases cardiac output and decreases hemoglobin concentration, the application of $\dot{D}O_2$ as a goal poses practical difficulties. Despite the straightforward arithmetic implications of simultaneous increases in cardiac output and decreases in $PaCO_2$, many clinicians attempt to increase cardiac output (whether or not it is directly measured) as a goal during rapid volume expansion.

Will clinicians routinely use hypertonic or combination hypertonic/hyperoncotic fluids for resuscitation in the future? Pending further preclinical work, the theoretical advantages of such fluids appear most attractive in the acute resuscitation of hypovolemic patients who have decreased intracranial compliance.¹⁰³

Fluid Status: Assessment and Monitoring

Assessment of Hypovolemia and Tissue Hypoperfusion

For most surgical patients, conventional clinical assessment of the adequacy of intravascular volume is appropriate. For high-risk patients, goal-directed hemodynamic management may be superior.

Conventional Clinical Assessment. Clinical quantification of blood volume and ECV begins with recognition of deficit-generating settings, such as bowel obstruction, preoperative bowel preparation, chronic diuretic use, sepsis, burns, and trauma. Physical signs that suggest hypovolemia include oliguria, supine hypotension, and a positive tilt test. Oliguria implies hypovolemia, although hypovolemic patients may be nonoliguric and normovolemic patients may be oliguric because of renal failure or stress-induced endocrine responses.¹⁰⁴ Supine hypotension implies a blood volume deficit exceeding 30%, although arterial blood pressure within the normal range could represent relative hypotension in an elderly or chronically hypertensive patient.

In the *tilt test*, a positive response is defined as an increase in heart rate by ≥ 20 beats $\cdot\ min^{-1}$ and a decrease in systolic blood pressure by ≥ 20 mm Hg when the subject assumes the upright position. However, young, healthy subjects can withstand acute loss of 20% of blood volume while exhibiting only postural tachycardia and variable postural hypotension. In contrast, orthostasis may occur in 20% to 30% of elderly patients despite normal blood volume.¹⁰⁵ In volunteers, withdrawal of 500 ml of blood¹⁰⁶ was associated with a greater increase in heart rate on standing than before blood withdrawal but no significant difference in the response of blood pressure or cardiac index. Orthostatic changes in filling pressure, assessed before and after fluid infusion, may represent a more sensitive test of the adequacy of circulating blood volume.¹⁰⁷

Laboratory evidence that suggests hypovolemia or ECV depletion includes azotemia, low urinary sodium, metabolic alkalosis, and metabolic acidosis. Hematocrit is virtually unchanged by acute hemorrhage until fluids are administered or until fluid shifts from the interstitial to the intravascular space. BUN, normally 8–20 $mg \cdot dl^{-1}$, is increased by hypovolemia, high protein intake, gastrointestinal bleeding, or accelerated catabolism and decreased by severe hepatic dysfunction. Serum creatinine (SCr), a product of muscle catabolism, may be misleadingly low in elderly adults, females, and debilitated or malnourished patients. In contrast, in muscular or acutely catabolic patients, SCr may exceed the normal range (0.5–1.5 $mg \cdot dl^{-1}$) because of more rapid muscle breakdown. A ratio of BUN:SCr exceeding the normal range (10–20) suggests dehydration. In prerenal oliguria, enhanced sodium reabsorption should reduce urinary $[Na^+]$ to ≤ 20 mEq $\cdot\ l^{-1}$ and enhanced water reabsorption should increase urinary concentration (*i.e.*, urinary osmolality >400 ; urine/plasma creatinine ratio $>40:1$). However, the sensitivity and specificity of measurements of urinary variables may be misleading. Although hypovolemia does not generate metabolic alkalosis, ECV depletion is a potent stimulus for the maintenance of metabolic alkalosis. Severe hypovolemia may result in systemic hypoperfusion and lactic acidosis.

Intraoperative Clinical Assessment. Visual estimation, the simplest technique for quantifying intraoperative blood loss, assesses the amount of blood absorbed by gauze squares and laparotomy pads and adds an estimate of blood accumulation on the floor and surgical drapes and in suction containers. Both surgeons and anesthesia providers tend to underestimate losses.

Assessment of the adequacy of intraoperative fluid resuscitation integrates multiple clinical variables, including heart rate, blood pressure, urinary output, arterial oxygenation, and pH. Tachycardia is an insensitive, nonspecific indicator of hypovolemia. In patients receiving potent inhalational agents, maintenance of a satisfactory blood pressure implies adequate intravascular volume. Preservation of blood pressure, accompanied by a CVP of 6–12 mm Hg, more strongly suggests adequate replacement. During profound hypovolemia, indirect measurements of blood pressure may significantly underestimate true blood pressure. In patients undergoing extensive procedures, direct arterial pressure measurements are more accurate than indirect techniques and provide convenient access for obtaining arterial blood samples. An additional advantage of direct arterial pressure monitoring may be recognition of increased systolic blood pressure variation accompanying positive pressure ventilation in the presence of hypovolemia.^{108,109,110 and 111}

Urinary output usually declines precipitously during moderate to severe hypovolemia. Therefore, in the absence of glycosuria or diuretic administration, a urinary output of 0.5–1.0 $ml \cdot kg^{-1} \cdot hr^{-1}$ during anesthesia suggests adequate renal perfusion. Arterial pH may decrease only when tissue hypoperfusion becomes severe. Cardiac output can be normal despite severely reduced regional blood flow. Mixed venous hemoglobin desaturation, a specific indicator of poor systemic perfusion, reflects average perfusion in multiple organs and cannot supplant regional monitors such as urinary output.

Oxygen Delivery as a Goal of Management. No intraoperative monitor is sufficiently sensitive or specific to detect hypoperfusion in all patients. Moreover, acute renal failure, hepatic failure, and sepsis may result from unrecognized, subclinical tissue hypoperfusion. In high-risk surgical patients, average cardiac output and $\dot{D}O_2$ are greater in those who survive than in those who succumb.^{112,113} One key variable that has been associated with survival is a $\dot{D}O_2 \geq 600$ $ml\ O_2 \cdot m^{-2} \cdot min^{-1}$ (equivalent to a CI of 3.0 $l \cdot m^{-2} \cdot min^{-1}$, a hemoglobin concentration of 14 $g \cdot dl^{-1}$, and 98% oxyhemoglobin saturation). Boyd *et al* randomized 107 patients to conventional treatment or fluid plus dopexamine to maintain oxygen delivery ≥ 600 $ml\ O_2 \cdot m^{-2} \cdot min^{-1}$ and demonstrated a decrease in mortality and in the number of complications in the patients managed at the higher level of oxygen delivery.¹¹⁴ Based on these results, the authors calculated that the cost of obtaining a survivor was 31% lower in the protocol group.¹¹⁵ Wilson *et al* randomized 138 patients undergoing major elective surgery into three groups.¹¹⁶ One group received routine perioperative care; one received fluid and dopexamine preoperatively, intraoperatively, and postoperatively to maintain oxygen delivery ≥ 600 $ml\ O_2 \cdot m^{-2} \cdot min^{-1}$; and the third received fluid plus epinephrine preoperatively, intraoperatively, and postoperatively to achieve the same end points. In the two groups in which oxygen delivery was supported, only 3 of 92 died, compared to 8 of 46 control patients. However, the complication rate was significantly lower in the dopexamine group than in the epinephrine group. In contrast, Hayes *et al*, who randomized 109 patients to conventional treatment, or oxygen delivery ≥ 600 $ml\ O_2 \cdot m^{-2} \cdot min^{-1}$, using a combination of volume and dobutamine, demonstrated an increase in mortality in the treatment group maintained at the higher levels. They speculated that aggressive elevations in $\dot{D}O_2$ actually may have been harmful.¹¹⁷ At present, available data are consistent with two inferences. First, there is no apparent benefit for patients other than surgical patients.¹¹⁸ Second, outcome may be strongly influenced by the choice of inotropic agents. One possibility is that dopexamine is associated with fewer complications because it better preserves splanchnic perfusion and is associated with reduced secretion of vasoactive hormones during major abdominal surgery.¹¹⁹

ELECTROLYTES

Sodium

Physiologic Role

Increases or decreases in total body sodium, the principal extracellular cation and solute, tend to increase or decrease ECV and PV. Disorders of sodium concentration—hyponatremia and hypernatremia—usually result from relative excesses or deficits, respectively, of water. Sodium also is essential for generation of action potentials in neurologic and cardiac tissue.

Regulation of the quantity and concentration of sodium is accomplished primarily by the endocrine and renal systems (Table 9-17). *Total body sodium* is controlled by secretion of aldosterone and ANP. *Sodium concentration* is primarily regulated by ADH, which is secreted in response to increased osmolality or decreased blood pressure. ADH stimulates renal reabsorption of water, diluting plasma $[Na^+]$; inadequate ADH secretion results in renal free water excretion, which, in the absence of adequate water intake, results in hypernatremia.

| Electrolyte | Regulated by |
|-------------|---|
| Sodium | Aldosterone ANP $[Na^+]$ altered by ADH |
| Potassium | Aldosterone Epinephrine Insulin Intrinsic renal mechanisms |
| Calcium | PTH Vitamin D |
| Phosphorus | Primarily renal mechanisms Minor: PTH |
| Magnesium | Primarily renal mechanisms Minor: PTH, vitamin D |

ANP = atrial natriuretic peptide; $[Na^+]$ = sodium concentration;
ADH = antidiuretic hormone; PTH = parathyroid hormone.

Table 9-17. REGULATION OF ELECTROLYTES

Hyponatremia

Hyponatremia ($[Na^+] < 130 \text{ mEq} \cdot \text{l}^{-1}$) indicates that body fluids are diluted by an excess of water relative to total solute. The majority of hyponatremic, hospitalized patients have normal or increased quantities of total body sodium. Usually, hyponatremia results from impaired urinary diluting capacity although the causes of the impairment are diverse.

Hyponatremia is the most common electrolyte disturbance in hospitalized patients.¹²⁰ The most common clinical circumstances associated with hyponatremia are the postoperative state (30% of patients), followed by acute intracranial disease (17%), malignant disease (17%), medications (9%), and pneumonia (5%).¹²⁰ Although hyponatremia is associated with a 7- to 60-fold increase in mortality,^{120,121} it is unclear whether the increased mortality is a direct effect of hyponatremia or whether hyponatremia simply serves as a secondary marker of severe systemic disease.⁴¹

The signs and symptoms of hyponatremia depend on both the rate and severity of the decrease in plasma $[Na^+]$. Symptoms that can accompany severe hyponatremia ($[Na^+] < 120 \text{ mEq} \cdot \text{l}^{-1}$) include loss of appetite, nausea, vomiting, cramps, weakness, altered level of consciousness, coma, and seizures.

Acute central nervous system (CNS) manifestations relate to brain overhydration. Because the blood–brain barrier is poorly permeable to sodium but freely permeable to water, a decrease in plasma $[Na^+]$ promptly increases both extracellular and intracellular brain water. Compensatory responses to cerebral edema include bulk movement of interstitial fluid into the cerebrospinal fluid and loss of intracellular solutes,¹²² including potassium and organic osmolytes (previously termed “idiogenic osmoles”) such as taurine, phosphocreatine, myoinositol, glutamine, and glutamate.¹²³ Because the brain rapidly compensates for changes in osmolality, the symptoms are considerably more severe in acute than in chronic hyponatremia. The symptoms of chronic hyponatremia probably relate to depletion of brain electrolytes. Once brain volume has compensated for hyponatremia, rapid correction may lead to abrupt brain dehydration.

Hyponatremia is classified as true hyponatremia or pseudohyponatremia. Pseudohyponatremia was diagnosed in severely hyperproteinemic or hyperlipidemic patients when flame photometry, now an archaic technique, was used to measure plasma $[Na^+]$. Because hyperproteinemia or hyperlipidemia displaced water from plasma, plasma $[Na^+]$ measurements were artifactually depressed. The current analytic method, direct potentiometry, directly measures $[Na^+]$ ⁴¹ and is uninfluenced by nonaqueous components.

True hyponatremia may be associated with normal, high, or low serum osmolality. In turn, hyponatremia with hypo-osmolality is associated with a high, low, or normal total body sodium and PV. Hyponatremia ($[Na^+] < 135 \text{ mEq} \cdot \text{l}^{-1}$) with a normal or high serum osmolality results from the presence of a nonsodium solute, such as glucose or mannitol, which does not diffuse freely across cell membranes (Fig. 9-9). The resulting osmotic gradient results in dilutional hyponatremia. For instance, plasma $[Na^+]$ decreases approximately $1.6 \text{ mEq} \cdot \text{l}^{-1}$ for each $100 \text{ mg} \cdot \text{dl}^{-1}$ rise in glucose concentration.¹²⁴ In anesthesia practice, a common cause of hyponatremia associated with a normal osmolality is the absorption of large volumes of sodium-free irrigating solutions (containing mannitol, glycerine, or sorbitol as the solute) during transurethral resection of the prostate.¹²⁵ These solutes cause a dilutional hyponatremia that is responsible for the clinical features of the *TURP syndrome*.^{126,127} (see Chapter 36). Neurologic symptoms are minimal if mannitol is employed because the agent does not cross the blood–brain barrier and is excreted with water in the urine. In contrast, as glycine or sorbitol is metabolized, hyposmolality will gradually develop and cerebral edema may appear as a late complication.¹²⁵ A discrepancy exceeding $10 \text{ mOsm} \cdot \text{kg}^{-1}$ between measured and calculated osmolality suggests either factitious hyponatremia or the presence of a nonsodium solute.

Figure 9-9. Algorithm by which hyponatremia can be evaluated.

True hyponatremia with a normal or elevated serum osmolality may occur in renal insufficiency. BUN, included in the calculation of total osmolality, distributes throughout both ECV and ICV. Calculation of *effective* osmolality ($2[Na^+] + \text{glucose}/18$) demonstrates true hypotonicity.

Hyponatremia with hyposmolality (Fig. 9-9) is evaluated by assessing BUN, SCr, total body sodium content, urinary osmolality, and urinary $[Na^+]$. Hyponatremia with increased total body sodium is characteristic of edematous states—congestive heart failure, cirrhosis, nephrosis, and renal failure. Aquaporin 2, the vasopressin-regulated water channel, is upregulated in experimental congestive heart failure¹²⁸ and cirrhosis¹²⁹ and decreased by chronic vasopressin stimulation.¹³⁰ In patients with renal insufficiency, reduced urinary diluting capacity can lead to hyponatremia if excess free water is given.

The underlying mechanism of hypovolemic hyponatremia is ongoing oral or intravenous intake of hypotonic fluid during secretion of ADH in response to volume contraction.¹³¹ Angiotensin II also decreases free water generation.⁴¹ Thiazide diuretics, unlike loop diuretics, promote hypovolemic hyponatremia by interfering with urinary dilution in the distal tubule.¹³¹ Hypovolemic hyponatremia associated with a urinary $[Na^+] > 20 \text{ mmol} \cdot l^{-1}$ suggests mineralocorticoid deficiency, especially if serum $[K^+]$, BUN, and SCr are increased.¹³¹

The cerebral salt-wasting syndrome is an often severe, symptomatic salt-losing diathesis that appears to be mediated by brain natriuretic peptide¹³² and is independent of the syndrome of inappropriate antidiuretic hormone (SIADH); patients at risk include those with cerebral lesions due to trauma, subarachnoid hemorrhage, tumors, and infection.^{133,134,135} and ¹³⁶

Euvolemic hyponatremia is most commonly associated with nonosmotic vasopressin secretion, such as glucocorticoid deficiency, hypothyroidism, thiazide-induced hyponatremia, SIADH, and the reset osmostat syndrome.⁴¹ Total body sodium and ECV are relatively normal and edema is rarely evident. SIADH may be idiopathic but also is associated with diseases of the central nervous system and with pulmonary disease (Table 9-18). Euvolemic hyponatremia is usually associated with exogenous ADH administration, pharmacologic potentiation of ADH action, drugs that mimic the action of ADH in the renal tubules or excessive ectopic ADH secretion. Tissues from some small-cell lung cancers, duodenal cancers, and pancreatic cancers increase ADH production in response to osmotic stimulation.¹³⁷

| Neoplasms | Pulmonary diseases |
|---------------------------------|-------------------------------|
| Bronchogenic carcinoma | Tuberculosis |
| Pancreatic carcinoma | Pneumonia |
| Carcinoma of the duodenum | Brucellosis |
| Prostate carcinoma | Aspergillosis |
| Thyroidoma | Cystic fibrosis |
| Lymphoma | Positive pressure ventilation |
| Mesothelioma | Medications |
| Central nervous system diseases | Opiates |
| Head trauma | Chlorpropamide |
| Subdural hematoma | Carbamazepine |
| Subarachnoid hemorrhage | Phenothiazines |
| Cerebrovascular accident | Tricyclic antidepressants |

Table 9-18. CAUSES OF THE SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE (SIADH)

The occasional postoperative occurrence of hyponatremia, mental status changes, and seizures has been attributed conventionally to intravenous administration of hypotonic fluids and inappropriate secretion of ADH. However, ADH is only one of many factors, including drugs, intravenous fluid administration, and renal function, that influence perioperative water balance.¹³⁸ At least 4.0% of postoperative patients develop plasma $[Na^+] < 130 \text{ mEq} \cdot l^{-1}$.¹³⁹ Although neurologic manifestations usually do not accompany postoperative hyponatremia, signs of hypervolemia are occasionally present.¹³⁹ Smaller patients change plasma $[Na^+]$ more in response to similar volumes of hypotonic fluids. In an editorial accompanying a report¹⁴⁰ of apparent postoperative SIADH in a 30-kg, 10-year-old-girl, Arieff¹⁴¹ suggested that children receive no sodium-free water perioperatively. Women may be particularly vulnerable because estrogens stimulate and androgens suppress ADH release.^{142,143} In extreme cases, administration of hypotonic fluids to young, healthy, female surgical patients has resulted in severe neurologic symptoms and death secondary to transtentorial herniation.¹⁴⁴ However, in experimental animals, hyponatremia produced greater brain swelling in males than females.¹⁴⁵

Postoperative hyponatremia can develop, even with infusion of isotonic fluids, if ADH is persistently increased.¹⁴⁶ Steele *et al*¹⁴⁶ studied 22 women (mean age 42 years) undergoing uncomplicated gynecologic surgery. Twenty-four hours after surgery, mean plasma $[Na^+]$ had decreased from $140 \pm 1 \text{ mEq} \cdot l^{-1}$ to $136 \pm 0.5 \text{ mEq} \cdot l^{-1}$.¹⁴⁶ Although the patients retained sodium perioperatively, they retained proportionately more water (an average of 1.1 l of electrolyte-free water). In a subsequent letter to the editor, Ayus and Arieff¹⁴⁷ stated that of 158 patients studied because of perioperative hyponatremic encephalopathy, none had received isotonic saline; the authors advised against routine perioperative use of hypotonic fluids. Careful postoperative attention to fluid and electrolyte balance may minimize the occurrence of symptomatic hyponatremia.

If both $[Na^+]$ and measured osmolality are below the normal range, hyponatremia is further evaluated by first assessing volume status using physical findings and laboratory data. In hypovolemic patients or edematous patients, the ratio of BUN to SCr should be $>20:1$. Urinary $[Na^+]$ is generally $<15 \text{ mEq} \cdot l^{-1}$ in edematous states and volume depletion and $>20 \text{ mEq} \cdot l^{-1}$ in hyponatremia secondary to renal salt wasting or renal failure with water retention.

The criteria for the diagnosis of SIADH include hypotonic hyponatremia, urinary osmolality $>100\text{--}150 \text{ mmol} \cdot \text{kg}^{-1}$, absence of extracellular volume depletion, normal thyroid and adrenal function, and normal cardiac, hepatic, and renal function.⁴¹ Urinary $[Na^+]$ should be $>30 \text{ mEq} \cdot l^{-1}$ unless fluids have been restricted. Arieff¹⁴¹ has argued that the diagnosis of SIADH may be inaccurately applied to postoperative patients because they are frequently functionally hypovolemic. Therefore, ADH secretion, by definition, would be “appropriate.”

Treatment of hyponatremia associated with a normal or high serum osmolality requires reduction of the elevated concentrations of the responsible solute. Uremic patients are treated by free-water restriction or dialysis. Treatment of edematous (hypervolemic) patients necessitates restriction of both sodium and water (Fig. 9-10). Therapy is directed toward improving cardiac output and renal perfusion and using diuretics to inhibit sodium reabsorption. In hypovolemic, hyponatremic patients, blood volume must be restored, usually by infusion of 0.9% saline, and excessive sodium losses must be curtailed. Correction of hypovolemia usually results in removal of the stimulus for ADH release, accompanied by a rapid water diuresis.

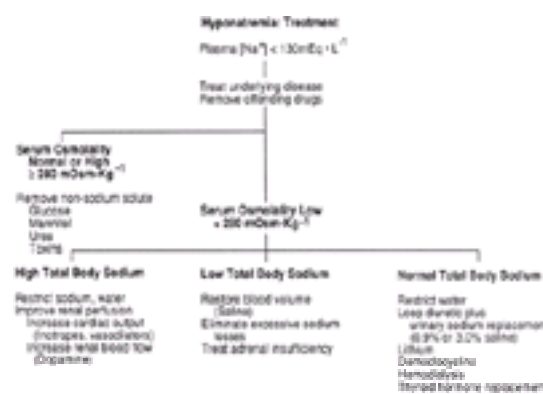

Figure 9-10. Hyponatremia is treated according to the etiology of the disturbance, the level of serum osmolality, and a clinical estimation of total body sodium.

The cornerstone of SIADH management is free-water restriction and elimination of precipitating causes. Water restriction, sufficient to decrease TBW by 0.5–1.0 l per day, decreases ECV even if excessive ADH secretion continues. The resultant reduction in GFR enhances proximal tubular reabsorption of salt and water, thereby decreasing free-water generation, and stimulates aldosterone secretion. As long as free-water losses (*i.e.*, renal, skin, gastrointestinal) exceed free-water intake, serum $[Na^+]$ will increase. During treatment of hyponatremia, increases in plasma $[Na^+]$ are determined not only by the composition of the infused fluid, but also, to a major degree, by the rate of renal free-water excretion.¹⁴⁸ Free-water excretion can be increased by administering furosemide.

To calculate the net water loss necessary to increase $[Na^+]$ in hyponatremia, use the following equation:

$$\text{Current } [Na^+] \times \text{current TBW} = \text{desired } [Na^+] \times \text{desired TBW}$$

where TBW is total body water, usually approximately $0.6 \times$ total body weight (kg).¹³¹

Neurologic symptoms or profound hyponatremia ($[\text{Na}^+] < 115\text{--}120 \text{ mEq} \cdot \text{l}^{-1}$) requires more aggressive therapy. Hypertonic (3%) saline is most clearly indicated in patients who have seizures or patients who acutely develop symptoms of water intoxication secondary to intravenous fluid administration. In such cases, 3% saline may be administered at a rate of $1\text{--}2 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$ to increase plasma $[\text{Na}^+]$ by $1\text{--}2 \text{ mEq} \cdot \text{l}^{-1} \cdot \text{hr}^{-1}$; however, this treatment should not continue for more than a few hours. Treatment of 25 hyponatremic children in this fashion promptly terminated seizures and resulted in no delayed neurologic sequelae.¹⁴⁹ Three percent saline may only transiently increase plasma $[\text{Na}^+]$ because ECV expansion results in increased urinary sodium excretion. Even 29.2% sodium chloride has been used safely in a dose of 50 ml in acute symptomatic hyponatremia.¹⁵⁰ Intravenous furosemide, combined with quantitative replacement of urinary sodium losses with 0.9% or 3.0% saline, can rapidly increase plasma $[\text{Na}^+]$, in part by increasing free-water clearance.

The rate of treatment of hyponatremia continues to generate controversy, extending from “too fast, too soon” to “too slow, too late.” Although delayed correction may result in neurologic injury, inappropriately rapid correction may result in abrupt brain dehydration (Fig. 9-11) or permanent neurologic sequelae (*i.e.*, central pontine myelinolysis or the osmotic demyelination syndrome),^{99,151,152} cerebral hemorrhage, or congestive heart failure. The symptoms of the osmotic demyelination syndrome vary from mild (transient behavioral disturbances or seizures) to severe (including pseudobulbar palsy and quadriparesis).^{122,152} Within 3 to 4 weeks of the clinical onset of the syndrome, areas of demyelination are apparent on magnetic resonance imaging.¹⁵³

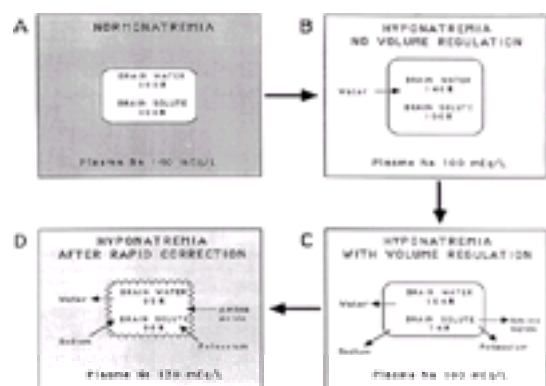

Figure 9-11. Brain water and solute concentrations in hyponatremia. If normal plasma sodium (Na) (A) suddenly decreased, the increase in brain water theoretically would be proportional to the decrease in plasma Na (B). However, because of adaptive loss of cerebral intracellular solute, cerebral edema is minimized in chronic hyponatremia (C). Once adaptation has occurred, a rapid return of plasma Na concentration toward a normal level results in brain dehydration (D). (Reprinted with permission from Sterns RH: Vignettes in clinical pathophysiology. Neurological deterioration following treatment for hyponatremia. *Am J Kidney Dis* 13:434, 1989.)

The principal determinants of neurologic injury appear to be the magnitude and chronicity of hyponatremia and the rate of correction. The osmotic demyelination syndrome is more likely when hyponatremia has persisted >48 hours.¹⁵⁴ Experimental demyelinating lesions are not observed if the rate of correction is $<2.5 \text{ mEq} \cdot \text{l}^{-1} \cdot \text{hr}^{-1}$ or if the magnitude of correction is limited to $<25 \text{ mEq}$ in 24 hours.¹⁵⁵ Most patients in whom the osmotic demyelination syndrome is fatal have undergone correction of plasma $[\text{Na}^+]$ of more than $20 \text{ mEq} \cdot \text{l}^{-1} \cdot \text{day}^{-1}$.¹⁵² Other risk factors for the development of this lesion include alcoholism, poor nutritional status, liver disease, burns, and hypokalemia.¹⁵⁶

The clinician faces formidable difficulties in predicting the rate at which plasma $[\text{Na}^+]$ will increase. During treatment of hyponatremia, increases in plasma $[\text{Na}^+]$ are determined not only by the composition of the infused fluid, but also, to a major degree, by the rate of renal free water excretion.¹⁴⁸ The expected change in plasma $[\text{Na}^+]$ resulting from 1 liter of selected infusate can be estimated using the following equation¹⁵⁷:

$$\Delta[\text{Na}^+]_s = \frac{[\text{Na}^+]_{\text{inf}} - [\text{Na}^+]_s}{\text{TBW} + 1} \quad (9-14)$$

where $\Delta[\text{Na}^+]_s$ is the change in the patient's serum sodium, $[\text{Na}^+]_{\text{inf}}$ is the sodium concentration of the infusate, $[\text{Na}^+]_s$ is the patient's serum sodium concentration, TBW is the patient's estimated total body water in liters, and 1 is a factor added to take into account the volume of infusate.

Treatment should be interrupted or slowed when symptoms improve. Frequent determinations of $[\text{Na}^+]$ are important to prevent correction at a rate of $>10 \text{ mEq} \cdot \text{l}^{-1}$ over 24 hours.¹⁵⁴ Initially, plasma $[\text{Na}^+]$ may be increased by $1\text{--}2 \text{ mEq} \cdot \text{l}^{-1} \cdot \text{hr}^{-1}$; however, plasma $[\text{Na}^+]$ should not be increased more than $10 \text{ mEq} \cdot \text{l}^{-1}$ in 24 hours or $25 \text{ mEq} \cdot \text{l}^{-1}$ in 48 hours.^{120,158,159,160,161} and ¹⁶² Another proposed sequence for treating symptomatic hyponatremia is to increase $[\text{Na}^+]$ promptly by about 10 mmol , then to proceed more slowly. The rationale is that cerebral water is increased by approximately 10% in chronic hyponatremia.¹³¹ Hypertatremia should be avoided. Once the plasma $[\text{Na}^+]$ exceeds $120\text{--}125 \text{ mEq} \cdot \text{l}^{-1}$, water restriction alone is usually sufficient to normalize $[\text{Na}^+]$. As acute hyponatremia is corrected, CNS signs and symptoms usually improve within 24 hours, although 96 hours may be necessary for maximal recovery.

Because lithium, the first drug used to antagonize ADH, is neurotoxic and has unpredictable effects, demeclocycline is now the drug of choice for patients who require long-term pharmacologic therapy.¹³¹ Up to 50% of patients receiving lithium develop nephrogenic diabetes insipidus (NDI), probably because Aquaporin 2 is downregulated.¹⁶³ Although better tolerated than lithium, demeclocycline may induce nephrotoxicity, a particular concern in patients with hepatic dysfunction. Hemodialysis is occasionally necessary in severely hyponatremic patients who cannot be adequately managed with drugs or hypertonic saline. Once hyponatremia has improved, careful fluid restriction is necessary to avoid recurrence of hyponatremia. In the future, vasopressin receptor antagonists may be used to treat hyponatremia.¹⁶⁴

Hypertatremia

Hypertatremia ($[\text{Na}^+] > 150 \text{ mEq} \cdot \text{l}^{-1}$) indicates an absolute or relative water deficit. Normally, minimal increases in tonicity or sodium stimulate thirst and ADH secretion. Severe, persistent hypertatremia occurs only in patients who cannot respond to thirst by voluntary ingestion of fluid—obtunded patients, anesthetized patients, and infants.

Hypertatremia produces neurologic symptoms (including stupor, coma, and seizures), hypovolemia, renal insufficiency (occasionally progressing to renal failure), and decreased urinary concentrating ability.^{165,166} Because hypertatremia frequently results from diabetes insipidus (DI) or osmotically induced losses of sodium and water, many patients are hypovolemic or bear the stigmata of renal disease. Postoperative neurosurgical patients who have undergone pituitary surgery are at particular risk of developing transient or prolonged DI.¹⁶⁷ Polyuria may be present for only a few days within the first week after surgery, may be permanent, or may demonstrate a triphasic sequence: early DI, return of urinary concentrating ability, then recurrent DI.

The clinical consequences of hypertatremia are most serious at the extremes of age and when hypertatremia develops abruptly. Geriatric patients are at increased risk of hypertatremia because of decreased renal concentrating ability and thirst, although the responsiveness of osmoreceptors to hypertatremia is maintained during normal aging.^{168,169} Brain shrinkage may damage delicate cerebral vessels, leading to subdural hematoma, subcortical parenchymal hemorrhage, subarachnoid hemorrhage, and venous thrombosis. Polyuria may cause bladder distention, hydronephrosis, and permanent renal damage. At the cellular level, restoration of cell volume occurs remarkably quickly after tonicity is altered (Fig. 9-12).¹⁷⁰ Although the mortality of hypertatremia is 40–55%, it is unclear whether hypertatremia is the cause or a marker of severe associated disease.⁴¹

Figure 9-12. Activation of mechanisms regulating cell volume in response to acute osmotic stress. Regulatory volume decrease and regulatory volume increase refer to compensatory losses and gains of solutes. Although the course of these regulatory volume decreases and increases varies with the type of cell and experimental conditions, typically the responses occur over a period of minutes. Returning volume-regulated cells to normotonic conditions causes shrinkage or swelling. (Reprinted with permission from McManus ML, Churchwill KB, Strange K: Regulation of cell volume in health and disease. *N Engl J Med* 333:1260, 1995.)

Surprisingly, if plasma $[Na^+]$ is initially normal, moderate acute increases do not appear to precipitate central pontine myelinolysis. However, larger accidental increases in plasma $[Na^+]$ have produced severe consequences in children. In a 12-year-old diabetic child who accidentally received 500 ml of 5.0% saline during treatment for diabetic ketoacidosis (DKA), plasma $[Na^+]$ acutely increased to $172 \text{ mEq} \cdot \text{l}^{-1}$; subsequent cranial computed tomography showed many subcortical hemorrhages, and the child suffered brain death.¹⁷¹ In experimental animals, acute hypernatremia (acute increase from 146 to $170 \text{ mEq} \cdot \text{l}^{-1}$) caused neuronal damage at 24 hours, suggestive of early central pontine myelinolysis.¹⁷²

By definition, hypernatremia indicates an absolute or relative water deficit and is always associated with hypertonicity. Hypernatremia can be generated by hypotonic fluid loss, as in burns, GI losses, diuretic therapy, osmotic diuresis, renal disease, mineralocorticoid excess or deficiency, and iatrogenic causes; or it can be generated by isolated water loss, as in DI (Fig. 9-13). The acquired form of NDI is more common and usually less severe than the congenital form. As chronic renal failure advances, most patients have defective concentrating ability, resulting in resistance to ADH associated with hypotonic urine.¹⁷³

Figure 9-13. Severe hypernatremia is evaluated by first assessing extracellular volume (ECV) to separate patients into hypovolemic, euvolemic, and hypervolemic groups. Next, potential etiologic factors are diagnostically assessed. $[Na^+]$, serum sodium concentration; U_{Na} , urinary sodium concentration; U_{Osm} , urinary osmolality.

Isolated sodium gain is uncommon but occurs in patients who receive large quantities of sodium, such as treatment of metabolic acidosis with 8.4% sodium bicarbonate, in which $[Na^+]$ is approximately $1000 \text{ mEq} \cdot \text{l}^{-1}$, or perioperative or prehospital treatment with hypertonic saline resuscitation solutions. Because hypovolemia accompanies most pathologic water loss, signs of hypoperfusion also may be present. In many patients, before the development of hypernatremia, an increased volume of hypotonic urine suggests an abnormality in water balance.¹⁷⁴

The TBW deficit can be estimated from the plasma $[Na^+]$ using the equation:

$$\text{TBW deficit} = 0.6 \times \text{body weight (kg)} \times \left(\frac{[Na^+] - 140}{140} \right) \quad (9-15)$$

where 140 is the middle of the normal range for $[Na^+]$.

Hypernatremic patients can be separated into three groups, based on clinical assessment of ECV (see Fig. 9-13). The plasma $[Na^+]$ does not reflect total body sodium, which must be estimated based on signs of the adequacy of ECV. In polyuric, hypernatremic patients, the next differential diagnostic decision is between solute diuresis and DI. Measurement of urinary sodium and osmolality can help to differentiate the various causes. A urinary osmolality of $<150 \text{ mOsm} \cdot \text{kg}^{-1}$ in the setting of hypertonicity and polyuria is diagnostic of DI.

Treatment of hypernatremia produced by water loss consists of repletion of water as well of associated deficits in total body sodium and other electrolytes (Table 9-19). Common errors in treating hypernatremia include excessively rapid correction as well as failing to appreciate the magnitude of the water deficit and failing to account for ongoing maintenance requirements and continued fluid losses in planning therapy.

| Restrict sodium, water intake |
| Thiazide diuretics |

Table 9-19. HYPERNATREMIA: ACUTE TREATMENT

Hypernatremia must be corrected slowly because of the risk of neurologic sequelae such as seizures or cerebral edema (Fig. 9-14).¹⁷⁵ At the cellular level, restoration of cell volume occurs remarkably quickly after tonicity is altered; as a consequence, acute treatment of hypertonicity may result in overshooting the original, normotonic cell volume.^{170,176,177} The water deficit should be replaced over 24–48 hours, and the plasma $[Na^+]$ should not be reduced by more than $1\text{--}2 \text{ mEq} \cdot \text{l}^{-1} \cdot \text{hr}^{-1}$. Reversible underlying causes should be treated. Hypovolemia should be corrected promptly with 0.9% saline. Although the $[Na^+]$ of 0.9% saline is $154 \text{ mEq} \cdot \text{l}^{-1}$, the solution is effective in treating the volume deficit and will reduce $[Na^+]$ if it is $>154 \text{ mEq} \cdot \text{l}^{-1}$. Once hypovolemia is corrected, water can be replaced orally or with intravenous hypotonic fluids, depending on the ability of the patient to tolerate oral hydration. In the occasional sodium-overloaded patient, sodium excretion can be accelerated

using loop diuretics or dialysis.

Figure 9-14. (A) The concentration of sodium is reflected in the intensity of the stippling: the upper figure, representing extracellular volume (smaller circle) and intracellular volume (larger circle), is more heavily stippled; that is, serum sodium is higher. (B) In response to an acute increase in serum sodium resulting from water loss, both intracellular and extracellular volume substantially decrease. The brain (schematically illustrated) shrinks in proportion to the reduction in intracellular volume in other tissues. (C) However, owing to the production of idiogenic osmoles, the brain rapidly restores its intracellular volume, despite the persistent reduction in intracellular volume in other tissues and in extracellular volume. (D) With excessively rapid correction of hypernatremia (the reduction in serum sodium is reflected in the decrease in the intensity of stippling), the brain expands to greater than its original size. The resulting increase in cerebral edema and intracranial pressure can cause severe neurologic damage. (Modified with permission from Feig PU: Hyponatremia and hypertonic syndromes. *Med Clin North Am* 65:271, 1981.)

The management of hypernatremia secondary to DI varies according to whether the etiology is central or nephrogenic (see [Table 9-19](#)). The two most suitable agents for correcting central DI (an ADH deficiency syndrome) are desmopressin (DDAVP) and aqueous vasopressin. DDAVP, given subcutaneously in a dose of 1–4 μg or intranasally in a dose of 5–20 μg every 12 to 24 hours, is effective in the vast majority of patients. DDAVP lacks the vasoconstrictor effects of vasopressin and is less likely to produce abdominal cramping.^{178,179,180 and 181} Incomplete ADH deficits (partial DI) often are effectively managed with pharmacologic agents that stimulate ADH release or enhance the renal response to ADH. Chlorpropamide, which potentiates the renal effects of vasopressin, and carbamazepine, which enhances vasopressin secretion, have been used to treat partial central DI, but are associated with clinically important side effects. In NDI, urinary water losses can be decreased by using salt and water restriction or thiazide diuretics to induce extracellular volume contraction, thereby enhancing fluid reabsorption in the proximal tubules. If less filtrate passes through into the collecting ducts, less water will be excreted.

Potassium

Physiologic Role

The intracellular potassium concentration ($[\text{K}^+]$) is normally $150 \text{ mEq} \cdot \text{l}^{-1}$ while the extracellular concentration is only $3.5\text{--}5.0 \text{ mEq} \cdot \text{l}^{-1}$. Serum $[\text{K}^+]$ is about $0.5 \text{ mEq} \cdot \text{l}^{-1}$ higher than plasma $[\text{K}^+]$ owing to cell lysis during clotting. Total body potassium in a 70-kg adult is approximately 4256 mEq, of which 4200 mEq is intracellular; of the 56 mEq in the ECV, only 12 mEq is located in the PV. Potassium plays an important role in cell membrane physiology, especially in maintaining resting membrane potentials and in generating action potentials in the central nervous system and heart.

Potassium is actively transported into cells by a Na/K ATPase pump, which maintains an intracellular potassium concentration $[\text{K}^+]$ that is at least 30-fold greater than extracellular $[\text{K}^+]$. The ratio of intracellular to extracellular potassium contributes to the resting potential difference across cell membranes and therefore to the integrity of cardiac and neuromuscular transmission. The primary mechanism that maintains potassium inside cells is the negative voltage created by the transport of three sodium ions out of the cell for every two potassium ions transported in ([Fig. 9-15](#)).¹⁸² Both insulin and catecholamines promote sodium entry and potassium exit.^{183,184} In contrast, a adrenergic agonists impair cellular potassium uptake.¹⁸⁵ Metabolic acidosis tends to shift potassium out of cells, while metabolic alkalosis favors movement into cells.

Figure 9-15. Hormones shifting potassium into cells. Major hormones involved are: (A) insulin and (B) β_2 -adrenergic agents. (Reproduced with permission from Halperin ML, Kamel KS: Potassium. *Lancet* 352:135, 1998.)

The usual potassium intake is between 50 and $150 \text{ mEq} \cdot \text{day}^{-1}$. Most is excreted in the urine, with some fecal elimination. Freely filtered at the glomerulus, 85–90% of potassium is reabsorbed in the proximal convoluted tubule and loop of Henle. The remaining 10–15% reaches the distal convoluted tubule, which is the major site at which potassium excretion is regulated. Excretion of potassium ions is a function of open potassium channels and the electrical driving force in the cortical collecting duct.¹⁸² As sodium reabsorption increases, the electrical driving force opposing reabsorption of potassium is increased. Aldosterone increases sodium reabsorption through promoting a more open configuration of the epithelial sodium channel¹⁸⁶; potassium-sparing diuretics (amiloride and triamterene) and trimethoprim block the epithelial sodium channel, thereby increasing potassium reabsorption.¹⁸⁷

Assuming a plasma $[\text{K}^+]$ of $4.0 \text{ mEq} \cdot \text{l}^{-1}$ and a normal GFR of $180 \text{ l} \cdot \text{day}^{-1}$, 720 mEq of potassium is filtered daily. Most is reabsorbed; usually, only the amount ingested is lost. As long as GFR is $>8 \text{ ml} \cdot \text{min}^{-1}$, dietary potassium intake, unless greater than normal, can be excreted. Four factors that favor K^+ excretion are alkalemia, increased aldosterone activity, increased delivery of Na^+ to the distal tubule and collecting duct, and increased urinary flow to these segments. Potassium secretion into the distal convoluted tubules and cortical collecting ducts is increased by aldosterone, hyperkalemia, high urinary flow rates, and the presence in luminal fluid of nonreabsorbable anions such as carbenicillin, phosphates, and sulfates.^{188,189} Additional potassium is reabsorbed from the medullary collecting ducts as part of a recycling loop.¹⁹⁰ Within the distal nephron, a magnesium-dependent Na/K ATPase enzyme plays a critical role in potassium reabsorption.¹⁹¹ Magnesium depletion impairs the activity of the enzyme, leading to renal potassium wasting. The two most important regulators of potassium secretion are the plasma $[\text{K}^+]$ and aldosterone, although there is some evidence to suggest the involvement of an enteric reflex mediated by a potassium-rich meal and of the central nervous system.¹⁹²

Hypokalemia

Uncommon among healthy persons, hypokalemia ($[\text{K}^+] < 3.0 \text{ mEq} \cdot \text{l}^{-1}$) is a frequent complication of treatment with diuretic drugs and occasionally complicates other diseases and treatment regimens ([Table 9-20](#)).¹⁸⁵ Hypokalemia ($[\text{K}^+] < 3.0 \text{ mEq} \cdot \text{l}^{-1}$) causes muscle weakness and, when severe, may even cause paralysis. With chronic potassium loss, the ratio of intracellular to extracellular $[\text{K}^+]$ remains relatively stable; in contrast, acute redistribution of potassium from the extracellular to the intracellular space substantially changes resting membrane potentials.

| Drugs | Bicarbonaturia |
|-------------------------------------|--|
| Diuretics | Distal renal tubular acidosis |
| Thiazide diuretics | Treatment of proximal renal tubular acidosis |
| Loop diuretics | Correction phase of metabolic alkalosis |
| Osmotic diuretics | |
| Antibiotics | Magnesium deficiency |
| Penicillin and penicillin analogues | Other less common causes |
| Amphotericin B | Cisplatin |
| Aminoglycosides | Carbonic anhydrase inhibitors |
| Hormones | Leukemia |
| Aldosterone | Diuretic phase of acute tubular necrosis |
| Glucocorticoid-excess states | Intrinsic renal transport defects |
| | Bartter's syndrome |
| | Gitelman's syndrome |

Table 9-20. CAUSES OF RENAL POTASSIUM LOSS

Cardiac rhythm disturbances are among the most dangerous complications of potassium deficiency. Acute hypokalemia causes hyperpolarization of the cardiac cell and may lead to ventricular escape activity, re-entrant phenomena, ectopic tachycardias, and delayed conduction. Surprisingly, a prospective clinical study demonstrated that preoperative chronic hypokalemia apparently does not increase the incidence of intraoperative dysrhythmias.¹⁹³ In patients taking digoxin, hypokalemia increases toxicity by increasing myocardial digoxin binding and pharmacologic effectiveness. Hypokalemia contributes to systemic hypertension, especially when combined with a high-sodium diet.¹⁹⁴ In diabetic patients, hypokalemia impairs insulin secretion and end-organ sensitivity to insulin, thereby worsening hyperglycemia.¹⁹⁵

Potassium depletion also induces defects in renal concentrating ability, resulting in polyuria and a reduction in GFR.¹⁹⁶ Potassium replacement improves GFR, although the concentrating deficit may not improve for several months after treatment. If hypokalemia is sufficiently prolonged, chronic renal interstitial damage may occur.

The plasma $[K^+]$ poorly reflects total body potassium; hypokalemia may occur with normal, low, or high total body potassium stores. As a general rule, a chronic decrement of $1.0 \text{ mEq} \cdot \text{l}^{-1}$ in the plasma $[K^+]$ corresponds to a total body deficit of approximately 200–300 mEq. In uncomplicated hypokalemia, the potassium deficit exceeds 300 mEq if plasma $[K^+]$ is $<3.0 \text{ mEq} \cdot \text{l}^{-1}$ and 700 mEq if plasma $[K^+]$ is $<2.0 \text{ mEq} \cdot \text{l}^{-1}$.

Hypokalemia may result from acute redistribution of potassium from the extracellular to intracellular space, in which case total body potassium will be normal, or from chronic depletion of total body potassium. Redistribution of potassium into cells occurs when the activity of the Na/K ATPase pump is acutely increased by extracellular hyperkalemia or increased intracellular concentrations of sodium, as well as by insulin, carbohydrate loading (which stimulates release of endogenous insulin), β_2 agonists, and aldosterone. Both metabolic and respiratory alkaloses lead to decreases in plasma $[K^+]$.¹⁹⁷

Causes of chronic hypokalemia include those etiologies associated with renal potassium conservation (extrarenal potassium losses; low urinary $[K^+]$) and those with renal potassium wasting (Fig. 9-16).¹⁸² A low urinary $[K^+]$ suggests inadequate dietary intake or extrarenal depletion (in the absence of recent diuretic use). Diuretic-induced urinary potassium losses are frequently associated with hypokalemia, secondary to increased aldosterone secretion, alkalemia, and increased renal tubular flow. Aldosterone does not cause renal potassium wasting unless sodium ions are present; that is, aldosterone primarily controls sodium reabsorption, not potassium excretion. Renal tubular damage due to nephrotoxins such as aminoglycosides or amphotericin B may also cause renal potassium wasting.

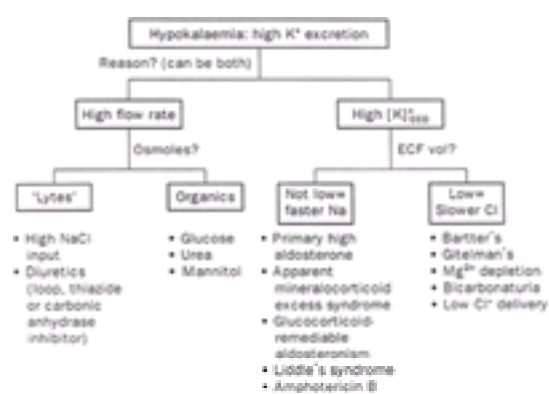

Figure 9-16. Approach to the patient with hypokalemia. Causes for excessive excretion of potassium ($>15 \text{ mmol} \cdot \text{day}^{-1}$) despite hypokalemia are too high a flow rate in the cortical collecting duct [(CCD), left limb] and/or too high a concentration of potassium $[K^+]$ in the lumen of the CCD (right limb). Both flow rate and CCD $[K^+]$ should be evaluated. Final considerations are shown by bullet symbols. A relatively slower Cl^- reabsorption in CCD is suggested by high plasma renin activity and NaCl wasting despite low extracellular fluid volume; the converse applies for relatively faster Na^+ reabsorption. (Reproduced with permission from Halperin ML, Kamel KS: Potassium. *Lancet* 352:135, 1998.)

Initial evaluation of hypokalemia includes a medical history (e.g. diarrhea, vomiting, diuretic or laxative use), physical examination (e.g., hypertension, cushingoid features, edema), measurement of serum electrolytes (e.g., magnesium), arterial pH assessment, and evaluation of the ECG. Measurement of 24-hour urinary excretion of sodium and potassium may distinguish extrarenal from renal causes. Magnesium deficiency, associated with aminoglycoside and cisplatin therapy, can generate hypokalemia that is resistant to replacement therapy. A stress response and release of catecholamines causes the majority of trauma patients to develop hypokalemia that returns to normal within 24 hours without specific therapy.¹⁸⁵ Plasma renin and aldosterone levels may be helpful in the differential diagnosis. Characteristic electrocardiographic changes associated with hypokalemia include flat or inverted T waves, prominent U waves, and ST segment depression.

The treatment of hypokalemia consists of potassium repletion, correction of alkalemia, and removal of offending drugs (Table 9-21). Hypokalemia secondary only to acute redistribution may not require treatment. The need for potassium replacement therapy in mild to moderate hypokalemia ($3\text{--}3.5 \text{ mEq} \cdot \text{l}^{-1}$) without clear symptoms has been questioned.¹⁹⁸ If total body potassium is decreased, oral potassium supplementation is preferable to intravenous replacement. Potassium is usually replaced as the chloride salt because coexisting chloride deficiency may limit the ability of the kidney to conserve potassium.

| Correct Precipitating Factors |
|---|
| Increased pH |
| Decreased $[Mg^{2+}]$ |
| Drugs |
| Mild Hypokalemia ($[K^+] > 2.0 \text{ mEq} \cdot \text{l}^{-1}$) |
| Intravenous KCl infusion $\leq 10 \text{ mEq} \cdot \text{hr}^{-1}$ |
| Severe Hypokalemia ($[K^+] \leq 2.0 \text{ mEq} \cdot \text{l}^{-1}$; paralysis or ECG changes) |
| Intravenous KCl infusion $\leq 40 \text{ mEq} \cdot \text{hr}^{-1}$ |
| Continuous ECG monitoring |
| If life-threatening, 5–6 mEq bolus |

Table 9-21. HYPOKALEMIA: TREATMENT

Potassium repletion must be performed cautiously (usually at a rate of $\leq 10\text{--}20 \text{ mEq} \cdot \text{hr}^{-1}$) since the absolute deficit is unpredictable. The plasma $[K^+]$ and the ECG

must be monitored during rapid repletion ($10\text{--}20\text{ mEq} \cdot \text{hr}^{-1}$) to avoid hyperkalemic complications.^{185,199} The plasma $[\text{K}^+]$ and ECG should be monitored to detect inadvertent hyperkalemia. Particular care should be taken in patients who have concurrent acidemia, type IV renal tubular acidosis, diabetes mellitus, or in those patients receiving nonsteroidal anti-inflammatory agents, ACE inhibitors, or beta blockers, all of which delay movement of extracellular potassium into cells.

However, in patients with life-threatening dysrhythmias secondary to hyperkalemia, serum $[\text{K}^+]$ must be rapidly increased. Assuming that PV in a 70-kg adult is 3.0 l, administration of $6.0\text{ mEq} \cdot \text{l}^{-1}$ of potassium in 1.0 min will increase serum $[\text{K}^+]$ by no more than $2.0\text{ mEq} \cdot \text{l}^{-1}$ because redistribution into interstitial fluid will decrease the quantity remaining in.¹⁸²

Hypokalemia associated with hyperaldosteronemia (e.g. primary aldosteronism, Cushing's syndrome) usually responds favorably to reduced sodium intake and increased potassium intake. Hypomagnesemia, if present, aggravates the effects of hypokalemia, impairs potassium conservation, and should be treated. Potassium supplements or potassium-sparing diuretics should be given cautiously to patients who have diabetes mellitus or renal insufficiency, both of which limit compensation for acute hyperkalemia. In patients who are both acidemic and hypokalemic, such as those who have diabetic ketoacidosis, potassium administration should precede correction of acidosis to avoid a precipitous decrease in plasma $[\text{K}^+]$ as pH increases.

In patients with normal serum potassium accompanied by symptoms of potassium depletion (e.g. muscle fatigue), history of potassium loss or insufficient intake, or in patients in whom potassium depletion may be of special threat (e.g. patients on diuretics, digitalis, or b_2 agonists), muscle biopsy with measurement of muscle potassium concentration may be a useful procedure to detect and quantify potassium depletion. Quantification of muscle potassium concentration is a useful tool for monitoring therapy.²⁰⁰

Hyperkalemia

The most lethal manifestations of hyperkalemia ($[\text{K}^+] > 5.0\text{ mEq} \cdot \text{l}^{-1}$) involve the cardiac conducting system and include dysrhythmias, conduction abnormalities, and cardiac arrest. In anesthesia practice, the classic example of hyperkalemic cardiac toxicity is associated with the administration of succinylcholine to paraplegic, quadriplegic,²⁰¹ or severely burned^{202,203} patients. If plasma $[\text{K}^+]$ is $<6.0\text{ mEq} \cdot \text{l}^{-1}$, cardiac effects are negligible. As the concentration increases further, the electrocardiogram shows tall, peaked T waves, especially in the precordial leads. With further increases, the PR interval becomes prolonged, followed by a decrease in the amplitude of the P wave. Finally, the QRS complex widens into a pattern resembling a sine wave, as a prelude to cardiac standstill (Fig. 9-17).²⁰⁴ Hyperkalemic cardiotoxicity is enhanced by hyponatremia, hypocalcemia, or acidosis. Because progression to fatal cardiotoxicity is unpredictable and often swift, the presence of hyperkalemic ECG changes mandates immediate therapy. The life-threatening cardiac effects usually require more urgent treatment than do other manifestations of hyperkalemia. However, ascending muscle weakness appears when plasma $[\text{K}^+]$ approaches $7.0\text{ mEq} \cdot \text{l}^{-1}$, and may progress to flaccid paralysis, inability to phonate, and respiratory arrest.

Figure 9-17. Electrocardiographic changes due to hyperkalemia occurring in a 42-year-old woman undergoing placement of an arteriovenous fistula for permanent hemodialysis access to treat end-stage renal disease. During dissection of the brachial artery under local anesthesia, her cardiac rhythm converted from normal sinus rhythm to complete heart block with ventricular escape (approximately 25 beats per minute) (A). Two ampules of calcium gluconate (9.2 mEq) were administered intravenously. An electrocardiogram revealed sinus tachycardia with profound prolongation of the QRS interval (left-bundle-branch morphology), first-degree atrioventricular block, and “peaked” T waves (B). The serum potassium concentration was $8.6\text{ mmol} \cdot \text{l}^{-1}$. After reduction of the serum potassium concentration, the electrocardiogram showed sinus rhythm with normalization of the PR and QRS intervals. Anteroseptal ST wave and T wave changes were noted on subsequent electrocardiograms (C). A cardiac exercise imaging study did not show ischemia. (Reprinted with permission from Kuvin JT: Electrocardiographic changes of hyperkalemia. *N Engl J Med* 338:662, 1998.)

Hyperkalemia may occur with normal, high, or low total body potassium stores. A deficiency of aldosterone, a major regulator of potassium excretion, leads to hyperkalemia in adrenal insufficiency and hyporeninemic hypoaldosteronism, a state associated with diabetes mellitus, renal insufficiency, and advanced age. Because the kidneys excrete potassium, severe renal insufficiency commonly causes hyperkalemia. Patients with chronic renal insufficiency can maintain normal plasma $[\text{K}^+]$ despite markedly decreased GFR because urinary potassium excretion depends on tubular secretion rather than glomerular filtration if GFR exceeds $8\text{ ml} \cdot \text{min}^{-1}$.

Drugs are now the most common cause of hyperkalemia.²⁰⁵ Drugs that may limit potassium excretion include nonsteroidal anti-inflammatory drugs, ACE inhibitors, cyclosporin, and potassium-sparing diuretics such as triamterene. Drug effects most commonly occur in patients with other factors that predispose to hyperkalemia, such as diabetes mellitus, renal insufficiency, advanced age, or hyporeninemic hypoaldosteronism. ACE inhibitors are particularly likely to produce hyperkalemia in patients who have renal insufficiency²⁰⁶ or severe congestive heart failure.²⁰⁷

In patients who have normal total body potassium, hyperkalemia may accompany a sudden shift of potassium from the ICV to the ECV because of acidemia, increased catabolism, or rhabdomyolysis. Metabolic acidosis and respiratory acidosis tend to cause an increase in plasma $[\text{K}^+]$. However, organic acidoses (i.e. lactic acidosis, ketoacidosis) have little effect on $[\text{K}^+]$, whereas mineral acids cause significant cellular shifts. In response to increased hydrogen ion activity because of addition of acids, potassium will increase if the anion remains in the extracellular volume.¹⁸² Neither lactate nor ketoacids remain in the extracellular fluid. Therefore, hyperkalemia in these circumstances reflects tissue injury or lack of insulin.¹⁸²

Pseudohyperkalemia, which occurs when potassium is released from cells in blood collection tubes, can be diagnosed by comparing serum and plasma $[\text{K}^+]$ levels from the same blood sample. Hyperkalemia usually accompanies malignant hyperthermia.

The most important aspects of diagnosis are a medical history, emphasizing recent drug therapy, and assessment of renal function. The ECG may provide the first suggestion of hyperkalemia in some patients. Despite the familiar effects of hyperkalemia on cardiac conduction and rhythm, the ECG is an insensitive and nonspecific method of detecting hyperkalemia.²⁰⁸ If hyponatremia is also present, adrenal function should be evaluated.

The treatment of hyperkalemia is aimed at eliminating the cause, reversing membrane hyperexcitability, and removing potassium from the body (Fig. 9-18).¹⁸² Emergent management of hyperkalemia is listed in detail in Table 9-22. Mineralocorticoid deficiency can be treated with 9- α -fludrocortisone ($0.025\text{--}0.10\text{ mg} \cdot \text{day}^{-1}$). Hyperkalemia secondary to digitalis intoxication may be resistant to therapy because attempts to shift potassium from the ECV to the ICV are often ineffective. In this situation, use of digoxin-specific antibodies has been successful.

Figure 9-18. Treatment of patient with hyperkalemia. If an emergency is present (usually cardiac), intravenous Ca^{2+} must be given. This treatment should act promptly. Efforts are also taken to shift potassium into cells with insulin with or without NaHCO_3 . Longer term strategies are to limit intake of potassium, prevent its absorption in the gastrointestinal tract, and promote its excretion; the latter includes measuring urine $[\text{K}^+]$ and flow rate to decide leverage for therapy. (Reproduced with permission from Halperin ML, Kamel KS: Potassium. Lancet 352:135, 1998.)

Reverse membrane effects
 Calcium (10 ml of 10% calcium chloride IV over 10 min)
 Transfer extracellular $[\text{K}^+]$ into cells
 Glucose and insulin (D10W + 5–10 U regular insulin per 25–50 g glucose)
 Sodium bicarbonate (50 to 100 mEq over 5–10 min)
 β_2 agonists
 Remove potassium from body
 Diuretics, proximal or loop
 Potassium-exchange resins (sodium polystyrene sulfonate)
 Hemodialysis
 Monitor ECG and serum $[\text{K}^+]$ level

* Potassium concentration $[\text{K}^+] > 7.0 \text{ mEq} \cdot \text{l}^{-1}$ or electrocardiographic (ECG) changes.

Table 9-22. SEVERE HYPERKALEMIA:* TREATMENT

Membrane hyperexcitability can be antagonized by translocating potassium from the ECV to the ICF, removing excess potassium, or (transiently) by infusing calcium chloride to depress the membrane threshold potential. Pending definitive treatment, rapid infusion of calcium chloride (1 g of CaCl_2 over 3 minutes, or two to three ampules of 10% calcium gluconate over 5 minutes) may stabilize cardiac rhythm (see Fig. 9-17). Calcium should be given cautiously if digitalis intoxication is likely. Acute alkalinization using sodium bicarbonate (50–100 mEq over 5–10 minutes in a 70-kg adult) transiently promotes movement of potassium from the ECV to the ICF. Bicarbonate can be administered even if pH exceeds 7.40; however, it should not be administered to patients with congestive cardiac failure or hypernatremia. Insulin, in a dose-dependent fashion, causes cellular uptake of potassium by increasing the activity of the Na/K ATPase pump. Insulin increases cellular uptake of potassium best when high insulin levels are achieved by intravenous injection of 5–10 U of regular insulin,²⁰⁹ accompanied by 50 ml of 50% glucose. β_2 -Adrenergic drugs also increase potassium uptake by skeletal muscle and reduce plasma $[\text{K}^+]$,²¹⁰ an action that may explain hypokalemia with severe, acute illness. β_2 agonists have been used to treat hyperkalemia.²¹¹ Salbutamol, a selective β_2 agonist, decreases serum potassium acutely when given by inhalation or intravenously. In 15 pediatric patients with baseline serum $[\text{K}^+]$ of $6.6 \text{ mEq} \cdot \text{l}^{-1}$, a single infusion of salbutamol ($5 \mu\text{g} \cdot \text{kg}^{-1}$ over 15 min) reduced serum $[\text{K}^+]$ to $5.7 \text{ mEq} \cdot \text{l}^{-1}$ after 30 minutes and $4.9 \text{ mEq} \cdot \text{l}^{-1}$ after 120 minutes.²¹² In using β_2 -adrenergic agents to reduce serum $[\text{K}^+]$, the potential for generating cardiac dysrhythmias should be recognized.^{213,214}

Potassium may be removed from the body by the renal or gastrointestinal routes. Furosemide promotes kaliuresis in a dose-dependent fashion. Sodium polystyrene sulfonate resin (Kayexalate), which exchanges sodium for potassium, can be given orally (30 g) or as a retention enema (50 g in 200 ml of 20% sorbitol). However, sodium overload and hypervolemia are potential risks. Rarely, when temporizing measures are insufficient, emergency hemodialysis may remove $25\text{--}50 \text{ mEq} \cdot \text{hr}^{-1}$. Peritoneal dialysis is less efficient. Mineralocorticoid deficiency can be treated with 9- α -fludrocortisone. Hyperkalemia secondary to digitalis intoxication may be resistant to therapy because attempts to shift potassium intracellularly are often ineffective. In this situation, administration of a digoxin-specific antibody may be lifesaving.

Calcium

Physiologic Role

Calcium is a divalent cation found primarily in the extracellular fluid. The free calcium concentration $[\text{Ca}^{2+}]$ in ECV is approximately 1 mM, whereas the free $[\text{Ca}^{2+}]$ in the ICF approximates 100 nM, a gradient of 10,000 to 1. Circulating calcium consists of a protein-bound fraction (40%), a chelated fraction (10%), and an ionized fraction (50%), which is the physiologically active and homeostatically regulated component.²¹⁵ Acute acidemia decreases protein-bound calcium (*i.e.*, increases ionized calcium) whereas acute alkalemia increases protein-bound calcium. Because mathematical formulae that “correct” total calcium measurements for albumin concentration are inaccurate in critically ill patients,²¹⁶ ionized calcium should be directly measured.

In general, all movement that occurs in mammalian systems requires calcium. Essential for normal excitation–contraction coupling, calcium is also necessary for proper function of muscle tissue, ciliary movement, mitosis, neurotransmitter release, enzyme secretion, and hormonal secretion. Cyclic AMP (cAMP) and phosphoinositides, which are major second messengers regulating cellular metabolism, function primarily through the regulation of calcium movement. Activation of numerous intracellular enzyme systems requires calcium. Important both for generation of the cardiac pacemaker activity and for generation of the cardiac action potential, calcium is the primary ion responsible for the plateau phase of the action potential. Calcium also plays vital functions in membrane and bone structure.

Serum $[\text{Ca}^{2+}]$ is regulated by multiple factors (Fig. 9-19),²¹⁷ including a calcium receptor^{218,219} and ²²⁰ and several hormones, the most important of which are parathyroid hormone (PTH) and calcitriol.²²¹ PTH and vitamin D (see Table 9-17), both of which mobilize calcium from bone, increase renal tubular reabsorption of calcium, and enhance intestinal absorption of calcium. Metabolites of vitamin D exert a major role in long-term control of circulating calcium. Vitamin D, after ingestion or manufacture of vitamin D in the skin under the stimulus of ultraviolet light, is 25-hydroxylated to calcidiol in the liver and then is 1-hydroxylated to calcitriol in the kidney. Calcitriol, the active metabolite, stimulates osseous calcium release, renal calcium reabsorption, and enteric calcium absorption. PTH and vitamin D can maintain a normal circulating $[\text{Ca}^{2+}]$, even in the absence of dietary calcium intake, by mobilizing calcium from bone.

Figure 9-19. Schematic representation of the regulatory system maintaining (Ca^{2+}) homeostasis. The solid arrows and lines delineate effects of parathyroid hormone and $1,25(\text{OH})_2\text{D}_3$ on their target tissues; dashed arrows and lines show examples of how extracellular Ca^{2+} or phosphate ions act directly on tissues

regulating mineral ion metabolism. Ca = calcium; PO₄ = phosphate; ECF = extracellular fluid; PTH = parathyroid hormone; 1,25(OH)₂D₃ = 1,25-dihydroxyvitamin D; 25(OH)D = 25-hydroxyvitamin D; minus signs indicate inhibitory actions and plus signs indicate stimulatory effects. (Reproduced with permission from Brown EM, Pollak M, Hebert SC: The extracellular calcium-sensing receptor: Its role in health and disease. *Annu Rev Med* 49:15, 1998.)

Hypocalcemia

The hallmark of hypocalcemia is increased neuronal membrane irritability and tetany (Table 9-23). Early symptoms include sensations of numbness and tingling involving fingers, toes, and the circumoral region. In frank tetany, tonic contraction of respiratory muscles may lead to laryngospasm, bronchospasm, or respiratory arrest. Smooth muscle spasm can result in abdominal cramping and urinary frequency. Mental status alterations include irritability, depression, psychosis, and dementia. Hypocalcemia may impair cardiovascular function and has been associated with heart failure, hypotension, dysrhythmias, insensitivity to digitalis, and impaired b-adrenergic action.

| Cardiovascular | Respiratory |
|-------------------------|-----------------|
| Dysrhythmias | Apnea |
| Digitalis insensitivity | Laryngeal spasm |
| ECG changes | Bronchospasm |
| Heart failure | Psychiatric |
| Hypotension | Anxiety |
| Neuromuscular | Dementia |
| Tetany | Depression |
| Muscle spasm | Psychosis |
| Papilledema | |
| Seizures | |
| Weakness | |
| Fatigue | |

ECG = electrocardiographic.

Table 9-23. HYPOCALCEMIA: CLINICAL MANIFESTATIONS

Reduced *total* serum calcium occurs in as many as 80% of critically ill and postsurgical patients.²¹⁵ However, *ionized* hypocalcemia develops in fewer patients, including 15–20% of critically ill patients, 20% of patients after cardiopulmonary bypass, and 30–40% after multiple trauma. In these situations, ionized hypocalcemia is clinically mild ($[Ca^{2+}] > 0.8$ mM).

Initial diagnostic evaluation should concentrate on history and physical examination, laboratory evaluation of renal function, and measurement of serum phosphate concentration. Latent hypocalcemia can be diagnosed by tapping on the facial nerve to elicit Chvostek's sign or by inflating a sphygmomanometer to 20 mm Hg above systolic pressure, which produces radial and ulnar nerve ischemia, causing carpal spasm known as Trousseau's sign.²²²

The differential diagnosis of hypocalcemia can be approached by addressing four issues: age of the patient, serum phosphate concentration, general clinical status, and duration of hypocalcemia.²²³ High phosphate concentrations suggest renal failure²²⁴ or hypoparathyroidism. In renal insufficiency, reduced phosphorus excretion results in hyperphosphatemia, which downregulates the 1 α -hydroxylase responsible for the renal conversion of calcidiol to calcitriol. This, in combination with decreased production of calcitriol secondary to reduced renal mass, causes reduced intestinal absorption of calcium and hypocalcemia.²²¹ Low or normal phosphate concentrations imply vitamin D or magnesium deficiency. An otherwise healthy patient with chronic hypocalcemia probably is hypoparathyroid. Chronically ill adults with hypocalcemia often have disorders such as malabsorption, osteomalacia, or osteoblastic metastases.

Hypocalcemia (ionized $[Ca^{2+}] < 4.0$ mg · dl⁻¹ or < 1 mM) occurs as a result of failure of PTH or calcitriol action or because of calcium chelation or precipitation, not because of calcium deficiency alone. PTH deficiency can result from surgical damage to or removal of the parathyroid glands and from suppression of the parathyroid glands by severe hypo- or hypermagnesemia. Burns, sepsis, and pancreatitis may suppress parathyroid function and interfere with vitamin D action. Vitamin D deficiency may result from lack of dietary vitamin D or vitamin D malabsorption in patients who lack sunlight exposure. Hyperphosphatemia-induced hypocalcemia may occur as a consequence of overzealous phosphate therapy, from cell lysis secondary to chemotherapy, or as a result of cellular destruction from rhabdomyolysis. Precipitation of CaHPO₄ complexes occurs with hyperphosphatemia. However, ionized $[Ca^{2+}]$ only decreases approximately 0.019 mM for each 1.0 mM increase in phosphate concentration.²²⁵ In massive transfusion, citrate may produce hypocalcemia by chelating calcium; however, decreases are usually transient and produce no cardiovascular effects. A healthy, normothermic adult who has intact hepatic and renal function can metabolize the citrate present in 20 units of blood per hour without becoming hypocalcemic.²²⁶ However, when citrate clearance is decreased (e.g., by hepatic or renal disease or hypothermia) and when blood transfusion rates are rapid (e.g., > 0.5 – 2 ml · kg⁻¹ · min⁻¹), hypocalcemia and cardiovascular compromise (usually manifested as hypotension without obvious hypovolemia) may occur. Alkalemia resulting from hyperventilation or sodium bicarbonate injection can acutely decrease $[Ca^{2+}]$.

The definitive treatment of hypocalcemia necessitates identification and treatment of the underlying cause (Table 9-24). Symptomatic hypocalcemia usually occurs when serum ionized $[Ca^{2+}]$ is < 0.7 mM. The clinician should determine whether mild ionized hypocalcemia requires therapy, particularly in ischemic and septic states in which experimental evidence suggests that calcium may increase cellular damage.

|--|
| Administer calcium |
| IV: 10 ml 10% calcium gluconate* over 10 min, followed by elemental calcium 0.3–2.0 mg · kg ⁻¹ · hr ⁻¹ |
| Oral: 500–1000 mg elemental calcium q 6 hours |
| Administer vitamin D |
| Ergocalciferol, 1200 μ g/day ($T_{1/2}$ = 30 days) |
| Dihydroxycholecalciferol, 200–400 μ g/day ($T_{1/2}$ = 7 days) |
| 1,25-dihydroxycholecalciferol, 0.25–1.0 μ g/day ($T_{1/2}$ = 1 day) |
| Monitor electrocardiogram |

* Calcium gluconate contains 93 mg elemental calcium per 10-ml vial; $T_{1/2}$ = half-life.

Table 9-24. HYPOCALCEMIA: ACUTE TREATMENT

Unnecessary offending drugs should be discontinued. Hypocalcemia resulting from hypomagnesemia or hyperphosphatemia is treated by repletion of magnesium or removal of phosphate. Treatment of a patient who has tetany and hyperphosphatemia requires coordination of therapy to avoid the consequences of metastatic soft tissue calcification.²²⁷ Potassium and other electrolytes should be measured and abnormalities should be corrected. Hyperkalemia and hypomagnesemia potentiate hypocalcemia-induced cardiac and neuromuscular irritability. In contrast, hypokalemia protects against hypocalcemic tetany; therefore, correction of hypokalemia without correction of hypocalcemia may provoke tetany.

Mild, ionized hypocalcemia should not be overtreated. For instance, in most patients after cardiac surgery, administration of calcium only increases mean arterial blood pressure (MAP)²²⁸ and actually attenuates the b-adrenergic effects of epinephrine.²²⁸ In normocalcemic dogs, calcium chloride primarily acts as a peripheral vasoconstrictor, with transient reduction of myocardial contractility; in hypocalcemic dogs, calcium infusion significantly improves contractile performance and MAP (Table 9-25).²²⁹ Therefore, calcium infusions should be of limited value during cardiac surgery unless there is demonstrable evidence of hypocalcemia.²²⁹ Calcium salts appear to confer no benefit to patients already receiving inotropic or vasoactive agents.

| | Normocalcemic | | Hypercalcemic | |
|-----------------------------|---------------|--------------|---------------|--------------|
| | Baseline | 1 min | Baseline | 1 min |
| Ca ²⁺ (mmol/l) | 1.24 ± 0.04 | 1.27 ± 0.04* | 1.24 ± 0.03 | 1.25 ± 0.03* |
| Ca ²⁺ (mg/dl) | 4.96 ± 0.16 | 5.08 ± 0.16* | 4.96 ± 0.12 | 5.03 ± 0.12* |
| HR (beats/min) | 151 ± 8 | 160 ± 9 | 154 ± 6 | 160 ± 7* |
| MAP (mm Hg) | 9 ± 1 | 9 ± 1 | 7 ± 1 | 8 ± 2 |
| MAP (mm Hg) | 120 ± 4 | 127 ± 4* | 117 ± 4 | 121 ± 4* |
| SVR (dyne/cm ²) | 269 ± 48 | 430 ± 54* | 447 ± 50 | 347 ± 49 |
| CO (l/min) | 2.7 ± 0.4 | 2.7 ± 0.4 | 3.4 ± 0.2 | 3.1 ± 0.3 |

Values are mean ± sem (n = 6). Ca²⁺, slope of the left ventricular end-systolic pressure-volume relationship; CO, stroke-volume/heart rate; HR, heart rate; MAP, pulmonary arterial occlusion pressure; MAP, mean arterial pressure; SVR, systemic vascular resistance; CO, cardiac output. *P < 0.05 vs. baseline; †P < 0.05 vs. CO.

Table 9-25. SERUM IONIZED [Ca²⁺] CONCENTRATION AND HEMODYNAMIC VARIABLES ONE MIN AFTER CALCIUM ADMINISTRATION (5 MG/KG INTRAVENOUS BOLUS) IN NORMOCALCEMIC AND HYPOCALCEMIC (PRODUCED BY CPD ADMINISTRATION) DOGS

The cornerstone of therapy for confirmed, symptomatic, ionized hypocalcemia ([Ca²⁺] <0.7 mM) is calcium administration. In patients who have severe hypocalcemia or hypocalcemic symptoms, calcium should be administered intravenously. In emergency situations, in an average-sized adult, the “rule of 10s” advises infusion of 10 ml of 10% calcium gluconate (93 mg elemental calcium) over 10 minutes, followed by a continuous infusion of elemental calcium, 0.3–2 mg · kg⁻¹ · hr⁻¹ (i.e., 3–16 ml · hr⁻¹ of 10% calcium gluconate for a 70-kg adult). Calcium salts should be diluted in 50–100 ml D5W (to limit venous irritation and thrombosis), should not be mixed with bicarbonate (to prevent precipitation), and must be given cautiously to digitalized patients because calcium increases the toxicity of digoxin. Continuous ECG monitoring during initial therapy will detect cardiotoxicity (e.g., heart block, ventricular fibrillation). During calcium replacement, the clinician should monitor serum calcium, magnesium, phosphate, potassium, and creatinine. Once the ionized [Ca²⁺] is stable in the range of 4–5 mg · dl⁻¹ (1.0–1.25 mM), oral calcium supplements can substitute for parenteral therapy. Urinary calcium should be monitored in an attempt to avoid hypercalciuria (>5 mg · kg⁻¹ per 24 hours) and urinary tract stone formation.

When supplementation fails to maintain serum calcium within the normal range, or if hypercalciuria develops, vitamin D may be added. Although the principal effect of vitamin D is to increase enteric calcium absorption, osseous calcium resorption is also enhanced. When rapid changes in dosage are anticipated or an immediate effect is required (e.g., postoperative hypoparathyroidism), shorter-acting calciferols such as dihydrotachysterol may be preferable. Because the effect of vitamin D is not regulated, the dosages of calcium and vitamin D should be adjusted to raise the serum calcium into the low normal range.

Adverse reactions to calcium and vitamin D include hypercalcemia and hypercalciuria. If hypercalcemia develops, calcium and vitamin D should be discontinued and appropriate therapy given. The toxic effects of vitamin D metabolites persist in proportion to their biologic half-lives (ergocalciferol, 20–60 days; dihydrotachysterol, 5–15 days; calcitriol, 2–10 days). Glucocorticoids antagonize the toxic effects of vitamin D metabolites.

Hypercalcemia

Although ionized [Ca²⁺] most accurately demonstrates hypercalcemia (total serum calcium >10.5 mg · dl⁻¹ or ionized [Ca²⁺] >1.3 mM), hypercalcemia is more frequently defined in terms of total serum calcium. In hypoalbuminemic patients, total serum calcium can be estimated by assuming an increase of 0.8 mg · dl⁻¹ for every 1 g · dl⁻¹ of albumin concentration below 4.0 g · dl⁻¹. Patients in whom total serum calcium is less than 11.5 mg · dl⁻¹ are usually asymptomatic. Patients with moderate hypercalcemia (total serum calcium 11.5–13 mg · dl⁻¹) may show symptoms of lethargy, anorexia, nausea, and polyuria. Severe hypercalcemia (total serum calcium >13 mg · dl⁻¹) is associated with more severe neuromyopathic symptoms, including muscle weakness, depression, impaired memory, emotional lability, lethargy, stupor, and coma. The cardiovascular effects of hypercalcemia include hypertension, dysrhythmias, heart block, cardiac arrest, and digitalis sensitivity.

Hypercalcemia impairs urinary concentrating ability and renal excretory capacity for calcium by irreversibly precipitating calcium salts within the renal parenchyma and by reducing RBF and GFR. In response to hypovolemia, renal tubular reabsorption of sodium enhances renal calcium reabsorption. Effective treatment of severe hypercalcemia is necessary to prevent progressive dehydration and renal failure leading to further increases in total serum calcium, because volume depletion exacerbates hypercalcemia.²³⁰ Skeletal disease may occur secondary to direct osteolysis or humoral bone resorption.

Hypercalcemia occurs when calcium enters the ECV more rapidly than the kidneys can excrete the excess. Clinically, hypercalcemia most commonly results from an excess of bone resorption over bone formation, usually secondary to malignant disease, hyperparathyroidism, hypocalciuric hypercalcemia, thyrotoxicosis, immobilization, and granulomatous diseases. Granulomatous diseases produce hypercalciuria and hypercalcemia due to conversion by granulomatous tissue of calcidiol to calcitriol.²²¹

Malignancy may produce hypercalcemia either through bone destruction or secretion by malignant tissue of hormones that promote hypercalcemia.²³¹ Although weakness, weight loss, and anemia associated with primary hyperparathyroidism may suggest malignancy, these may result simply from the primary disease process. Hypercalcemia associated with granulomatous diseases (e.g., sarcoidosis) results from the production of calcitriol by granulomatous tissue. To compensate for increased gut absorption or bone resorption of calcium, renal excretion can readily increase from 100 to more than 400 mg · day⁻¹. Factors that promote hypercalcemia may be offset by coexisting disorders, such as pancreatitis, sepsis, or hyperphosphatemia, that cause hypocalcemia.

Although definitive treatment of hypercalcemia requires correction of underlying causes, temporizing therapy may be necessary to avoid complications and to relieve symptoms. Total serum calcium exceeding 14 mg · dl⁻¹ represents a medical emergency. General supportive treatment includes hydration, correction of associated electrolyte abnormalities, removal of offending drugs, dietary calcium restriction, and increased physical activity. Because anorexia and antagonism by calcium of ADH action invariably lead to sodium and water depletion, infusion of 0.9% saline will dilute serum calcium, promote renal excretion, and can reduce total serum calcium by 1.5–3 mg · dl⁻¹. Urinary output should be maintained at 200–300 ml · hr⁻¹. As GFR increases, the sodium ion increases calcium excretion by competing with the calcium ion for reabsorption in the proximal renal tubules and loop of Henle. Furosemide further enhances calcium excretion by increasing tubular sodium. Patients who have renal impairment may require higher doses of furosemide. During saline infusion and forced diuresis, careful monitoring of cardiopulmonary status and electrolytes, especially magnesium and potassium, is required. Intensive diuresis and saline administration can achieve net calcium excretion rates of 2000 to 4000 mg per 24 hours, a rate eight times greater than saline alone, but still somewhat less than the rate of removal achieved by hemodialysis (i.e., 6000 mg every 8 hours). Patients treated with phosphates should be well hydrated. Slow calcium channel antagonists such as verapamil and nifedipine may also be useful in reversing hypercalcemic cardiotoxicity.²³²

Bone resorption, the primary cause of hypercalcemia, can be minimized by physical activity and drug therapy (Table 9-26).²¹⁷ Bisphosphonates, currently the first-line therapy for acute hypercalcemia, have an inhibitory effect on osteoclast function and viability. Bisphosphonates are the principal drugs for the management of hypercalcemia mediated by osteoclastic bone resorption.^{233,234} Pamidronate, an aminobisphosphonate 100 times more potent than etidronate, normalized serum calcium in 70% of patients with malignancy-related hypercalcemia.²³⁵ Pamidronate, unlike earlier bisphosphonates, does not appear to worsen renal insufficiency.²³⁴

| Generic Name | Trade Name | Recommended Starting Dose |
|-----------------------------|------------|--|
| Synthetic human calcitonin | Calcitonin | 0.5 mg sc daily |
| Synthetic salmon calcitonin | Calcimar | 4 IU · kg ⁻¹ body weight every 12 hours sc or intravenously |
| Etidronate | Dicalcium | 75 mg · kg ⁻¹ body weight/day for 3 days |
| Pamidronate | Amdia | 90–90 mg iv over 24 hours |
| Plicamycin | Mithracin | 25 µg · kg ⁻¹ body weight/day iv for 3–4 days |
| Calcium nitrate | Canite | 200 mg (m ²) body surface area/day for 5 days |

Table 9-26. DRUGS CURRENTLY APPROVED BY THE FOOD AND DRUG ADMINISTRATION THAT ARE EFFECTIVE IN LOWERING SERUM CALCIUM ACUTELY

Other osteoclast-inhibiting agents used to treat hypercalcemia include mithramycin and calcitonin.²³⁶ Mithramycin, a cytotoxic agent, lowers serum calcium primarily by inhibiting bone resorption, probably because of toxicity to osteoclasts.²³⁷ The hypocalcemia effect, usually seen within 12–24 hours following a single intravenous dose of $25 \mu\text{g} \cdot \text{kg}^{-1}$, peaks at 48–72 hours, and persists for 5–7 days. Major toxic effects of mithramycin, more likely to occur in renal insufficiency, include thrombocytopenia, nephrotoxicity, and hepatotoxicity. Calcitonin is useful in severe cases of hypercalcemia when added to mithramycin or bisphosphonates.²³⁸ Usually calcitonin reduces total serum calcium by only $1\text{--}2 \text{ mg} \cdot \text{dl}^{-1}$. Although calcitonin is relatively nontoxic, more than 25% of patients may not respond. Thus, calcitonin is unsuitable as a first-line drug during life-threatening hypercalcemia.

Hydrocortisone is effective in treating hypercalcemic patients with lymphatic malignancies, vitamin D or A intoxication, and diseases associated with production by tumor or granulomas of $1,25(\text{OH})_2\text{D}$ or osteoclast-activating factor. Glucocorticoids rarely improve hypercalcemia secondary to malignancy or hyperparathyroidism. Gallium nitrate, an antineoplastic agent, reduces bone resorption by reducing the solubility of hydroxyapatite rather than by affecting osteoclasts. Nephrotoxicity is the most common side effect of gallium nitrate; therefore, the agent should not be administered to patients with SCr values greater than $2.5 \text{ mg} \cdot \text{l}^{-1}$ or to patients on chronic nephrotoxic drugs such as aminoglycosides or amphotericin.²³⁹ The calcium-receptor antagonist R-568 causes a dose-dependent inhibition of parathyroid hormone secretion and decreases serum calcium,²⁴⁰ but its role in management has yet to be determined.²²¹

Phosphates lower serum calcium by causing deposition of calcium in bone and soft tissue. Because the risk of extraskeletal calcification of organs such as the kidneys and myocardium is less if phosphates are given orally, the intravenous route should be reserved for patients with life-threatening hypercalcemia or patients in whom other measures have failed.

Phosphate

Physiologic Role

Phosphorus, in the form of phosphate, is distributed in similar concentrations throughout intracellular and extracellular fluid. Of total body phosphorus, 90% exists in bone, 10% is intracellular, and the remainder, <1%, is found in the extracellular fluid. Phosphate circulates as the free ion (55%), complexed ion (33%), and in a protein-bound form (12%). Blood levels vary widely: the normal total serum phosphate level ranges from 2.7 to $4.5 \text{ mg} \cdot \text{dl}^{-1}$ in adults.

Control of phosphate concentration is achieved by altered renal excretion and redistribution within the body compartments. Absorption occurs in the duodenum and jejunum and is largely unregulated. Phosphate reabsorption in the kidney is primarily regulated by PTH, dietary intake, and insulin-like growth factor.²⁴¹ Phosphate is freely filtered at the glomerulus and its concentration in the glomerular ultrafiltrate is similar to plasma. The filtered phosphate is then reabsorbed in the proximal tubule where it is co-transported with sodium.²⁴¹ Proximal tubular reabsorption of phosphorus occurs by passive co-transport with sodium.²⁴² Co-transport is regulated by phosphorus intake and PTH.²⁴³ Phosphate excretion is increased by volume expansion and decreased by respiratory alkalosis.

Phosphates provide the primary energy bond in ATP and creatine phosphate. Therefore, severe phosphate depletion results in cellular energy depletion. Phosphorus is an essential element of second-messenger systems, including cAMP and phosphoinositides, and a major component of nucleic acids, phospholipids, and cell membranes. As part of 2,3-diphosphoglycerate, phosphate is important for off-loading oxygen from the hemoglobin molecule. Phosphorus also functions in protein phosphorylation and acts as a urinary buffer.

Hypophosphatemia

Hypophosphatemia is characterized by low levels of phosphate-containing cellular components, including ATP, 2,3-diphosphoglycerate, and membrane phospholipids. Serious life-threatening organ dysfunction may occur when the serum phosphate (PO_4) concentration falls below $1 \text{ mg} \cdot \text{dl}^{-1}$. Neurologic manifestations of hypophosphatemia include paresthesias, myopathy, encephalopathy, delirium, seizures, and coma.²⁴⁴ Hematologic abnormalities include dysfunction of erythrocytes, platelets, and leukocytes. Muscle weakness and malaise are common. Respiratory muscle failure²⁴⁵ and myocardial dysfunction²⁴⁶ are potential problems of particular concern to anesthesiologists. Rhabdomyolysis is a complication of severe hypophosphatemia.²⁴⁷

Common in postoperative and traumatized patients, hypophosphatemia ($\text{PO}_4 < 2.5 \text{ mg} \cdot \text{dl}^{-1}$) is caused by three primary abnormalities in PO_4 homeostasis: an intracellular shift of PO_4 , an increase in renal PO_4 loss, and a decrease in gastrointestinal PO_4 absorption. Carbohydrate-induced hypophosphatemia (the “refeeding syndrome”),²⁴⁸ mediated by insulin-induced cellular PO_4 uptake, is the type most commonly encountered in hospitalized patients. Hypophosphatemia may also occur as catabolic patients become anabolic, and during medical management of diabetic ketoacidosis. Acute alkalemia, which may reduce serum PO_4 to $1\text{--}2 \text{ mg} \cdot \text{dl}^{-1}$, increases intracellular consumption of PO_4 by increasing the rate of glycolysis. Hyperventilation to a PaCO_2 of 20 mm Hg may reduce the serum PO_4 level by $2\text{--}3 \text{ mg} \cdot \text{dl}^{-1}$.²⁴⁹ Acute correction of respiratory acidemia may also result in severe hypophosphatemia. Respiratory alkalosis probably explains the hypophosphatemia associated with gram-negative bacteremia and salicylate poisoning. Excessive renal loss of PO_4 explains the hypophosphatemia associated with hyperparathyroidism, hypomagnesemia, hypothermia, diuretic therapy, and renal tubular defects in PO_4 absorption. Excess gastrointestinal loss of PO_4 is most commonly secondary to the use of PO_4 -binding antacids or to malabsorption syndromes.

Measurement of urinary PO_4 aids in differentiation of hypophosphatemia due to renal losses from that due to excessive gastrointestinal losses or redistribution of PO_4 into cells. Extrarenal causes of hypophosphatemia cause avid renal tubular PO_4 reabsorption, reducing urinary excretion to $<100 \text{ mg} \cdot \text{day}^{-1}$.

Patients who have severe ($<1 \text{ mg} \cdot \text{dl}^{-1}$) or symptomatic hypophosphatemia require intravenous phosphate administration (Table 9-27).²⁴⁴ In chronically hypophosphatemic patients, $0.2\text{--}0.68 \text{ mmol} \cdot \text{kg}^{-1}$ ($5\text{--}16 \text{ mg} \cdot \text{kg}^{-1}$ elemental phosphorus) should be infused over 12 hours. For moderately hypophosphatemic adult patients suffering from critical illness, the use of 15-mmol boluses (465 mg) mixed with 100 ml of 0.9% sodium chloride and given over a 2-hour period safely repletes phosphate.²⁵⁰ The dosage is then adjusted as indicated by the serum PO_4 level, because the cumulative deficit cannot be predicted accurately. Oral therapy can be substituted for parenteral PO_4 once the serum PO_4 level exceeds $2.0 \text{ mg} \cdot \text{dl}^{-1}$. Continued therapy with PO_4 supplements is required for 5–10 days in order to replenish body stores.

Parenteral phosphate, $0.2 \text{ mM--}0.68 \text{ mM/kg}$ ($5\text{--}16 \text{ mg} \cdot \text{kg}^{-1}$) over
12 hours
Potassium phosphate ($93 \text{ mg} \cdot \text{ml}^{-1}$ of phosphate)
Sodium phosphate ($93 \text{ mg} \cdot \text{ml}^{-1}$ of phosphate)

Table 9-27. HYPOPHOSPHATEMIA: ACUTE TREATMENT

Phosphate should be administered cautiously to hypocalcemic patients because of the risk of precipitating more severe hypocalcemia. In hypercalcemic patients, PO_4 may cause soft-tissue calcification. Phosphorus must be given cautiously to patients with renal insufficiency because of impaired excretory ability. During treatment, close monitoring of serum PO_4 , calcium, magnesium, and potassium is essential to avoid complications.

Hyperphosphatemia

The clinical features of hyperphosphatemia ($\text{PO}_4 > 5.0 \text{ mg} \cdot \text{dl}^{-1}$) relate primarily to the development of hypocalcemia and ectopic calcification. Hyperphosphatemia is caused by three basic mechanisms: inadequate renal excretion, increased movement of PO_4 out of cells, and increased PO_4 or vitamin D intake. Rapid cell lysis from chemotherapy, rhabdomyolysis, and sepsis can cause hyperphosphatemia, especially when renal function is impaired. Renal failure is the most common cause of hyperphosphatemia.²⁴³ Renal excretion of PO_4 remains adequate until the GFR falls below $20\text{--}25 \text{ ml} \cdot \text{min}^{-1}$.

Measurements of BUN, creatinine, GFR, and urinary PO_4 are helpful in the differential diagnosis of hyperphosphatemia. Normal renal function accompanied by high PO_4 excretion ($>1500 \text{ mg} \cdot \text{day}^{-1}$) indicates an oversupply of PO_4 . An elevated BUN, elevated creatinine, and low GFR suggest impaired renal excretion of PO_4 . Normal renal function and PO_4 excretion less than $1500 \text{ mg} \cdot \text{day}^{-1}$ suggest increased PO_4 reabsorption (*i.e.*, hypoparathyroidism).

Hyperphosphatemia is corrected by eliminating the cause of the PO_4 elevation and correcting the associated hypocalcemia. Calcium supplementation of hypocalcemic patients should be delayed until serum phosphate has fallen below $2.0 \text{ mmol} \cdot \text{l}^{-1}$ ($6.0 \text{ mg} \cdot \text{dl}^{-1}$).²²¹ The serum concentration of PO_4 is reduced by restricting intake, increasing urinary excretion with saline and acetazolamide (500 mg every 6 hours), and increasing gastrointestinal losses by enteric administration of aluminum hydroxide ($30\text{--}45 \text{ ml}$ every 6 hours). Aluminum hydroxide absorbs PO_4 secreted into the bowel lumen and increases PO_4 loss even if none is ingested. Hemodialysis and peritoneal dialysis are effective in removing PO_4 in patients who have renal failure.

Magnesium

Physiologic Role

Magnesium is an important, multifunctional, divalent cation located primarily in the intracellular space (intracellular magnesium $\sim 2400 \text{ mg}$; extracellular magnesium $\sim 280 \text{ mg}$). Approximately 50% of magnesium is located in bone, 25% is found in muscle, and less than 1% of total body magnesium circulates in the serum. Of the normal circulating total magnesium concentration ($1.5\text{--}1.9 \text{ mEq} \cdot \text{l}^{-1}$ or $0.75\text{--}0.95 \text{ mmol} \cdot \text{l}^{-1}$ or $1.5\text{--}1.9 \text{ mg} \cdot \text{dl}^{-1}$),²⁴³ there are three components: protein-bound (30%), chelated (15%), and ionized (55%), of which only ionized magnesium is active.

Magnesium is necessary for enzymatic reactions involving DNA and protein synthesis.²⁵¹ As a primary regulator or cofactor in many enzyme systems, magnesium is important for the regulation of the sodium–potassium pump, Ca-ATPase enzymes, adenylyl cyclase, proton pumps, and slow calcium channels. Magnesium has been called an endogenous calcium antagonist because regulation of slow calcium channels contributes to maintenance of normal vascular tone, prevention of vasospasm, and perhaps to prevention of calcium overload in many tissues. Because magnesium partially regulates PTH secretion and is important for the maintenance of end-organ sensitivity to both PTH and vitamin D, abnormalities in ionized magnesium concentration ($[\text{Mg}^{2+}]$) may result in abnormal calcium metabolism. Magnesium functions in potassium metabolism primarily through regulating sodium–potassium ATPase, an enzyme that controls potassium entry into cells, especially in potassium-depleted states, and controls reabsorption of potassium by the renal tubules. In addition, magnesium functions as a regulator of membrane excitability and serves as a structural component in both cell membranes and the skeleton.

Because magnesium stabilizes axonal membranes, hypomagnesemia decreases the threshold of axonal stimulation and increases nerve conduction velocity. Magnesium also influences the release of neurotransmitters at the neuromuscular junction by competitively inhibiting the entry of calcium into the presynaptic nerve terminals. The concentration of calcium required to trigger calcium release and the rate at which calcium is released from the sarcoplasmic reticulum are inversely related to the ambient magnesium concentration. Thus, the net effect of hypomagnesemia is muscle that contracts more in response to stimuli and is tetany prone.

The distal tubule of the kidney is the major site of magnesium regulation. Plasma $[\text{Mg}^{2+}]$ regulates magnesium reabsorption through the $\text{Ca}^{2+}/\text{Mg}^{2+}$ -sensing receptor, located on the capillary side of cells in the thick ascending limb.²⁵² Magnesium is widely available in foods and is absorbed through the GI tract.²⁵³ Whereas both magnesium and PO_4 are primarily regulated by intrinsic renal mechanisms,²⁵¹ PTH exerts a greater effect on renal loss of PO_4 .

Magnesium has been used to help manage an impressive array of clinical problems in patients who are not hypomagnesemic.²⁵⁴ Therapeutic hypermagnesemia is used to treat patients with premature labor, preeclampsia, and eclampsia. Because magnesium blocks the release of catecholamines from adrenergic nerve terminals and the adrenal glands, magnesium has been used to reduce the hypertensive response to tracheal intubation,²⁵⁵ and to reduce the effects of catecholamine excess in patients with tetanus and pheochromocytoma. Magnesium administration may influence dysrhythmias by direct effects on myocardial membranes, by altering cellular potassium and sodium concentrations, by inhibiting cellular calcium entry, by improving myocardial oxygen supply and demand, by prolonging the effective refractory period, by depressing conduction, by antagonizing catecholamine action on the conducting system, and by preventing vasospasm. Administration of magnesium reduces the incidence of dysrhythmias after myocardial infarction.²⁵⁶ In humans with ischemic myocardium, magnesium prevented the ischemic increase in action potential duration and membrane repolarization.²⁵⁷ After acute myocardial infarction, intravenous magnesium administration decreased short-term mortality.²⁵⁸ In addition, magnesium may be useful as treatment for *torsades de pointes* dysrhythmias, even in normomagnesemic patients.²⁵⁹

Hypomagnesemia

The clinical features of hypomagnesemia ($[\text{Mg}^{2+}] < 1.7 \text{ mg} \cdot \text{dl}^{-1}$), like those of hypocalcemia, are characterized by increased neuronal irritability and tetany.²⁶⁰ Severe hypomagnesemia may reduce the response of adenylyl cyclase to stimulation of the PTH receptor.²⁶¹ Hypomagnesemia can aggravate digoxin toxicity and congestive heart failure. Symptoms are rare when the serum $[\text{Mg}^{2+}]$ is $1.5\text{--}1.7 \text{ mg} \cdot \text{dl}^{-1}$; in most symptomatic patients serum $[\text{Mg}^{2+}]$ is $<1.0 \text{ mg} \cdot \text{dl}^{-1}$. Patients frequently complain of weakness, lethargy, muscle spasms, paresthesias, and depression. When severe, hypomagnesemia may induce seizures, confusion, and coma. Cardiovascular abnormalities include coronary artery spasm, cardiac failure, dysrhythmias, and hypotension.

Hypomagnesemia, identified in 11% of hospitalized patients²⁶² and as many as 47% of blood samples collected for determination of other electrolytes,²⁶³ is associated with hypokalemia, hyponatremia, hypophosphatemia, and hypocalcemia. Of alcoholic patients admitted to the hospital, 30% are hypomagnesemic.²⁶⁴ Serum $[\text{Mg}^{2+}]$ may not reflect intracellular magnesium content. Peripheral lymphocyte magnesium concentration correlates well with skeletal and cardiac magnesium content.

Rarely resulting from inadequate dietary intake, hypomagnesemia is most commonly caused by inadequate gastrointestinal absorption, excessive magnesium losses, or failure of renal magnesium conservation. Excessive magnesium loss is associated with prolonged nasogastric suctioning, gastrointestinal or biliary fistulas, and intestinal drains. Inability of the renal tubules to conserve magnesium complicates a variety of systemic and renal diseases, although advanced renal disease with a decreased GFR may lead to magnesium retention. Polyuria, whether secondary to ECV expansion or to pharmacologic or pathologic diuresis, may result in excessive urinary magnesium excretion. Various drugs, including aminoglycosides,²⁶⁵ cis-platinum, cardiac glycosides, and diuretics, enhance urinary magnesium excretion. Intracellular shifts of magnesium as a result of thyroid hormone or insulin administration may also decrease serum $[\text{Mg}^{2+}]$.

Measurement of 24-hour urinary magnesium excretion is useful in separating renal from nonrenal causes of hypomagnesemia. Normal kidneys can reduce magnesium excretion to less than $1\text{--}2 \text{ mEq} \cdot \text{day}^{-1}$ in response to magnesium depletion. Hypomagnesemia accompanied by high urinary excretion of magnesium ($>3\text{--}4 \text{ mEq} \cdot \text{day}^{-1}$) suggests a renal etiology. In the magnesium-loading test, urinary Mg^{2+} excretion is measured for 24 hours after an intravenous magnesium load.²²⁶

Magnesium deficiency is treated by the administration of magnesium supplements (Table 9-28). One gram of magnesium sulfate provides approximately 4 mmol (8 mEq, or 98 mg) of elemental magnesium. Mild deficiencies can be treated with diet alone. Replacement must be added to daily magnesium requirements ($0.3\text{--}0.4 \text{ mEq} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$). Symptomatic or severe hypomagnesemia ($[\text{Mg}^{2+}] < 1.0 \text{ mg} \cdot \text{dl}^{-1}$) should be treated with parenteral magnesium: $1\text{--}2 \text{ g}$ ($8\text{--}16 \text{ mEq}$) of magnesium sulfate as an intravenous bolus over the first hour, followed by a continuous infusion of $2\text{--}4 \text{ mEq} \cdot \text{hr}^{-1}$. Therapy should be guided subsequently by the serum magnesium level. The rate of infusion should not exceed $1 \text{ mEq} \cdot \text{min}^{-1}$, even in emergency situations, and the patient should receive continuous cardiac monitoring to detect cardiotoxicity. Because magnesium antagonizes calcium, blood pressure and cardiac function should be monitored, although clinical effects on myocardial contractility and blood pressure appear to be modest. Treatment of hypomagnesemia after cardiopulmonary bypass decreased the incidence of ventricular dysrhythmias after heart surgery from 63% to 22%.²⁶⁷

Table 9-28. HYPOMAGNESEMIA: ACUTE TREATMENT

Intravenous Mg²⁺: 8–16 mEq bolus over 1 hour, followed by 2–4 mEq·hr⁻¹ as continuous infusion
 Intramuscular Mg²⁺: 10 mEq q 4–6 hours

* MgSO₄: 1 g = 8 mEq Mg; MgCl₂: 1 g = 10 mEq Mg

Table 9-28. HYPOMAGNESEMIA: ACUTE TREATMENT

Because the sodium–potassium pump is magnesium-dependent, hypomagnesemia increases myocardial sensitivity to digitalis preparations and may cause hypokalemia as a result of renal potassium wasting. Attempts to correct potassium deficits with potassium replacement therapy alone may not be successful without simultaneous magnesium therapy. Magnesium is important in the regulation of potassium channels. The interrelationships of magnesium and potassium in cardiac tissue have probably the greatest clinical relevance in terms of dysrhythmias, digoxin toxicity, and myocardial infarction. Both severe hypomagnesemia and hypermagnesemia suppress PTH secretion and can cause hypocalcemia. Severe hypomagnesemia may also impair end-organ response to PTH.

During repletion, the patellar reflexes should be monitored frequently and magnesium withheld if they become suppressed. Patients who have renal insufficiency have a diminished ability to excrete magnesium and require careful monitoring during therapy. Repletion of systemic magnesium stores usually requires 5–7 days of therapy, after which daily maintenance doses of magnesium should be provided. Magnesium can be given orally, usually in a dose of 60–90 mEq·day⁻¹ of magnesium oxide. Hypocalcemic, hypomagnesemic patients should receive magnesium as the chloride salt, because the sulfate ion can chelate calcium and further reduce the serum [Ca²⁺].

Hypermagnesemia

Most cases of hypermagnesemia ([Mg²⁺] >2.5 mg·dl⁻¹) are iatrogenic, resulting from the administration of magnesium in antacids, enemas, or parenteral nutrition, especially to patients with impaired renal function. Other rarer causes of mild hypermagnesemia are hypothyroidism, Addison's disease, lithium intoxication, and familial hypocalciuric hypercalcemia. Hypermagnesemia is detected in 5.7–9.3% of blood samples drawn for electrolyte determinations.^{262,263} Hypermagnesemia antagonizes the release and effect of acetylcholine at the neuromuscular junction. The result is depressed skeletal muscle function and neuromuscular blockade. Magnesium potentiates the action of nondepolarizing muscle relaxants²⁶⁸ and decreases potassium release in response to succinylcholine.²⁶⁹ The clinical features of progressive hypermagnesemia are listed in [Table 9-29](#).

Table 9-29. HYPERMAGNESEMIA: CLINICAL FINDINGS

| Clinical Findings | Serum [Mg ²⁺] (mg·dl ⁻¹) |
|--|---|
| Normal | 1.7–2.4 |
| Therapeutic range (preeclampsia) | 5–8 |
| Hypotension | 3–5 |
| Deep tendon hyporeflexia | 5 |
| Somnolence | 8.5 |
| Respiratory insufficiency, deep tendon areflexia | 12 |
| Heart block, respiratory paralysis | 18 |
| Cardiac arrest | 24 |

Table 9-29. HYPERMAGNESEMIA: CLINICAL FINDINGS

The neuromuscular and cardiac toxicity of hypermagnesemia can be acutely, but transiently, antagonized by giving intravenous calcium (5–10 mEq) to buy time while more definitive therapy is instituted.²⁷⁰ All magnesium-containing preparations must be stopped. Urinary excretion of magnesium can be increased by expanding ECV and inducing diuresis with a combination of saline and furosemide. In emergency situations and in patients with renal failure, magnesium may be removed by dialysis.

EVOLUTION OF TRANSFUSION PRACTICES

The knowledge that the acquired immune deficiency syndrome (AIDS) is transmitted by blood administration generated public fear of blood transfusion and led to dramatic changes in the way physicians approach the patient requiring blood products. For decades prior to 1985, anesthesiologists and surgeons applied, without question, the maxim that patients must have a hemoglobin (Hgb) level of $10 \text{ g} \cdot \text{dl}^{-1}$ or a hematocrit (Hct) of 30% prior to surgery. Other blood components (platelets, fresh frozen plasma) were similarly administered without reference to well-founded criteria. However, the AIDS epidemic prompted a reassessment of transfusion criteria, and contemporary practice requires that physicians take a patient-specific approach to the decision to transfuse blood components.

RBC TRANSFUSION THRESHOLDS

The Rationale

The question of what hemoglobin/hematocrit level poses greater risks to the patient than the threat of contracting a transfusion-transmitted disease has been widely discussed. However, there are no randomized controlled trials in the literature that provide a thorough risk–benefit analysis.¹ Experience with the ability of surgical patients to tolerate lower hematocrits was initially limited because the *10 & 30 rule* ($10 \text{ g} \cdot \text{dl}^{-1}$ Hgb, Hct = 30%) was so widely applied. However, several patient subpopulations revealed that considerably greater degrees of anemia could be well tolerated. Chronically anemic renal failure patients tolerated many surgical procedures and anesthetics. Many surgeons had military experience that demonstrated that maintaining blood volume was more critical than correcting anemia, and these surgeons began to operate on patients with much lower hematocrits.² Finally, experience with Jehovah's Witnesses, who refuse blood transfusion for religious reasons, indicated that morbidity and mortality rates did not increase until hemoglobin levels fell below $7 \text{ g} \cdot \text{dl}^{-1}$.^{1,3,4,5 and 6}

Concerns about many adverse physiologic effects of anemia have proved unfounded. There is no evidence that mild to moderate anemia impairs wound healing, increases bleeding, or increases the length of the patient's hospital stay. The cause of the anemia is thought to be more important in influencing the patient's perioperative course than the severity of the anemia.⁷ In animal studies, wound healing is only impaired below a hematocrit of 15%.⁶ The suspicion that anemia might increase the frequency or severity of postoperative infections has now been supplanted by evidence that transfusion, because of immunomodulatory effects (see [Risks of Blood Product Administration](#)) is actually associated with an increased incidence of postoperative infections.

The goal now is to anticipate, on a patient-by-patient basis, the minimum hemoglobin level that will avoid organ damage due to oxygen deprivation. This “transfusion trigger” requires more than a review of the patient's hemoglobin level. The physician must first consider the determinants of oxygen delivery (D_{O_2}) and oxygen consumption (V_{O_2}) at the tissue level and, in addition, assess the patient's physiologic capacity for the compensatory mechanisms that enhance oxygen delivery to the tissues under conditions of anemia. Ultimately, the decision to transfuse red blood cells should be based upon the clinical judgment that the oxygen-carrying capacity of the blood must be increased to prevent oxygen consumption from outstripping oxygen delivery.

Oxygen Delivery and Oxygen Consumption

Oxygen Delivery. Oxygen delivery is a function of arterial oxygen content (Ca_{O_2}) and cardiac output. Ca_{O_2} is, in turn, a function of hemoglobin level, hemoglobin saturation (Sa_{O_2}), and oxygen dissolved in plasma (Pa_{O_2}). Ca_{O_2} is expressed as the number of milliliters of oxygen contained in 100 ml of blood and is calculated as follows:

$$C_{aO_2} = (\text{Hgb} \times 1.34 \times S_{aO_2}) + (0.003 \times P_{aO_2})$$

If hemoglobin concentration is $15 \text{ g} \cdot \text{dl}^{-1}$ and the hemoglobin molecule is 100% saturated, the oxygen content of blood will be $20 \text{ ml} \cdot \text{dl}^{-1}$. The rate of oxygen delivery (D_{O_2}) to the tissues is dependent on the product of cardiac output (CO) and the arterial oxygen content of blood. Normal average adult cardiac output is $5 \text{ l} \cdot \text{min}^{-1}$ (or $70 \text{ ml} \cdot \text{kg}^{-1}$) at rest. Oxygen delivery to the tissues is calculated as follows:

$$\begin{aligned} \text{Oxygen delivery} &= \text{CO} \times C_{aO_2} \\ D_{O_2} &= 5 \text{ l} \cdot \text{min}^{-1} \times (20 \text{ ml} / 100 \text{ ml} \cdot \text{min}^{-1}) \\ &= (200 \text{ ml} \cdot \text{l}^{-1} \cdot \text{min}^{-1}) \\ &= 1000 \text{ ml} \cdot \text{min}^{-1} \end{aligned}$$

These simple calculations highlight the inadequacy of previous transfusion practices that considered hemoglobin concentration without reference to cardiac output or hemoglobin saturation.

Oxygen Consumption. Oxygen consumption can be calculated as the product of cardiac output and the difference between the arterial oxygen content and the venous ($C\bar{V}_{O_2}$):

$$O_2 \text{ consumption} = \text{CO} \times (C_{aO_2} - C\bar{V}_{O_2})$$

The normal arteriovenous oxygen content difference is 5 vol%. Accordingly, normal oxygen consumption is $250 \text{ ml} \cdot \text{min}^{-1}$ ($5 \text{ l} \cdot \text{min}^{-1} \times 5 \text{ ml} / 100 \text{ ml}$ or $50 \text{ ml} \cdot \text{l}^{-1} = 250 \text{ ml} \cdot \text{min}^{-1}$). Factors that increase oxygen extraction include sepsis, hyperthermia, and any state of increased metabolic activity, such as hyperthyroidism.

Note that these formulas provide a calculation of whole-body oxygen delivery and consumption. However, regional oxygen requirements differ substantially, and normal global oxygen delivery may occur in spite of critical levels of regional ischemia.⁸

Oxygen Extraction Ratios and the Mixed Venous Oxygen Saturation

Rather than calculating global oxygen delivery and oxygen consumption, it may be more useful to consider the extraction ratios of individual organs. The extraction ratio (ER) defines what fraction of the total oxygen delivered is consumed or extracted by the tissues as follows:

$$\begin{aligned} \text{ER} &= \text{Oxygen consumption} / \text{Oxygen delivery} \\ \text{ER} &= [\text{CO} \times (C_{aO_2} - C\bar{V}_{O_2})] / (\text{CO} \times C_{aO_2}) \\ &= (C_{aO_2} - C\bar{V}_{O_2}) / C_{aO_2} \end{aligned}$$

Oxygen consumption for the entire body has already been calculated to be $250 \text{ ml} \cdot \text{l}^{-1} \cdot \text{min}^{-1}$ and oxygen delivery to be $1000 \text{ ml} \cdot \text{l}^{-1} \cdot \text{min}^{-1}$, which produces an ER of 25%. With a normal arterial oxygen content of 20 vol% ($200 \text{ ml} \cdot \text{l}^{-1}$) and an extraction ratio of 25%, 5 vol% or $50 \text{ ml} \cdot \text{l}^{-1}$ of oxygen will be delivered to the tissues (the arteriovenous oxygen difference) and the mixed venous blood will have an oxygen content of 15 vol% ($150 \text{ ml} \cdot \text{l}^{-1}$) and an oxygen saturation ($S\bar{V}_{O_2}$) of 75%.

The mixed venous oxygen saturation reflects the oxygen consumption of many vascular beds, with some tissues (muscle, skin, viscera) extracting less oxygen and others (brain, heart) extracting proportionally more.⁹ Under conditions of isovolemic hemodilution, increased oxygen extraction may occur in those tissue beds that normally consume a small proportion of the available oxygen (D_{O_2}). The increase in extraction ratio of these tissue beds will increase the whole-body oxygen ER and will lower the mixed venous oxygen saturation ($S\bar{V}_{O_2}$), making it a useful tool for assessing oxygen reserves in the venous blood.

In clinical practice, we cannot measure the extraction ratios of the various organs. However, it is known that the heart, under basal conditions, extracts between 55 and 70% of the oxygen delivered.^{10,11} In contrast, in kidney and skin, ER is 7–10%. Organs with the greatest extraction ratios will have the least oxygen reserve. Because the heart has the highest ER, it is the organ at greatest risk under conditions of normovolemic anemia.⁹ This is important to keep in mind when assessing the risks of anemia.

Compensatory Mechanisms During Anemia

When anemia develops but blood volume is maintained (isovolemic hemodilution), four compensatory mechanisms serve to maintain oxygen delivery: (1) an increase in cardiac output, (2) a redistribution of blood flow to organs with greater oxygen requirements, (3) increases in the extraction ratios of some vascular beds, and (4) alteration of oxygen-hemoglobin binding to allow the hemoglobin to deliver oxygen at lower oxygen tensions.

Increased Cardiac Output

With isovolemic hemodilution, cardiac output increases primarily because of an increase in stroke volume brought about by reductions in systemic vascular resistance (SVR). There are two principal determinants of SVR: vascular tone and the viscosity of blood.¹² As hematocrit decreases, reduction of blood viscosity decreases SVR. This decrease in SVR increases stroke volume and consequently cardiac output and blood flow to the tissues. Over a wide range of hematocrits, isovolemic hemodilution is self-correcting. Linear decreases in the oxygen-carrying capacity of the blood are matched by improvements in oxygen transport. Because oxygen transport peaks at hematocrits of 30%, oxygen delivery may remain constant between the hematocrits of 45 and 30%.¹² Transfusing red blood cells in this range of hematocrits would do little to increase oxygen delivery.⁹ Further reductions in hematocrit are accompanied by increases in cardiac output, which peaks at 180% of control as the hematocrit approaches 20%.

The exact hemoglobin value at which cardiac output rises varies among individuals and is influenced by age and whether the anemia is acute or develops slowly.³ In some patients, the cardiac output will not increase until the hemoglobin level falls to 7 or $8 \text{ g} \cdot \text{dl}^{-1}$.¹³ Increases in cardiac output due to changes in contractility or preload appear to play a lesser role in the maintenance of cardiac output than do increases in stroke volume.⁵ Some increase in venous return is thought to occur as a result of the reduction in viscosity and a passive increase in blood flow in the postcapillary venules.⁹

Redistribution of Cardiac Output

With isovolemic hemodilution, blood flow to the tissues increases, but this increased blood flow is not distributed equally to all tissue beds. Organs with higher extraction ratios (brain and heart) receive disproportionately more of the increase in blood flow than organs with low extraction ratios (muscle, skin, viscera).

The redistribution of blood flow to the coronary circulation is the principal means by which the healthy heart compensates for anemia.¹² Coronary blood flow may increase by 400–600%. Because the heart under basal conditions already has a high extraction ratio (between 50 and 70% vs. 30% in most tissues) and the primary compensation for anemia involves cardiac work (increasing CO), the heart must rely upon redistributing blood flow to increase oxygen supply.¹³ These factors make the heart the organ at greatest risk under conditions of isovolemic hemodilution. When the heart can no longer increase either cardiac output or coronary blood flow, the limits of isovolemic hemodilution are reached. Further decreases in oxygen delivery will result in myocardial injury.

Increased Oxygen Extraction

The third mechanism for adapting to isovolemic hemodilution involves increasing oxygen extraction ratios. This mechanism is thought to play an important adaptive role when the normovolemic hematocrit drops below 25%. Increased oxygen extraction in multiple tissue beds leads to an increase in the whole-body ER and consequently to a decrease in mixed venous oxygen saturation. One investigation demonstrated that as hematocrit decreases to 15%, whole-body oxygen ER increases from 38% to 60% and the $S\bar{V}_{O_2}$ decreases from 70% to 50% or less.⁹ Some organs (brain and heart) already have high extraction ratios under basal conditions, and have a limited

capacity to increase oxygen delivery by this mechanism.

Changes in Oxygen–Hemoglobin Affinity

The fourth mechanism of compensation for anemia involves a change in the binding of oxygen to hemoglobin. The affinity of hemoglobin for oxygen is described by the sigmoid-shaped oxygen–hemoglobin dissociation curve. This curve relates the partial pressure of oxygen in the blood to the percentage saturation of the hemoglobin molecule with oxygen.

The partial pressure of oxygen at which the hemoglobin molecule is 50% saturated with oxygen and 50% unsaturated is termed the P_{50} . P_{50} for normal adult hemoglobin at 37°C and a pH of 7.4 is 27 mm Hg. Hemoglobins differ in their P_{50} values, and changes in the acid–base status or the temperature of blood can shift the oxyhemoglobin dissociation curve to the left or right, respectively lowering or raising the P_{50} value. When the curve is shifted to the left, as with hypothermia or alkalosis, the P_{50} is lowered.¹⁴ With a lower P_{50} , the hemoglobin molecule is more “stingy” and requires lower oxygen lower partial pressures to release oxygen to the tissues; that is, the hemoglobin molecule does not release 50% of its oxygen until an ambient P_{O_2} less than 27 mm Hg is reached. This may impair tissue oxygenation. By contrast, right-shifting of the oxygen-hemoglobin dissociation curve, as occurs with increases in temperature or acidosis, results in an increase of P_{50} , decreased hemoglobin affinity for the oxygen molecule, and release of oxygen to tissues at higher partial pressures of oxygen.

When anemia develops slowly, the affinity of hemoglobin for oxygen may be decreased (*i.e.*, the curve is right-shifted) as a result of the accumulation in red blood cells of 2,3-phosphoglycerate (2,3-DPG).¹⁴ Synthesis of supranormal levels of 2,3-DPG begins at a Hgb of $9\text{ g} \cdot \text{dl}^{-1}$. At Hgb levels of 6.5, the curve is shifted more prominently.³ All stored red blood cells become depleted of 2,3-DPG. Temperature reduction and storage-related pH decreases also reduces the P_{50} of stored blood. These changes, however, are quickly reversed *in vivo*, but the resynthesis of 2,3-DPG by red blood cells may require from 12 to 24 hours or longer.¹³

Isovolemic Anemia vs. Acute Blood Loss

Although the same compensatory mechanisms are operative in acute and chronic anemias, they have different degrees of importance and occur at different levels of hemoglobin. With acute blood loss, hypovolemia induces stimulation of the adrenergic nervous system, leading to vasoconstriction and tachycardia. Increased cardiac output does not contribute. In chronically anemic patients, cardiac output may not change until the hemoglobin decreases to approximately $7\text{--}8\text{ g} \cdot \text{dl}^{-1}$.³ In these patients, the accumulation of 2,3-DPG in the red blood cells, increasing the P_{50} of Hgb, is the important first mechanism for compensation.⁷

Establishing the RBC Transfusion Threshold

Guidelines

There has been extensive discussion of the red blood cell (RBC) transfusion “trigger”—the hemoglobin or hematocrit threshold that justifies RBC transfusion for individual patients. At this transfusion threshold, it is presumed that the benefits of red blood cell transfusion outweigh the risks. It was evident during the 1980s that transfusion practices varied significantly.¹⁵ As a consequence, the National Institutes of Health convened a Consensus Conference on Perioperative Red Cell Transfusions in 1988 to review the evidence regarding the relative benefits of transfusing a patient at a given hemoglobin level versus the risk of not transfusing.⁴ They concluded that no single criterion (*e.g.*, no specific Hgb level) could replace clinical judgment as the basis for decision-making. They concluded that the majority of patients with Hgb values of $10\text{ g} \cdot \text{dl}^{-1}$ or greater rarely required perioperative transfusion, whereas those with hemoglobin values of less than $7\text{ g} \cdot \text{dl}^{-1}$ would frequently require RBC transfusion. They recommended that clinical assessment “aided by laboratory data such as arterial oxygenation, mixed venous oxygen tension, cardiac output, the oxygen extraction ratio, and blood volume, when indicated,”⁴ should guide therapy. They further concluded that there existed “no evidence that mild-to-moderate anemia contributes to perioperative morbidity.”

There have been subsequent consensus statements by other bodies. These have added little to the 1988 statement other than placing greater emphasis on the development and application of perioperative blood conservation strategies.^{1,16,17} The focus remains on evaluation of the individual patient. [Table 10-1](#), the contents of which follow logically from the preceding description of the mechanisms of physiologic compensation for anemia, lists conditions that may reduce patient tolerance for anemia and thereby justify transfusion of RBCs at Hgb levels greater than $7\text{ g} \cdot \text{dl}^{-1}$. The greatest emphasis in that evaluation will usually be placed on an estimation of the patient's myocardial/coronary reserve.

Table 10-1. CONDITIONS THAT MAY DECREASE TOLERANCE FOR ANEMIA AND INFLUENCE THE RBC TRANSFUSION THRESHOLD

Myocardial/Coronary Reserve

Studies have been conducted on healthy animals with normal hearts and patent coronary arteries in an attempt to define the lowest hemoglobin or hematocrit that can be tolerated before death ensues.⁵ These studies have revealed that, if normovolemia is maintained, the whole-body ER increases linearly as the Hct decreases until a critical point is reached.¹⁸ At a hematocrit of 10% and a whole-body ER of approximately 50%, no further increases in oxygen consumption (V_{O_2}) occur; the tissues convert to anaerobic metabolism, which leads to metabolic acidosis and hemodynamic instability. Death is due to high output cardiac failure with severe tissue hypoxia. Nonetheless, survival at even lower hematocrits has occasionally been reported in humans who refuse blood for religious reasons.²

There is some systematically derived evidence to confirm the intuitive suspicion that patients with coronary vascular disease tolerate anemia less well than other acutely ill patients. Hebert *et al*¹⁹ performed a prospective study of the outcome impact of a restrictive transfusion practice in a broad spectrum of critically ill patients. They observed that the restrictive approach improved outcome in some patient subsets but that the benefit was not apparent in patients with myocardial infarction or unstable angina. Although this is consistent with an adverse effect of anemia in this population, it does not allow delineation of specific transfusion thresholds. This must remain a matter of clinician judgment.

In summary, in order to establish the threshold Hgb level at which RBC transfusion is appropriate, the physician must evaluate the risks that anemia poses in the context of the patient's medical condition. The transfusion trigger for each patient will lie somewhere between a hemoglobin of $6\text{--}7\text{ g} \cdot \text{dl}^{-1}$ (Hct of 18–21%) and a hemoglobin of $10\text{ g} \cdot \text{dl}^{-1}$ (Hct of 30%). The lowest transfusion thresholds should be reserved for young healthy patients with acute blood loss but no other complicating factors and for those patients with well-compensated chronic anemia. The latter may be well compensated at hemoglobin values between 6 and $8\text{ g} \cdot \text{dl}^{-1}$.⁶ A “middle of the road” hematocrit threshold (*e.g.*, Hct 25%) may be appropriate for the patient with well-compensated medical problems but no cardiac disease. Finally, in patients with coronary artery disease, a transfusion threshold approaching 30% may be necessary to avoid ischemia. Anticipated blood loss and the anticipated physiologic stresses of the intraoperative and postoperative course should also be factors in transfusion decisions.²⁰ Cardiac output, arterial and mixed venous oxygen, and the whole-body ER data should be used to provide objective criteria for these judgments when available. Mixed venous P_{O_2} of less than 25 mm Hg, a whole-body oxygen ER greater than 50%, and reduction of total oxygen consumption (V_{O_2}) to less than 50% of baseline indicate significantly impaired oxygen delivery. The final rationale for transfusion should be entered in the medical record.

COLLECTION AND PREPARATION OF BLOOD PRODUCTS FOR TRANSFUSION

Several steps are required in the preparation and selection of red blood cells for transfusion. Whole blood is first collected in bags containing citrate-phosphate-dextrose-adenine (CPDA) as a preservative and stored at 4°C. The citrate chelates the calcium present in blood and prevents coagulation. CPDA results in a longer shelf life than the once widely used acid-citrate-dextrose (ACD). Nonetheless, RBC viability at 4°C declines with time and shelf life is limited to 35–42 days. RBCs can be frozen and stored indefinitely. However, preservatives to prevent freeze/thaw-associated damage must be added and subsequently removed before administration. The process is expensive and hence not widely used.

Sequential centrifugation at various spin speeds and durations is used to separate whole blood into components including packed RBCs, platelet concentrates, cryoprecipitate, leukocyte-poor RBCs, and cell-free plasma. For preparation of platelet concentrates, centrifugation is first performed at room temperature. This separates the platelet-rich plasma fraction from the red blood cells. To separate all other blood components, centrifugation is carried out between 1° and 6°C.

The volume of the derived unit of packed RBCs is 200–220 ml with a hematocrit of 70–80% and a residual plasma volume of 50–60 ml. That plasma contains clotting factors. However, the residual concentrations of the two labile factors, V and VIII, may be too small to prevent a dilutional coagulopathy in association with very large volume transfusion. There are retained platelets but they become nonfunctional within 24 hours. Leukocytes are also present and can cause both febrile reactions and immunomodulatory effects (see [White Cell-Related Transfusion Reactions](#)). There are alternative RBC preparations that eliminate the various “passengers.” Saline-washed RBCs may be used for patients who experience reactions to foreign proteins. White cells can be removed by washing, irradiation, or leukofiltration. The administration of one unit of packed RBCs will increase the Hgb and Hct of a 70-kg adult by approximately 1 g · dl⁻¹ and 3%, respectively.

Compatibility Testing

Compatibility testing involves three separate procedures: ABO Rh blood type identification, antibody screening of donor plasma, and the donor–recipient cross-match.

ABO Rhesus Typing

Compatibility testing is carried out on both donor and recipient blood. The first step is to determine the ABO blood group type and the Rh status for both donor and recipient blood. This is a critical step because most fatal hemolytic transfusion reactions result from the transfusion of ABO-incompatible blood. Blood types are defined according to the antigens present on the surface of the red blood cell. Patients with Type A blood have type A antigens on the surface of their red cells. Type B blood has B antigens. When both antigens are present, the patient is said to have Type AB blood; and when both antigens are lacking, the patient is said to have Type O blood.

ABO typing involves determining not only which antigens are on the surface of the RBCs but also which antibodies are present in the serum. The serum constitutively contains antibodies to the AB antigens that are lacking on the RBC. Patients with Type A blood have antibodies against the B antigen and vice versa. Patients with no antigens on their cells, Type O blood, will have both anti-A and anti-B antibodies in the plasma.

Another important antigen may be present on the surface of red blood cells, the rhesus or Rho(D) antigen. Patients with this antigen are said to be Rh-positive and those who lack it are termed Rh-negative. Approximately 85% of the population is Rh-positive. In contrast to the A and B blood groups, when the D antigen is not present on the surface of the red cells, anti-D antibodies are not constitutively present in the serum. However, Rh-negative patients exposed to donor RBCs with the D antigen (Rh-positive blood) will usually produce anti-D antibodies. There is a latency before these antibodies are synthesized. As a consequence, the reaction between the Rh-positive donor cells and the anti-D evolves slowly and may not be clinically apparent on first exposure. This process whereby a foreign antigen stimulates the synthesis of the corresponding antibody is termed *alloimmunization* and is very significant. Approximately 60–70% of Rh-negative recipients will produce anti-D antibodies after receiving Rh-positive blood.²¹ Subsequent exposure of these Rh-negative individuals to Rh(D)-positive cells may result in an acute hemolytic reaction.

When determining what donor blood group types may be compatible for transfusion to a particular recipient, it is useful to focus on which antibodies will be present in the recipient serum. It is the reaction of these antibodies with donor RBC antigens that can activate complement and lead to hemolysis of the red cell. Type O+ recipients [Type O, Rh(D)-positive] will have both anti-A and anti-B antibodies, but not the anti-D antibody in their plasma. These patients must not receive Type A, Type B, or Type AB blood. They must receive Type O blood, but it may be either Rh-positive or Rh-negative. In contrast, patients with Type AB– blood (Type AB, Rh-negative) will lack both the A and B antibodies in their plasma, and may or may not have the anti-D antibody in their plasma. They can receive Type A–, Type B–, Type AB–, or Type O– blood. It should be clear that, in attempting to determine blood group and Rh compatibility between donor and recipient, patients with the fewest antigens on their cells (Type O-negative) have the most antibodies in their plasma. Patients with Type O-negative blood are called *universal donors*. In contrast patients with the most antigens on their cells (Type AB-positive) will have no antibodies to the A, B, or D antigens. These patients can receive all blood types (Types A+, A–, B+, B–, AB+, AB–, O+, and O–) and are referred to as *universal recipients* ([Table 10-2](#)).

| Antigen | O | A | B | AB | D |
|------------|----|----|----|----|----|
| Caucasians | 45 | 40 | 11 | 4 | 85 |
| Blacks | 49 | 27 | 20 | 4 | 92 |

Data from the Technical Manual (13th ed) of the American Association of Blood Banks.

Table 10-2. PREVALENCE (%) OF ABO AND Rh(D) BLOOD TYPES IN THE POPULATION OF THE UNITED STATES

The Antibody Screen

The second step in compatibility testing is called the antibody screen. It seeks the presence of recipient antibodies against RBC antigens. Commercially supplied RBCs, selected for the panel of antigens they possess, are mixed with both donor and recipient serum to screen for the presence of unexpected antibodies. Only about four blood donations in one thousand demonstrate unexpected antibodies. The likelihood that the antibody screen will miss a potentially dangerous antibody has been estimated to be no more than 1 in 10,000.²¹ If the recipient plasma screen is positive, the antibody must be identified and the appropriate antigen-negative donor units selected. The antibody screening of recipient plasma should be repeated if the patient has been transfused since the last antibody screening test. This is because transfusions produce newly detectable antibodies in about 1% of the units used.

The Cross-match

The third phase of compatibility testing is called the cross-match. Donor RBCs are mixed with recipient serum, simulating the actual anticipated transfusion. This test requires about 45 minutes and is carried out in three phases: (1) the immediate phase, (2) the incubation phase, and (3) the antiglobulin phase.

The immediate phase serves primarily to ensure that there have been no errors in ABO-Rh typing. The test entails examination of a mixture of donor RBCs and patient serum for macroscopic agglutination. This immediate phase cross-match requires only 1–5 minutes and detects both ABO incompatibilities and those caused by antibodies in the MN, P, and Lewis systems. These latter antibodies are naturally occurring antibodies that are usually present in low titers and are not reactive at physiologic temperatures. For this reason, the immediate phase crossmatch is carried out at room temperature.

The incubation phase requires 30–45 minutes and detects antibodies primarily in the Rh system. This phase is more time-consuming because, following the immediate cross-match, the donor RBCs and recipient serum must be incubated in albumin or low-ionic strength salt solution. This incubation phase aids in the detection of incomplete antibodies—antibodies that attach to a specific antigen but do not cause agglutination in a saline suspension of RBCs.²¹

The antiglobulin phase, or indirect antiglobulin test, involves the addition of antiglobulin sera at the end of the incubation phase. These antiglobulin sera contain antibodies that will bind to antiglobulins attached to antigens on the surface of the donor red blood cells. This phase is an attempt to identify the most incomplete antibodies (*i.e.*, those that do not cause agglutination) from all blood group systems, including the Rh, Kell, Kidd, and Duffy blood group systems.²¹ The incomplete antibodies that may be identified by the incubation and antiglobulin phases of the cross-match can cause serious hemolytic reactions.

Some have questioned the necessity for cross-matching. In patients who have been transfused previously or who may have been exposed to foreign red blood cell antigens during pregnancy, only 1 in 100 will have an antibody other than the anti-A, anti-B, and/or anti-Rh antibodies, and many of these are not reactive at physiologic temperatures. Determining the ABO blood group type and Rh status alone yields the probability that the transfusion will be compatible in 99.8% of instances. The addition of the 30–45-minute antibody screen improves the likelihood of a compatible transfusion to 99.94%; the addition of a complete cross-match increases this to 99.95%.⁷ In other words, in those patients who have not previously been transfused or pregnant, the odds that an incompatible transfusion will occur when uncross-matched blood is administered is just 1 in 1000.²¹ For those who have previously been exposed to foreign red blood cell antigens, the likelihood that they will have developed an antibody is about 1 in 100.²¹ Nonetheless, all blood banks perform the cross-match. However, these data reveal that the administration, in emergency situations, of uncross-matched blood to patients with no history of pregnancy or transfusion entails relatively low risk.

Type and Screen Orders

When blood is ordered preoperatively for surgical cases in which transfusion is unlikely, the orders should be for a “type and screen” only. If the need arises, the blood can be cross-matched prior to transfusion. The advantage of ordering a type and screen instead of type and cross-match is twofold. First, if the blood is not needed for that particular case, the additional expense of carrying out the cross-match step is eliminated. The first two steps of compatibility testing—determining the ABO and Rh type as well as performing the antibody screen using commercially supplied RBCs—must be performed on all donor units of blood regardless of who the recipient is to be. Second, if a cross-match is performed and compatible units identified, those units are held in reserve for that specific patient and hence are at least temporarily out of the blood supply. If the blood is not used, it is returned to the general supply; however, owing to blood’s limited shelf life, this process will have contributed to wastage by outdating.

C/T Ratios

If a unit of blood that has been cross-matched and reserved for a particular patient is not needed, that unit must be cross-matched again before administration to another patient. This duplication of the cross-match procedure is costly and inefficient. Blood banks track their “cross-match-to-transfusion” (C/T) ratios and attempt to maintain ratios of 2.1–2.7.²¹

The Maximal Surgical Blood Order Schedule

The maximal surgical blood order schedule (MSBOS) is another process that seeks to decrease the number of unnecessary cross-match procedures. Blood banks accumulate data on the average number of units of red blood cells actually transfused for each type of operation performed, by each surgeon. These data are used to define the maximal number of units that the blood bank will cross-match in advance of elective surgery.

Emergency Transfusions

The exsanguinating patient may require RBCs before complete compatibility testing can be performed. If testing is to be abbreviated, there is a preferred order for selecting partially tested blood. The first choice is to transfuse type-specific, partially cross-matched blood. Only the immediate phase macroagglutination test is performed on a mixture of donor RBCs and recipient serum. This immediate phase cross-match requires 1–5 minutes. This test is useful to confirm that there are no clerical or laboratory errors in defining the blood type of the patient and of the donor. The second preference is to give type-specific uncross-matched blood. The last option is to administer O-negative (universal donor) packed RBCs. O-negative whole blood should not be used because it may contain high titers of the anti-A and anti-B hemolytic antibodies. This would be harmful unless the patient also had Type O blood. It is recommended that even if the patient’s blood type becomes known and available, after 2 units of Type O-negative blood have been transfused, subsequent transfusion should continue with universal donor, Type O-negative blood. This is because even packed RBCs contain some plasma and in this plasma are antibodies. With transfusion of type O-negative blood, both anti-A and anti-B antibodies will be transfused as well. If subsequent units of donor blood are Type A, B, or AB, hemolysis may result because of a reaction between antibodies found in the plasma of the first donor units and antigens on RBCs of the new donor units. The patient should not receive his or her own type-specific blood until the transfused anti-A and anti-B antibody titers have fallen to safe levels.²¹

RISKS OF BLOOD PRODUCT ADMINISTRATION

Risks Associated with Transfusion of RBCs

The rapid transfusion of large volumes of stored blood can have several consequences. Some of these are functions of properties of the blood itself, of the agents used to preserve and anticoagulate it, and of the biochemical reactions that occur during storage.²¹ There are other complications that are not unique to blood transfusions, but which may occur with the rapid transfusion of any large volume of fluid.

Citrate Intoxication

Blood is stored in a CPDA anticoagulant preservative solution. The citrate in the solution prevents coagulation of stored blood by chelating ionized calcium. When large volumes of stored blood (>1 blood volume)²² are administered rapidly, the citrate can cause a temporary reduction in ionized calcium levels. Signs of citrate intoxication (hypocalcemia) include the following hemodynamic changes: hypotension, narrow pulse pressure, and elevated ventricular end-diastolic pressure and central venous pressure.²¹ ECG changes include prolonged Q-T interval, widened QRS complexes, and flattened T waves. The hypocalcemia is directly related to the rate and volume of blood being transfused. Citrate is metabolized efficiently by the liver, and decreased ionized calcium levels should not occur unless the rate of transfusion exceeds 1 ml · kg⁻¹ · min⁻¹ or about 1 unit of blood per 5 minutes in an average-sized adult.²¹ Impaired liver function or perfusion will lower the rate threshold for developing citrate intoxication. Treatment of hypocalcemia-related myocardial depression and hemodynamic instability entails iv administration of calcium, ideally after laboratory confirmation of the diagnosis.⁷

Acid–Base Changes

When citrate-phosphate-dextrose (CPD) solution is added to a unit of freshly drawn blood, pH decreases to ~7.0–7.1.²¹ Further reduction of pH will occur during storage as a consequence of ongoing metabolism of glucose to lactate. At the end of 21 days, the pH may be as low as 6.9, but much of this acidity is the result of the production of CO₂, which is rapidly eliminated following the transfusion. Whether rapid infusion of this acidic bank blood leads to metabolic acidosis is debated. In the past, some clinicians administered sodium bicarbonate empirically to patients on a fixed schedule (*e.g.*, sodium bicarbonate 44.6 mEq after each 5 units of bank blood infused). Others contend that the citrate from the CPD solution is metabolized by the patient to endogenous bicarbonate and that the acid–base disturbance is therefore self-correcting. Clinically, in the injured patient who is hypotensive, poorly perfused, and has inadequate tissue oxygenation, it is difficult to differentiate what portion of the metabolic acidosis is due to rapid transfusion and what portion is due to the production of lactic acid.²² The appropriate course is to base bicarbonate therapy on blood gas analysis.

Decreases in 2,3-Diphosphoglycerate (2,3-DPG)

Storage of RBCs is associated with a progressive decrease in intracellular ATP and 2,3-diphosphoglycerate (2,3-DPG). The resultant left shift of the O₂–Hgb dissociation curve has been described above. Accordingly, transfusing the 2,3-DPG-depleted blood, while increasing the patient’s Hgb value will result in less efficient oxygen delivery than would occur with native Hgb at the same Hct. After transfusion, 2,3-DPG levels return toward normal over 12–24 hours.²³

Hyperkalemia

During storage, potassium moves out of the RBCs, in part to maintain electrochemical neutrality as hydrogen ions generated during storage redistribute. The potassium concentration in plasma may reach levels variously reported to be between 17 and 35 mEq · l⁻¹ in blood stored for 21 days.²¹ With normal infusion rates, the potassium is redistributed throughout the extracellular space and does not present a clinical problem. However, hazard exists if large volumes of stored blood are administered rapidly. Rates in excess of 90–120 ml · min⁻¹ have been associated with hyperkalemia. Furthermore, while there is only 40–60 ml of plasma in a unit of

packed RBCs, contemporary infusion devices allow blood to be transfused at rates of 500–1000 ml · min⁻¹ and the replacement of four blood volumes per hour. With these infusion rates, critical hyperkalemia can occur quickly, and intraoperative arrests have been documented.²⁴ It is proposed that the hyperkalemia is aggravated by hypovolemia, hypothermia, and acidosis.²² ECG changes associated with hyperkalemia include peaked T waves, a prolonged PR interval, and a widened QRS complex. If ECG changes are observed, the transfusion should be stopped and intravenous calcium should be administered. Bicarbonate, dextrose, and insulin may also be appropriate according to the severity of the episode.⁷

Volume Overload

Circulatory volume overload occurs when blood or fluid is transfused too rapidly for compensatory fluid redistribution to take place.

Hypothermia

Packed red blood cells are stored at temperatures between 1° and 6°C, and hypothermia may result from the rapid transfusion of large volumes of cold blood. The administration of 1 unit of packed RBCs at 4°C will reduce the core temperature of a 70-kg patient by ~0.25°C. Transfusions administered rapidly or in substantial volume should be warmed to prevent hypothermia. With decreasing body temperature, cardiac output declines, tissue perfusion is impaired (as a consequence of both vasoconstriction and left-shifting of the O₂-Hgb dissociation curve), and metabolic acidosis may develop. Shivering on emergence can increase oxygen consumption by 400%. Hemostatic dysfunction (both primary hemostasis and coagulation) and ventricular irritability will become evident as body temperature declines. The latter is most likely to occur at and below 30°C and may be seen at higher core temperatures if unwarmed blood is administered, particularly through central access catheters, in a patient who is already moderately hypothermic. Hypothermia has been associated with increased postoperative morbidity and mortality including increased rates of postoperative infection.^{22,25}

Microaggregate Delivery

Stored blood contains microaggregates.²² Platelet aggregates form during the second to fifth day of storage; and after ~10 days, larger aggregates composed of fibrin, degenerated white cells, and platelets appear.²¹ Macroaggregates of RBCs also develop. Standard fluid administration sets contain 170mm filters, which will remove these larger “clots.” Micropore filters, typically with a 40mm pore size, have been advocated, but neither their efficiency at removing the microaggregates nor their contribution to patient well-being is certain. Microaggregates have been implicated in the pathogenesis of pulmonary insufficiency and the development of adult respiratory distress syndrome (ARDS), which often follows large-volume transfusions (defined as >110–12 units in 24 hours).^{22,26} However, the available data do not confirm this suspicion and suggest that pulmonary injury and the occurrence of ARDS are more often related to the type of injury and the magnitude or severity of the injury than to the volume of blood transfused.^{27,28} Hypotension and sepsis may play a much greater role in the development of ARDS than do microaggregates. Nonetheless, a practical consideration frequently prompts clinicians to introduce a micropore filter between the blood unit and the administration set. Unfiltered blood may clog the 170mm filter of the standard set and it is less time-consuming to change the 40mm filter periodically (e.g., after every fourth RBC unit) than to exchange the entire administration set.

Red blood cells are frequently diluted with crystalloid solutions to increase the rate at which the blood can be transfused. Normal saline is commonly recommended in preference to lactated Ringer's solution (LR). In fact, the amount of citrate present in stored blood is more than sufficient to bind the small amounts of calcium in the 100–300 ml of LR typically used for dilution.²⁹ Saline may nonetheless be preferable because, once the blood transfusion has finished, residual blood in the set may not have adequate amounts of citrate to bind the calcium in LR. It is then passed through the set, and clot formation may occur. There is no evidence that any clinically significant sequelae have resulted from the use of LR as an RBC diluent.²²

Dilutional Coagulopathy

Administration of large volumes of fluid deficient in or devoid of platelets and clotting factors predictably leads to the development of a coagulopathy as a consequence of dilution. There has been considerable discussion of whether, in the face of massive transfusion of blood products, patients will first manifest deficiencies of platelets or clotting factors. The initial conclusion was that thrombocytopenia would develop first. In retrospect, this clinical conclusion may have been a consequence of a wider use of whole blood than prevails today. In spite of the lability of factors V and VIII, sufficient concentrations of these factors probably remain in banked whole blood to maintain coagulation function even in the face of very large transfusions. The same is probably not true when patients receive only the small residual plasma volume associated with packed RBCs. Investigations of patients receiving large-volume isovolemic transfusions suggest that clinically significant dilution of fibrinogen; factors II, V, and VIII; and platelets will occur after volume exchanges of approximately 140%, 200–230%, and 230% (*i.e.*, 1.4, 2, and 2.3 blood volumes), respectively.³⁰ Resuscitation from hypovolemia will result in reaching these thresholds at smaller percentage volume exchanges. However, calculations of this nature should not be used as a guide to blood product administration but merely as a means of anticipating clinically relevant occurrences. The decision to administer fresh frozen plasma or platelets will depend on clinical and laboratory evidence of coagulopathy.

Immunologically Mediated Transfusion Reactions

Reactions to transfused blood products can occur as a result of the presence of constitutive antibodies (*e.g.*, anti-A, anti-B); antibodies formed as a result of prior exposure to donor RBCs, white blood cells, platelets, and/or proteins⁶; or as a consequence of the effects of transfused white cells.

Reactions to RBC Antigens

Immediate Hemolytic Transfusion Reactions

The most feared of the immune reactions is the immediate hemolytic transfusion reaction against foreign red blood cells. Hemolysis of the donor RBCs often leads to acute renal failure, disseminated intravascular coagulation, and death. There are more than 300 different antigens on human red cells, but many are weak immunogens that usually do not elicit a clinically detectable antibody response. The antibodies that fix complement and commonly produce immediate intravascular hemolysis include anti-A, anti-B, anti-Kell, anti-Kidd, anti-Lewis, and anti-Duffy.³¹

The incidence of immediate hemolytic transfusion reactions is estimated to be 1 per 6000–7000 units transfused.¹⁵ The result is commonly catastrophic, with mortality ranging from 20–60%.²¹ Physician errors have been reported to be responsible for 20% of the incompatible blood transfusions that have resulted in patient death.²²

When incompatible blood is administered, antibodies and complement in recipient plasma attack the corresponding antigens on donor RBCs. Hemolysis ensues. The hemolytic reaction may take place in the intravascular space and/or it may occur extravascularly within the endoplasmic reticulum. The antigen–antibody complexes activate Hageman factor (factor XII) which in turn acts on the kinin system to produce bradykinin. The release of bradykinin increases capillary permeability and dilates arterioles, both of which contribute to hypotension. Activation of the complement system results in the release of histamine and serotonin from mast cells, resulting in bronchospasm. Thirty to fifty percent of patients develop disseminated intravascular coagulation (DIC).³¹

Hemolysis releases hemoglobin into the blood. Initially it is bound to haptoglobin and albumin until the binding sites are saturated, then it circulates freely in the blood until it is excreted by the kidneys. Renal damage occurs for several reasons. Blood flow to the kidneys is reduced in the presence of systemic hypotension and renal vasoconstriction. Free hemoglobin and RBC stroma (not Hgb) may precipitate in the renal tubules, causing mechanical obstruction and nephrotoxicity.^{21,31} Antigen–antibody complexes may be deposited in the glomeruli. If the patient develops DIC, fibrin thrombi will also be deposited in the renal vasculature, further compromising perfusion.

The signs and symptoms of a hemolytic transfusion reaction include fever, chills, nausea and vomiting, diarrhea, and rigors. The patient is hypotensive and tachycardic (bradykinin effects), and may appear flushed and dyspneic (histamine). Chest and back pains result from diffuse intravascular occlusion by agglutinated RBCs. The patient is often restless, has a headache, and feels a sense of impending doom. Hemoglobinuria will occur as well as diffuse bleeding with the development of DIC. With renal failure, oliguria develops. During general anesthesia, many signs are masked. Hypotension and hemoglobinuria and diffuse bleeding may be the only clues that a hemolytic transfusion reaction has occurred. However, hypotension and bleeding are nonspecific and fairly common in the operating room environment; thus the diagnosis may not be suspected until hemoglobinuria is observed. A reasonable index of suspicion should be maintained during administration of RBCs to anesthetized patients in order to avoid critical delay in diagnosis.

If a reaction is suspected, the transfusion should be stopped and the identity of the patient and the labeling of the blood should be rechecked. Management has three main objectives—maintenance of systemic blood pressure, preservation of renal function, and the prevention of DIC. Systemic blood pressure should be supported by administration of volume, pressors, and ionotropes as required. Urine output should be promoted by administration of fluids and the use of diuretics, either mannitol or furosemide, or both. Sodium bicarbonate can be administered to alkalinize the urine. Currently, there is no specific therapy to prevent the development of DIC.

However, preventing hypotension and supporting cardiac output to prevent stasis and hypoperfusion, both of which contribute to the evolution of DIC, are important.

Blood samples should be collected in an EDTA tube. The specific tests should include (1) a repeat cross-match and (2) a direct antiglobulin (Coombs) test. The direct antiglobulin test is the definitive test for an acute hemolytic transfusion reaction. It examines recipient RBCs for the presence of surface immunoglobulins and complement. Patient serum is also examined for the presence of antibodies that react with the donor cells. Serum haptoglobin level, plasma and urine Hgb, and bilirubin assays are usually performed. However, these are evidence only of hemolysis, not specifically of an immune reaction.³¹ Laboratory tests to establish baseline coagulation status—including platelet count, prothrombin time (PT), “activated” partial thromboplastin time (aPTT), thrombin time (TT), fibrinogen level, and fibrin degradation products (FDPs)—should be performed.

Examination of the patient's plasma after brief centrifugation for the pinkish discoloration caused by free hemoglobin is a simple, rapid screening test when a hemolytic transfusion reaction is suspected.³¹ Hemolysis can be due to other causes including overheating prior to transfusion or inadvertent use of a hypotonic solution as a diluent. However, hemolysis should be assumed to indicate a hemolytic transfusion reaction until proven otherwise.

Delayed Hemolytic Transfusion Reactions

Numerous instances have been reported in which transfused RBCs are quickly eliminated from the circulation of the recipient after an apparently “compatible” cross-match. Many of these events are delayed hemolytic transfusion reactions. These reactions occur when the donor RBCs bear an antigen to which the recipient has previously been exposed, either by transfusion or by pregnancy. Over time, the recipient antibodies fall to levels too low to be detected by compatibility testing. When transfused again with RBCs containing the original immunizing antigen, the recipient undergoes an anamnestic response and produces more antibody, which eventually lyses the foreign RBCs. Typically, the antibody-coated RBC is sequestered extravascularly and lysis occurs in the spleen and reticuloendothelial system. Because the RBC destruction occurs extravascularly, symptoms are less severe and the reaction is less likely to be fatal. Unlike immediate hemolytic reactions, which usually involve antibodies in the ABO system, delayed hemolytic reactions commonly involve antibodies in the Rh and Kidd systems. The frequency of delayed hemolytic reactions is reported to be 1 per 800–2500 transfusions.^{6,31}

Evidence of hemolysis is usually detected by the first or second week following transfusion. The reaction may be undetected or may be identified because of the combination of a low-grade fever, increased bilirubin with or without mild jaundice, and/or an unexplained reduction in hemoglobin concentration.⁶ The diagnosis is confirmed by a positive direct antiglobulin test (Coombs test). The reaction is self-limiting, and the clinical manifestations resolve as the transfused cells are removed from the circulation.³¹

Transfusion Reactions to Donor Proteins

Allergic reactions to proteins in donor plasma cause urticarial reactions in 0.2–2% of all transfusions.²² The reaction is almost always associated with the transfusion of fresh frozen plasma; but because a small volume of donor plasma is present in other blood products (RBCs, platelets), allergic reactions can occur with transfusion of these components as well. The patient may have itching, swelling, and a rash due to the release of histamine. These mild symptoms can be treated with diphenhydramine. Patients who experience severe urticarial reactions may benefit from the use of saline-washed cells.³¹

Infrequently, a more severe form of allergic reaction involving anaphylaxis will occur in which the patient experiences dyspnea, bronchospasm, hypotension, laryngeal edema, chest pain, and shock. Anaphylaxis precipitated by a transfusion is a rare, but potentially fatal, event. It occurs when patients with hereditary IgA deficiency who have been sensitized by previous transfusions or pregnancy are exposed to blood with “foreign” IgA protein. Treatment consists of discontinuation of the transfusion and administration of epinephrine and methylprednisolone. Washed RBCs, frozen deglycerolized RBCs, or RBCs from IgA-deficient donors should subsequently be used for these patients.³¹

White Cell–Related Transfusion Reactions

Febrile Reactions

Patients who receive multiple transfusions of packed RBCs or platelets often develop antibodies to the human leukocyte antigens (HLAs) on the passenger leukocytes in these products. During future RBC transfusions, febrile reactions may occur as a result of antibody attack on donor leukocytes. The leukocyte antigen–antibody reaction is thought to cause lysis of donor granulocytes with the release of chemical mediators. Phagocytosis of donor leukocyte fragments may also stimulate host macrophages to produce pyrogens.

The febrile response occurs in about 1% of all RBC transfusions. For most patients, the reaction can be characterized as troublesome and unpleasant, rather than clinically serious. Typically, the patient experiences a temperature increase of more than 1°C within 4 hours of a blood transfusion and defervesces within 48 hours.³¹ Patients may experience fever only, but they may also develop chills, respiratory distress, anxiety,²⁶ headache, myalgias, nausea, and a nonproductive cough. Febrile reactions can be treated with acetaminophen.

A leukocyte-mediated febrile transfusion reaction should be distinguished from a hemolytic transfusion reaction (direct Coombs test), which also presents with a fever but may be life-threatening. Commercially available leukodepletion filters may be used to prevent febrile, nonhemolytic transfusion reactions.

Graft-versus-Host Disease (GVHD)

Packed RBCs and platelet concentrates both contain a significant number of viable donor lymphocytes. When transfused (“transplanted”) into immunocompromised patients, the donor lymphocytes may become engrafted, proliferate, and establish an immune response against the recipient. In essence, the engrafted lymphocytes reject the host.³²

Patients at risk for GVHD include organ transplant recipients, neonates who have undergone a blood-exchange transfusion,³¹ and patients immunocompromised by many other disease processes. GVHD typically progresses rapidly to pancytopenia, and the fatality rate is very high.

Transfusion-associated GVHD has also been reported in apparently immunocompetent patients when a genetic relationship exists between the donor and the recipient. In these tragic cases, the patient shares human leukocyte antigen haplotypes with the donor lymphocytes. The patients, although immunologically competent, fail to reject the transfused cells because they do not recognize them as foreign. The transfused donor lymphocytes, however, recognize the host as foreign, and a GVHD reaction takes place.³³ Because of this phenomenon, the American Association of Blood Banks has recommended that directed donations from first-degree relatives be irradiated to inactivate donor lymphocytes.

GVHD has been reported with the transfusion of whole blood, packed RBCs, granulocytes, platelets, and fresh, not frozen, plasma. It has not occurred following transfusion of FFP, cryoprecipitate, or frozen RBCs.³³ Irradiation of cellular blood products should be done prior to transfusion in immunocompromised patients. Because of the increased probability of HLA haplotype sharing, directed donor units from relatives should always be irradiated.²⁶

Transfusion-Related Acute Lung Injury (TRALI)

Transfusion-related acute lung injury is a rare reaction (~1/10,000 transfusions³⁴) that occurs as a consequence of the deposition of white cell–antibody aggregates in the pulmonary vasculature. In most instances, it occurs when agents present in the plasma phase of donor blood activate leukocytes in the host.³⁵ Those agents are probably most often antileukocyte antibodies formed as a result of previous transfusion or pregnancy, although cytokines and biologically active lipids may also provide the trigger. In other instances, the opposite reaction, aggregation of donor leukocytes and recipient antibodies, may be the cause when the recipient has been alloimmunized to WBC antigens. The clinical picture is very similar to the adult respiratory distress syndrome (ARDS). Beginning soon after transfusion, the patient complains of dyspnea and chills and presents with a fever and noncardiogenic pulmonary edema. Chest x-ray reveals bilateral infiltrates. Severe pulmonary insufficiency develops. Treatment is largely supportive. The transfusion should be stopped if the reaction is recognized in time. The patient should be given supplemental oxygen and methylprednisolone every 6 hours. While outcome is more favorable than for ARDS, the reaction can be fatal in as many as 20% of patients. Patients who have experienced this reaction previously may benefit from the use of washed PRBCs.

Immunomodulation

Alteration of immune function has been associated with allogenic transfusion. The initial observations were of decreased rates of transplant rejection and decreased rates of spontaneous abortion in patients who had received homologous transfusions. Alteration in immune surveillance was inferred. Subsequently other,

nonbeneficial effects of diminished immunocompetence were reported. These include increased incidence of postoperative infection, earlier recurrence of cancer,^{36,37,38,39,40,41,42,43,44,45} and ⁴⁶ and more rapid progression of HIV/AIDS.⁴⁷ Transfused white cells are thought to be the mediators of these effects, although the precise mechanisms have not been defined. These observations have led to the development and application of techniques for leukocyte depletion of donor blood products.⁴⁸

Leukodepletion

The first widely accepted application of leukodepletion was in oncologic patients, in particular, those with leukemias who faced the prospect of multiple transfusions and were therefore at risk for the development of alloimmunization and platelet refractoriness.⁴⁹ Other benefits of leukodepletion have subsequently been demonstrated. These include: prevention of febrile reactions to RBC transfusions, reduction of postoperative infections and duration of hospitalization,⁵⁰ and prevention of transmission of cytomegalovirus (but not other viruses).⁵¹ As noted earlier, increased rates of tumor recurrence have also been reported in cancer patients who receive transfusions. However, this association has not been consistently evident in carefully controlled trials,⁴⁸ and the relevance of leukodepletion to cancer recurrence or progression remains undefined. Blood administration has also been identified as a correlate of decreased survival in HIV infected patients, though a cause-and-effect relationship has not been established.⁵² Again the relevance of leukodepletion must be viewed as unproven. Leukodepletion does not appear to prevent the occurrence of GVHD, apparently because of incomplete elimination of lymphocytes. Irradiation remains the only effective means for preventing GVHD.⁴⁸ Table 10-3 lists the benefits of leukodepletion.

| CONFIRMED BENEFITS | |
|---|--|
| Decreased alloimmunization / platelet refractoriness in multiply transfused leukemics | |
| Prevention of febrile reactions to RBC transfusions | |
| Decreased postoperative infections | |
| Shortened hospitalization | |
| UNCONFIRMED BENEFITS | |
| Prevention of transfusion-related HIV acceleration | |
| Prevention of transfusion-related increase in tumor recurrence | |

Table 10-3. BENEFITS OF LEUKODEPLETION

Taken together, these benefits have produced substantial interest in leukodepletion. However, the issue of whether or not a clinician should request leukodepleted blood (or administer blood components through a bedside leukodepletion filter) will soon be moot. Because of the perceived benefits, many countries—including Canada, France, Portugal, and the United Kingdom—and certain states and regions within the United States have already adopted the practice of leukodepleting 100% of their blood supplies. Others will follow. Most will employ prestorage depletion to prevent the release of mediators from WBCs during storage. This is especially relevant to platelets that are stored at room temperature. In the interim, clinicians using bedside filtering should appreciate that the available filters are less efficient at higher temperatures and filtering should therefore ideally be performed before blood warms to room temperature. Clinicians should also be attentive to the possibility of severe, apparently bradykinin-mediated, hypotension in patients who receive bedside-filtered blood. The reaction appears to occur more frequently, though not exclusively, in patients receiving angiotensin-converting enzyme inhibitors (which reduce breakdown of bradykinin).⁵³

Infectious Risks Associated with Blood Product Administration

The transfusion of blood products may be life-saving. However, the purpose may be in part defeated if the transfusion results in a life-threatening infectious disease. The appearance of HIV/AIDS in the early 1980s initiated a heightened consciousness of the infectious hazards of transfusion and brought new restraint to transfusion practices. The potentially transmittable diseases/agents are numerous. They include several viruses—hepatitis A, B, C, D, E, and G; the human T-cell lymphotropic viruses (HTLV-1, HTLV-2); the human immunodeficiency viruses 1 and 2; cytomegalovirus (CMV); and the Epstein-Barr virus—as well as prions (Jacob-Creutzfeldt) bacteria, parasites (malaria, Chagas' disease), and syphilis.^{54,55} Bacterial and parasitic contamination of blood products is rare, and transmission of the CMV virus, though common, is usually a threat only to immunocompromised patients or neonates and infants. It is HIV and the various forms of hepatitis that pose the greatest risk to immunologically normal patients. Goodnough *et al* have provided a detailed review of this topic.⁵⁵

Incidence of Viral Diseases

The rate of infectivity in the North American blood supply has decreased dramatically in the last two decades. The 1996 estimates of the risks of transmission of HIV, HTLV, hepatitis B, and hepatitis C are presented in Table 10-4. Those estimates are derived from the observed rates of seropositivity among donors and the statistical likelihood of administration of blood from donors whose infection is in the window period between contracting the virus and detectability by the available assays.

| | |
|--|-----------|
| Hepatitis B (HBV) | 1/63,000 |
| Hepatitis C (HCV) | 1/103,000 |
| Human immunodeficiency virus (HIV) | 1/493,000 |
| Human T-cell lymphotropic virus (HTLV) | 1/641,000 |

Table 10-4. ESTIMATES OF THE RATE (PER DONOR EXPOSURE) OF TRANSFUSION-TRANSMITTED VIRAL DISEASE⁵⁶

The dramatic reduction in the rate of HIV transmission after the early 1980s was the product of social screening of donors and HIV antibody testing (introduced in 1985). The 1996 transmission estimate of 1 infection per 493,000 donor exposures was made just at the time of the implementation of testing for the HIV p24 antigen. Because the HIV antigen appears prior to the antibody, the window of silent infectivity is shortened and the transmission rate should be even further decreased. A new generation of tests for HIV and HCV based on amplification of nucleic acid antigens by polymerase chain reaction has been developed recently. However, this nucleic acid antigen test (NAT) procedure will probably have only a small additional impact on absolute number of transfusion-related HIV events because the current rate is so low and because the silent window will only be reduced by an additional 6 days (from 16 to 10). The effect on HCV (hepatitis C) rates should be greater as the window is reduced from ~75 days to 30 days. Schreiber *et al* estimated HCV and HBV (hepatitis C) risk reductions of 72 and 42%, respectively, as a consequence of NAT testing.⁵⁶

Post-Transfusion Viral Hepatitis (PTH)

Since the 1940s, when blood transfusions first became possible, viral hepatitis has been the foremost risk to patients who receive blood. Hepatitis B and C account for 88% of the 1/34,000 risk of a significant transfusion-related viral disease blood transfusion that prevailed in 1996 (prior to implementation of p24 and NAT testing). The hepatitis A virus, cytomegalovirus, and the Epstein-Barr virus (EBV) cause hepatitis at much lower frequencies. The diagnosis of PTH is frequently missed or delayed because fewer than 50% of patients become jaundiced during the acute phase of the disease and many are asymptomatic as well as anicteric.

Hepatitis C. HCV (the agent responsible for most of what was previously termed non-A, non-B; NANB) is more common and conveys greater patient risk than HBV.

Despite HCV's commonly mild initial presentation, in 85% of patients it progresses to a chronic state with significant associated morbidity and mortality. Twenty percent of chronic carriers develop cirrhosis and 1–5% develop hepatocellular carcinoma.^{57,58}

Hepatitis B. It is estimated that 35% of HBV-exposed patients will develop acute disease,⁵⁵ although ~1% will develop fulminant acute hepatitis. In ~85% of patients, the disease resolves spontaneously, 9% develop chronic persistent hepatitis, 3% develop chronic active hepatitis, 1% develop cirrhosis with or without chronic active hepatitis, and 1% develop hepatocellular carcinoma.¹⁵ The diagnosis of HBV depends on the presence of hepatitis B surface antigen (HbsAg) or the antibody to hepatitis B core antigen (anti-HBc).

Hepatitis A

Hepatitis A does not play an important role in PTH. Blood banks do not screen for hepatitis A, and there is no carrier state for this virus. The infectious period is limited to 1–2 weeks. The diagnosis depends on hepatitis antibody seroconversion.

Human Immunodeficiency Virus (HIV)

The most feared complication of a blood transfusion is the transmission of HIV, the causative agent of the acquired immune deficiency syndrome (AIDS). It is a retrovirus, so called because its propagation requires translation of RNA to DNA. Current screening tests are directed at both HIV 1 and HIV 2, though the latter has been an extremely infrequent cause of human disease. The incidence of transfusion-related HIV infection has fallen dramatically since the implementation of serologic screening of donors. There were 714 reports to the Centers for Disease Control in 1984, but only five cases per year over the ensuing five years.⁵⁵

Human T-Cell Lymphotropic Virus (HTLV)

HTLV-1 and HTLV-2 belong to the same retrovirus family as HIV. The incidence of clinical disease resulting from transmitted virus appears to be very low. They are associated with T-cell leukemia and lymphoma rather than the generalized immunodeficiency of AIDS. In the United States, all donor units are screened for the presence of antibody to HTLV-1 and HTLV-2.

Cytomegalovirus (CMV)

Transfusion-associated CMV infections are usually benign and self-limited. However CMV may cause serious, even fatal, infections in immunocompromised patients. Patients at risk include premature neonates, solid organ and bone marrow transplant recipients, and those patients with severely depressed immune function. CMV pneumonia is an important infectious cause of death in allogenic bone marrow transplant recipients.⁵¹ Leukodepletion effectively prevents CMV transmission.⁵¹

Bacterial Contamination of Blood Components

RBCs

Bacterial contamination, estimated at 1/1,000,000 RBC units, is relatively uncommon.⁵⁹ *Yersinia enterocolitica* is the most common contaminant and is associated with substantial mortality. The patient who receives contaminated blood transfusion will rapidly experience some combination of fever, chills, tachycardia, emesis, shock, and may develop DIC and acute renal failure. The symptoms are very similar to those of immediate hemolytic transfusion reaction. The transfusion should be stopped immediately and blood cultures obtained.³¹

Platelets

Platelets, which are stored at room temperature, are more commonly contaminated. Goodnough *et al* quote the incidence as 1/12,000 and identify the organisms in order of frequency as *Staphylococcus aureus*, *Klebsiella Pneumoniae*, *Serratia marcescens*, and *Staphylococcus epidermidis*.⁵⁵ The reactions are variable in severity, and an index of suspicion should be maintained in order to distinguish these reactions from other major and minor transfusion reactions.

BLOOD CONSERVATION STRATEGIES

Autologous Donation

Preoperative donation and perioperative salvage of autologous blood have been used extensively as part of programs to reduce homologous blood administration. Autologous blood may be collected days to weeks prior to surgery (predonation); it may be donated immediately prior to surgery (isovolemic hemodilution); or it may be salvaged from the surgical field or wound drains and reinfused (blood salvage). Deciding whether any of these options is appropriate for individual patients presents another challenge in transfusion medicine.

Preoperative Autologous Donation

Preoperative donation of autologous blood (PAD) should be considered for patients undergoing elective surgical procedures in which the administration of homologous blood is expected.⁶⁰ Major orthopedic surgical procedures, such as total hip or total knee replacement, scoliosis procedures, and cardiac surgery are well suited to PAD.⁶¹ PAD should not be recommended for patients undergoing surgery that usually does not require transfusion. The PAD procedure is more expensive than the collection of homologous blood. In addition, if autologous blood is unused, most institutions discard it and do not permit "crossover" to other patients.

Practices with respect to infectious agent testing also vary. Some institutions will store and permit return to the donor of HIV-, hepatitis-, or CMV-infected blood, while others discard it. Note also that the transfusion of autologous blood eliminates neither the chance of human error during blood collection, processing, and reinfusion nor the risk of bacterial contamination. Some institutions perform a crossmatch prior to return of blood to the donor, others do not. This underscores the caveat that no transfusion is without risk.

The medical condition of the patient must be considered prior to recommending predonation of blood.⁶⁰ Severe aortic stenosis, significant coronary disease or myocardial dysfunction, low initial hematocrit, and low blood volume (weight less than ~110 pounds) are relative contraindications to PAD.⁶² If the patient's hemoglobin level, cardiac status, and general condition permit, blood can be donated at weekly intervals prior to surgery. Four units is typically the maximum donation given the shelf life of the first unit collected. The blood is stored at 4°C or, if it must be kept for longer periods of time, it can be stored as frozen RBCs.²¹

PAD has been widely, but not universally, effective in reducing exposure to homologous blood.⁶³ Open prostatic surgery and joint replacement have been most widely studied. Effectiveness has been limited when the patients' erythropoietic response is not vigorous, in which case the process may simply result in an anemia at the time of surgery. Patients making PAD should invariably receive supplemental iron. In addition, PAD can be supplemented with administration of recombinant erythropoietin (Epo). The effectiveness of Epo in hastening recovery of hematocrit in conjunction with PAD and in improving hematocrit in patients not submitted to PAD has been demonstrated.^{64,65,66} and ⁶⁷ However, the practice has not become widespread, in part because of the expense of the agent and in part because of the necessity for frequent (*e.g.*, thrice weekly) parenteral (sc or iv) administration of Epo. Epo is usually accepted by Jehovah's Witnesses, and its efficacy in that population has been demonstrated.⁶⁸

Acute Normovolemic Hemodilution

Normovolemic hemodilution entails withdrawal of the patient's blood, usually *via* an intra-arterial catheter, early in the intraoperative period with concurrent administration of crystalloids or colloids to maintain normovolemia. The rationale is that during the ensuing surgery, the patient will lose blood of low hematocrit and the withdrawn blood will be available for reinfusion at the end of the operation. The end point for the initial withdrawal is an Hct of 27–33%, depending on the patient's cardiovascular¹ and respiratory reserves.⁷ Selection for this technique should rely on careful evaluation of the patient for coronary or cerebral vascular disease. This procedure evolved in the anticipation that it would reduce total RBC loss and homologous blood administration. However, both mathematical modeling and empirical experience have revealed a very modest benefit with respect to reducing the necessity for homologous RBCs.^{67,69,70,71,72} and ⁷³ The technique has also been employed for the purpose of making fresh autologous blood at the end of procedures in which either a dilutional or cardiopulmonary bypass-related coagulopathy may occur. The efficacy in this context has not been confirmed by systematic study. Blood collected and reinfused for this purpose should not be passed through a 40mm filter to avoid

platelet elimination.

Perioperative Blood Salvage

Perioperative blood salvage is the recovery of shed blood from the surgical field or wound drains and readministration to the patient. In most instances, the process involves “washing” of the salvaged material with return of only the RBC component of blood. In some instances, usually those involving wound drainage, blood is returned filtered but otherwise unprocessed.

Intraoperative Blood Salvage

Intraoperative blood salvage (IBS) is employed with many surgical procedures that might otherwise necessitate homologous transfusion. Relatively simple devices that anticoagulate the suctioned blood and return it through a standard 170mm filter without other processing are available. However, most current IBS involves more complicated apparatus (“cell savers”), entailing significant costs including that of dedicated personnel.⁷ These cell saver devices anticoagulate the salvaged blood as it leaves the surgical field, separate the RBCs from other liquid and cellular elements by centrifugation, then wash the salvaged RBCs extensively with saline. The cells are typically returned to the patient in aliquots of 125 or 225 ml of saline-suspended RBCs with an Hct of 45–65%.⁷⁴ Higher hematocrits can be achieved at the expense of the time required for more prolonged centrifugation.

IBS has been used commonly during cardiovascular surgical procedures, aortic reconstruction, spinal instrumentation, joint arthroplasty, liver transplantation, resection of arteriovenous malformations,²⁰ and occasionally in the management of trauma patients. There have been numerous demonstrations that IBS can reduce the use of homologous RBCs.^{75,76}

The presence of malignant cells has been viewed as a contraindication, as have infection and the presence of urine, bowel contents, and amniotic fluid in the operative field. However, IBS has been applied in the management of hepatic and urologic malignancies without evidence of metastasis, even though malignant cells are known to be retained with RBCs after the washing process.^{77,78} At least one IBS washing device has also been shown to remove the critical procoagulant factors present in amniotic fluid,⁷⁹ and IBS has been employed successfully in cesarean section.⁸⁰

The potential complications of IBS are largely a function of the reinfusion of materials that might remain after the washing process. These include fat, microaggregates (platelets and leukocytes), air, red cell stroma, free hemoglobin, heparin, bacteria, and debris from the surgical field. Most of these are in fact removed quite efficiently by contemporary cell saver equipment. Bacteria are the exception, and contamination of cell saver return with skin organisms is relatively common.⁷⁵ Massive air embolism has occurred as a result of user error. Direct return from the cell saver apparatus has now been largely abandoned in favor of return *via* an intermediary bag under the control of the anesthesiologist. Care should still be taken in the event that pressure infusor devices are applied to these bags.

A dilutional coagulopathy in association with large-volume IBS is to be expected because essentially all clotting factors and most platelets are removed by the washing process. Management is the same as that for a dilutional coagulopathy occurring with administration of homologous or PAD blood. However, a DIC-like coagulopathy, the “salvaged blood syndrome,”⁸¹ has also been associated with IBS. It seems likely that this syndrome was the result of inadequate preparation of blood by older cell saver devices. Unwashed, salvaged blood has been shown to contain numerous constituents that influence the coagulation process: thromboplastic material, interleukins, complement, fibrin degradation products, and factors released from activated leukocytes and platelets.²⁰ The majority of these, however, are quite efficiently removed by contemporary processing devices and their presence is used as an argument against the return of unprocessed blood.⁸²

An additional coagulopathy risk arises with the use of thrombin and microfibrillar collagen or cellulose products in the surgical field.⁸³ These agents are not reliably removed by the washing process; suction of blood to the IBS device should be discontinued during the use of these agents and resumed after the field has been irrigated.

Postoperative Blood Salvage

Post-operative recovery of blood from mediastinal chest tubes and wound drains after hip and knee replacement with immediate reinfusion of “unwashed” blood has been employed quite commonly. The many substances present in the unprocessed blood (previous section) suggest that coagulation dysfunction might result and some authorities are skeptical regarding the wisdom of this practice.^{74,82} However, there have been only occasional reports of apparent adverse consequences.⁸⁴ This may reflect the fact that the recovered and reinfused volumes are usually small.

The Jehovah's Witness

In general, Jehovah's Witnesses will accept neither administration of homologous blood products nor the readministration of autologous products that have left the circulation. However, their faith allows significant personal discretion, so the wishes of each patient must be clarified. Few will permit the administration of the common whole blood components and the majority will decline PAD. But many will accept procedures that maintain extracorporeal blood in continuity with the circulation. The acceptability of cardiopulmonary bypass, acute normovolemic hemodilution, and perioperative cell salvage must be clarified with each patient individually. Most will permit administration of Epo.

THE HEMOSTATIC MECHANISM

Normal “hemostasis” involves a remarkable series of physiologic checks and balances that assure that blood remains in an invariably liquid state as it circulates throughout the body but transforms rapidly to a solid state once the vascular network is violated. The balance is delicate and complex, and it is the responsibility of the anesthesiologist to anticipate, prevent, and treat disturbances of that balance. Preoperative evaluation must identify those patients whose inherited or acquired medical conditions or whose current medications may influence these processes. With respect to medications, there are a rapidly increasing number of agents that are administered specifically for the purpose of altering the hemostatic balance, including ticlopidine, tissue plasminogen activator (t-PA), and low-molecular-weight heparin. As the patient proceeds through surgery and the postoperative period, the anesthesiologist must determine whether bleeding is surgical in nature or the result of a pre-existing or evolving hemostatic defect that will require the transfusion of hemostatic blood components—platelets, fresh frozen plasma, or cryoprecipitate—or the administration of pharmacologic agents.

Normal hemostasis involves three intertwined processes that occur almost simultaneously: primary hemostasis (formation of a friable platelet plug); coagulation or secondary hemostasis (reinforcement of the friable platelet plug by the formation of a firm fibrin clot); and fibrinolysis (clot lysis and restoration of blood flow through the recanalized vessel).

Step 1: Primary Hemostasis

Primary hemostasis begins within seconds of vascular injury and is complete within ~5 minutes. It results in the formation of a friable platelet plug that temporarily arrests bleeding until clot formation (coagulation) and vascular repair can occur. It requires the concerted actions of blood vessels and platelets.

Role of the Blood Vessels

Blood vessels are crucial to all three processes of the hemostatic mechanism. The intima of blood vessels is lined with a single layer of endothelial cells (Fig. 10-1). Deep to the endothelium is a layer of supportive collagenous tissue and smooth muscle cells. Loss of the endothelial surface is the critical event that sets the hemostatic mechanism in motion. When the endothelial layer is denuded, circulating platelets are exposed to collagen and platelet activation is initiated. In addition, injured blood vessels constrict, thereby shunting blood flow away from the site of vascular injury.

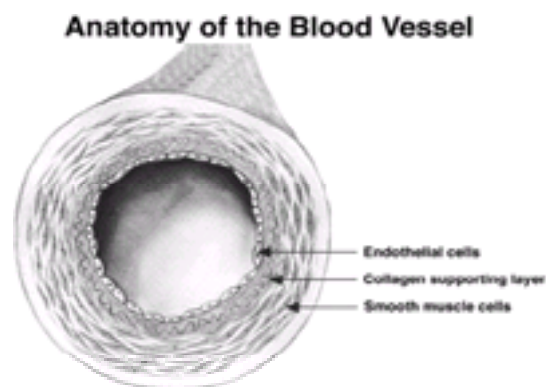

Figure 10-1. Blood vessel anatomy. The normal vascular tree resists thrombogenesis primarily because of the presence of the endothelium. By contrast, the subendothelial layer is highly thrombogenic. When exposed, proteins (collagen, fibronectin, etc.) in the subendothelium stimulate platelet adhesion and initiate the coagulation cascade.

Role of Platelets

Because of their small size, circulating platelets move preferentially along the walls of blood vessels where flow is slower.⁸⁵ These margined platelets, in essence, “patrol” the vessel wall until they encounter a break in the endothelial surface. When platelets are exposed to collagen and other proteins in the subendothelial matrix, “platelet activation” occurs. Activation involves four processes: adhesion, shape change and mediator release, aggregation, and the appearance of surface phospholipid.

Platelet Adhesion. Platelet adhesion to collagen results in conformational and surface changes by the platelet. A series glycoprotein surface receptors appear. Some of these receptors facilitate platelet adhesion to collagen and other vessel wall proteins and other receptors permit platelet to platelet binding (aggregation) (Fig. 10-2). The nomenclature of platelet receptors (GPI, GPIa, GPII, GPIII, etc.) is related to their electrophoretic mobility.⁸⁵

Figure 10-2. Platelet adhesion and aggregation. When the endothelium is denuded, von Willebrand factor (vWF) binds to collagen in the subendothelial layer. Platelets patrolling the blood vessel lining adhere *via* their glycoprotein (GP) 1b receptors to vWF. The binding of vWF to the GP1b receptors initiates platelet activation. Platelets change their shape from discoid to spheroid and extrude multiple pseudopods. Platelets aggregate to one another by crosslinking *via* fibrinogen (or vWF, not shown) between glycoprotein IIb/IIIa receptors expressed on the platelet surface during the process of platelet activation.

VON WILLEBRAND FACTOR. *In vitro* studies indicate that under conditions of stasis or low flow in the venous circulation, platelets will adhere to surfaces coated with collagen, fibronectin, or laminin. However, under the high-shear conditions that prevail in arterioles and the microcirculation, collagen, fibronectin, or laminin are insufficient to support platelet adhesion.⁸⁶ These conditions require the von Willebrand factor (vWF). vWF is a multimeric glycoprotein that circulates in plasma attached to Factor VIII. It is synthesized by endothelial cells, which both secrete it into the plasma and deposit it in the subendothelial matrix. vWF is also synthesized by megakaryocytes and stored in the alpha granules of platelets.

When the subendothelium of a vessel is damaged, circulating vWF binds to the exposed collagen. Circulating platelets adhere to the vWF *via* GPIb receptors on the platelet surface.^{85,87,88,89} and ⁹⁰ In this way, the vWF helps platelets to adhere to the collagen. Defects in vWF cause the von Willebrand syndrome, while defects in the corresponding platelet receptor (GPIb) are responsible for the Bernard-Soulier syndrome.⁹¹

Platelet Shape Change and Mediator Release. Adhesion of platelets to collagen converts the metabolically quiescent platelets to active cells which undergo rapid membrane, cytoskeletal, and metabolic changes. The activated platelets change from flattened discs to irregular spheroids which extend numerous pseudopods or “spiney” cytoplasmic processes.^{85,91} This shape change is reversible in its early stages, but sustained stimuli quickly lead to irreversible shape changes and granule release.

Platelets contain both dense granules and alpha granules. In the process of platelet activation, the granule membranes are disrupted and the contents released.⁹² Substances released from the alpha granules include adhesive proteins (vWF, fibrinogen, fibronectin, thrombospondin), growth modulators [e.g., platelet-derived growth factor (PDGF)], and coagulation factors (V and XI, protein S, plasminogen activator inhibitor). Dense granules release calcium, ADP, ATP, serotonin, and histamine^{85,93} (Fig. 10-3). The ADP released from the alpha granules is a powerful platelet activator and proaggregant which rapidly recruits other platelets to the growing platelet mass.

Figure 10-3. Platelet release reaction. Platelets undergo a release reaction coincident with shape change or in response to physiologic agonists including epinephrine, ADP, and thrombin. The numerous substances released from the alpha and dense granules of platelets contribute to platelet aggregation (fibrinogen, vWF), clot formation (Ca²⁺, Factors V and XI), and adhesion and activation of additional platelets (vWF, fibronectin, and ADP).

Platelet Aggregation. The glycoprotein receptors that appear in association with granule release and shape change allow platelets to bind to one another in a process referred to as platelet aggregation. Fibrinogen also contributes to the growth and stability of the evolving platelet plug. In the presence of Ca⁺, it binds to certain of the newly exposed glycoprotein receptors on the platelet surface (glycoproteins IIb and IIIa). Fibrinogen is multi-stranded and bridges and binds many platelets simultaneously. This stage of aggregation is reversible because the fibrinogen linkage is weak. Thrombospondin (from the alpha granules) can also bind to the platelets

and further strengthen the aggregation.⁹⁴

ADP released from platelet granules promotes platelet aggregation. ADP release, in turn, is greatly increased by a potent prostaglandin, thromboxane A₂ (TxA₂), synthesized from arachidonic acid by activated platelets. Platelet activators, such as collagen and thrombin, cause mobilization of arachidonic acid from platelet membrane phospholipids. In a series of enzymatic reactions involving cyclooxygenase and thromboxane synthase, arachidonic acid is converted to TxA₂. The actions of TxA₂ are important to the control of primary hemostasis (see below).

Appearance of New Phospholipid Procoagulant Activity. In addition to the appearance of glycoprotein receptors, platelet activation causes other surface conformation changes. Quiescent platelets possess heterogeneous phospholipids located primarily on the inner aspect of the cell membrane. With platelet activation, specific phospholipids are translocated to the outer half of the membrane. This phospholipid movement changes the surface charge of the platelet and results in procoagulant activity. This new phospholipid procoagulant property of platelets is called platelet factor-3 activity, or PF3.

The new surface phospholipids (PF3) serve as binding sites for those coagulation factors that require the formation of “reaction complexes.” Those complexes involve factor pairs that must bind in a specific spatial arrangement in order to activate a third clotting factor. They depend upon the platelet phospholipid binding sites for the proper spatial interaction to occur. Factors VIIIa and IXa bind on PF3 to result in the activation of Factors X to Xa. Thereafter, Factors Va and Xa bind to the surface of the platelet and, in the presence of calcium, convert prothrombin (Factor II) to thrombin (IIa). Thrombin produced in this manner and localized to the platelet membrane surface is a potent activator of additional platelets, resulting in further release of ADP and amplification of platelet aggregation.

Control of Primary Hemostasis

The Thromboxane–Prostacyclin Balance. Primary hemostasis is, in part, controlled by the balance between the actions of two prostaglandins, thromboxane A₂ and prostacyclin. Thromboxane A₂ (TxA₂) is synthesized at the site of vascular damage by activated platelets. TxA₂ has two hemostatic effects: (1) it is a potent vasoconstrictor that causes blood vessels to constrict locally and shunt blood flow away from the site of injury; (2) it stimulates additional ADP release from platelets and thereby causes recruitment of additional platelets.^{86,93}

Remote from the site of vascular damage, normal endothelial cells synthesize prostacyclin (PGI₂). PGI₂, which is also synthesized from arachidonic acid (Fig. 10-4), has actions opposite to those of TxA₂. PGI₂ inhibits platelet activation, secretion, and aggregation⁹⁵ and is a potent vasodilator. It therefore serves to prevent platelet aggregation and clot formation on the endothelial surface beyond the site of injury. An imbalance in the production of these two prostaglandins can lead to a defect in primary hemostasis.

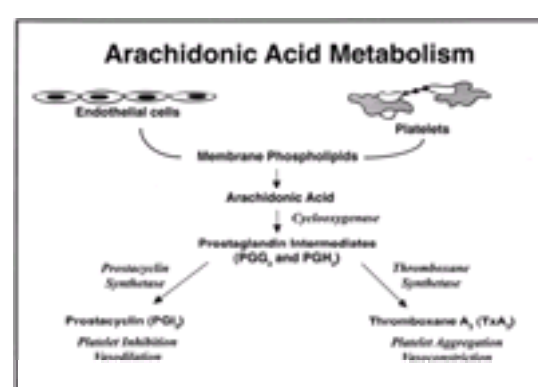

Figure 10-4. The participation of arachidonic acid metabolites in hemostasis. Prostacyclin and thromboxane A₂ are synthesized from arachidonic acid derived from phospholipids in the membranes of both endothelial cells and platelets. The balance between these two prostaglandins controls primary hemostasis and localizes clot formation to sites of vascular injury.

Nitric Oxide and ADPase. The effects of prostacyclin are potentiated by nitric oxide (formerly called endothelium-dependent relaxing factor, EDRF), which is constitutively synthesized by normal endothelium and which also has vasodilatory and platelet antiaggregant effects.⁸⁸ As an additional means of preventing clot formation on the surface of normal endothelium, ADPases are expressed on the outer membrane of endothelial cells and serve to degrade “surplus” ADP which might otherwise initiate platelet aggregation on normal surfaces.

Summary of Primary Hemostasis

In summary, after vascular injury exposes collagen, platelets adhere to the injured vessel wall, largely *via* the GPIa platelet receptor and the von Willebrand factor. The platelets change shape and release the contents of their cytoplasmic granules. ADP, thus released, causes the platelets to expose the GPIIb/IIIa receptor. Fibrinogen binds *via* this GPIIb/IIIa receptor, bridging platelets together and inducing platelet aggregation. Activated platelets synthesize thromboxane A₂ which induces vasoconstriction and increases ADP release. The additional ADP further increases platelet aggregation. The aggregated platelets form the platelet plug which temporarily arrests bleeding. The aggregated platelets expose a new surface phospholipid, platelet factor 3, which serves to localize the coagulation process, which by now is underway, to the site of platelet plug formation.

Step 2: Coagulation

Coagulation is the second phase of the hemostatic process. Coagulation involves the interaction of numerous plasma proteins, referred to as clotting factors, in a cascade of reactions that generate fibrin to reinforce the friable platelet plug.

The Nomenclature of Coagulation

Understanding the coagulation process has been made more difficult by the complexity of the nomenclature. An early attempt was made to standardize it by assigning Roman numerals to each of the twelve known clotting factors. Unfortunately, especially for non-hematologists, they were numbered in the order in which they were discovered and not in the sequence in which they interact. To complicate matters, the first four of the original 12 factors are always referred to by their common names, fibrinogen, prothrombin, tissue thromboplastin (tissue factor), and calcium and not by their Roman numerals. Factor VI no longer exists; it proved to be activated Factor V. The more recently discovered clotting factors, *e.g.*, prekallikrein and high-molecular-weight kininogen have not been assigned Roman numerals. They too are identified by common names, and to further complicate matters, some have more than one name (Table 10-5).

| Factor | Synonyms | In Vitro Half-life (hours) |
|---------------|---|----------------------------|
| I | Fibrinogen | 100–150 |
| II | Prothrombin | 50–80 |
| III | Tissue thromboplastin, tissue factor (TF) | |
| IV | Calcium ion | |
| V | Proaccelerin, labile factor | 24 |
| VIII | Serum prothrombin conversion accelerator (SPCA), stable factor | |
| VIII | Antithromboplastin factor (ATF) | 12 |
| vWF | von Willebrand factor | 24 |
| IX | Christmas factor | 24 |
| X | Stuart-Prower factor | 25–60 |
| XI | Plasma thromboplastin antecedent (PTA) | 40–80 |
| XII | Hageman factor | 50–70 |
| XIII | Fibrin stabilizing factor (FSF) | 150 |
| Prekallikrein | Fletcher factor | 35 |
| HMW kininogen | Fitzgerald, Flaxjone, or Williams factor; contact activation cofactor | 150 |

Table 10-5. CLOTTING FACTORS

The Broad Principles of Coagulation

Although the complexity of the coagulation mechanism appears forbidding and the nomenclature chaotic, some basic principles can help to develop a broad understanding of the process.

1. *Most clotting factors circulate in an inactive form.* Most of the clotting factors circulate in an inactive form referred to as a procoagulant or proenzyme. During the process of coagulation, a portion of this molecule is cleaved off. The remaining protein is an active cleavage enzyme, a serine protease. The “activated clotting factor” is designated by the addition of a lowercase “a” after the Roman numeral, e.g., Xa. The activated clotting factor cleaves off a portion of the next procoagulant factor, thereby “activating” it in turn. Chain reaction–like, one factor “activates” another, until fibrinogen (factor I) is cleaved to yield fibrin.
2. *Most clotting factors are synthesized by the liver.* Most of the coagulation proteins are synthesized by the liver. This means that their normal structure and function are dependent upon normal hepatic activity. One possible exception is Factor VIII which may have some extrahepatic synthesis.
3. *Factor VIII is a large, two-molecule complex (vWF and coagulant Factor VIII).* Factor VIII circulates as a very large complex of two distinct protein components, each under separate genetic control.⁹⁴ The high–molecular-weight portion (VIII:Ag) encompasses both the Factor VIII antigen (used to identify “Factor VIII” in the laboratory assay) and vWF. The vWF portion serves as a carrier protein for the second and smaller component of this macromolecular complex, VIII:C, which contains the Factor VIII coagulant activity. In addition to its role as carrier protein, the vWF has a second function. During the process of primary hemostasis when the endothelial lining has been denuded, vWF mediates adhesion of platelets to collagen. Absence of VIII:C results in hemophilia A. Absence of vWF causes two hemostatic abnormalities: (1) a defect in primary hemostasis because of a failure of platelet adhesion to the sites of vascular injury; (2) clinical hemophilia A because of an absence of circulating Factor VIII:C. Restoration of vWF levels restores normal hemostasis. Synthesis of the vWF occurs in endothelial cells and megakaryocytes. The site of synthesis of the coagulant portion of Factor VIII is unknown, but may be located in the hepatic sinusoidal endothelial cells.
4. *Four clotting factors are vitamin K–dependent.* Four of the clotting factors—II, VII, IX, and X—are said to be vitamin K–dependent factors because they require vitamin K for completion of their synthesis in the liver. Each undergoes a final enzymatic addition of a carboxyl group that requires the presence of vitamin K. The carboxyl group enables these factors to bind (with calcium as a cofactor) to phospholipid surfaces. Without vitamin K, Factors II, VII, IX, and X are produced in normal amounts but are nonfunctional. These nonfunctional factors are called PIVKAs [proteins induced by vitamin K absence/antagonist]. The anticoagulant action of vitamin K antagonists is the result of their ability to inhibit this final carboxylation step. The coumadin-like drugs compete with vitamin K for binding sites on the hepatocyte. With sufficient coumadin administration, vitamin K is displaced and the vitamin K–dependent factors are not carboxylated. Of the four vitamin K–dependent factors, Factor VII has the shortest half-life. It is the first clotting factor to disappear from the circulation when a patient is placed on coumadin or begins to develop vitamin K deficiency.
5. *Coagulation requires the presence of a phospholipid surface.* The coagulation process involves several surface-mediated reactions that serve both to localize and control the production of fibrin. These reactions can take place on two different phospholipid surfaces. One is provided by tissue factor, which is normally extrinsic to blood⁹⁶ but which can be exposed to or released into the circulation by tissue injury. The second is provided by platelets which, when activated, expose PF3 phospholipid on their surface.
6. *Coagulation requires the formation of reaction complexes.* Many of the reactions of the coagulation cascade involve one factor activating another. However, some clotting factors are activated by the combined action of a pair of factors, bound in a particular spatial arrangement on a phospholipid surface. One factor serves as an active cleavage enzyme and the other as a “cofactor.” The complex (the two factors plus phospholipid) together activate a third clotting factor, converting it into an active cleavage enzyme.
7. *Two factors, V and VIII, serve as cofactors in reaction complexes.* Factors V and VIII serve as cofactors in “reaction complexes.” They do not become active cleavage enzymes. Without these cofactors in a reaction complex, the reaction may proceed, but only at a very slow rate. Thrombin modulates the activity of the cofactors (V and VIII) by a variety of feedback loops (see [Protein C and Protein S](#)).
8. *Factors V and VIII have short storage half-lives.* Factors V and VIII are also referred to as the “labile factors” because their coagulant activity is not durable in stored blood. While packed RBCs contain residual plasma with clotting factors, massive transfusion with stored blood will nonetheless lead to a dilutional coagulopathy because of diminished activity of Factors V and VIII.

The Classic Model of Coagulation: Two Distinct Pathways

The cascade or waterfall description of coagulation was proposed in 1964. It proposed that coagulation could be initiated by either of two pathways: (1) an “extrinsic” pathway that required the presence of a substance “extrinsic to blood.” That substance has been called tissue thromboplastin and, more recently, tissue factor (TF); (2) an “intrinsic” pathway that could proceed in a test tube containing only clotting factors intrinsic to blood. The two pathways, intrinsic and extrinsic, were thought to converge with the formation of activated Factor X. Thereafter, thrombin and subsequently fibrin were generated through a final common pathway of coagulation.

The Classic Intrinsic Pathway (coagulation initiated by contact activation). Previously, the “intrinsic pathway” was thought to be the more physiologically important of the two pathways. It was described as follows. The contact factors (Factor XII, prekallikrein, and high–molecular-weight kininogen) are activated by exposure to a negatively charged surface. They in turn activate Factor XI which then activates Factor IX. Activated Factor IX (IXa) then binds to the phospholipid surface of activated platelets (PF3) together with the cofactor, Factor VIII:C, to form a reaction complex. The IXa–VIII:C–phospholipid reaction complex then activates Factor X to produce Xa.

THE COMMON PATHWAY OF COAGULATION. With the formation of Factor Xa, the common pathway of coagulation is initiated. Factor X, once activated, binds with its cofactor, Factor V, and platelet phospholipid (PF3) and the complex activates Factor II, prothrombin, to thrombin (IIa). Thrombin, bound to PF3, cleaves fibrinogen, and “fibrin monomers” are released into the circulation ([Fig. 10-5](#)).

Figure 10-5. The classic intrinsic pathway of coagulation. This cascade of reactions is initiated by contact activation factors or exposure of blood to a foreign surface and leads to the formation of fibrin. The dotted arrows indicate the occurrence of an enzymatically mediated conversion of an inactive factor to its active form. The open-headed arrows indicate the translocation of an activated factor to a phospholipid surface to participate in a reaction complex. The shaded spheroids represent the phospholipid surfaces (usually provided by activated platelets).

FROM A SOLUBLE CLOT TO A STABLE (INSOLUBLE) CLOT. Fibrin monomers aggregate end-to-end and side-by-side to form a fibrin polymer. This fibrin clot, referred to as fibrin S (soluble), is held together only by hydrogen bonds. Subsequently, Factor XIII (fibrin stabilizing factor), which is activated by thrombin and calcium ions, mediates the formation of covalent peptide bonds between the fibrin monomers to yield a stable (insoluble) fibrin clot ([Fig. 10-6](#)).

Figure 10-6. The formation of crosslinked fibrin. Several steps are required for the formation of a stable, crosslinked, insoluble fibrin clot. The dotted arrows indicate the occurrence of a reaction mediated enzymatically by an activated clotting factor.

Although this series of reactions does occur, it probably most accurately describes clot formation in a test tube and not what occurs following tissue injury.

The Classic Extrinsic Pathway (coagulation initiated by tissue factor). Coagulation initiated by exposure to a “tissue factor” was thought to involve the activation of Factor VII and the formation of a complex of VIIa and tissue factor. This complex then activated Factor X and fibrin formation proceeded via the “common pathway of coagulation” just described (Fig. 10-7).

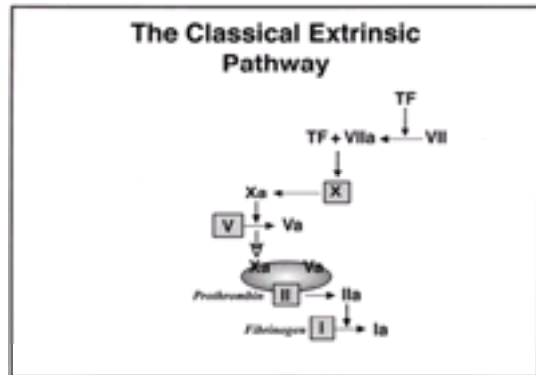

Figure 10-7. The classic extrinsic pathway of coagulation. This pathway is depicted as it was originally thought to occur—i.e., largely extravascularly and independent of the classic intrinsic pathway (cf. Fig. 10-8). The dotted arrows indicate the occurrence of an enzymatically mediated conversion of an inactive factor to its active form. The open-headed arrows indicate the translocation of an activated factor to a phospholipid surface to participate in a reaction complex. The shaded spheroid represents the phospholipid surface (usually provided by activated platelets).

Limitations of the Classic Theories. These theories failed to explain several clinical phenomena. First, persons lacking Factor XII, prekallikrein, or high-molecular-weight kininogen do not bleed abnormally, suggesting that contact activation is not critical for normal hemostasis. Second, patients with only trace quantities of Factor XI withstand major trauma without unusual bleeding and those completely lacking Factor XI have only a mild hemorrhagic disorder. Factor XI therefore appears to have a more minor role in coagulation than that ascribed to it by classic theory. Next, deficiencies of Factor VIII and Factor IX (both in the intrinsic pathway) lead to hemophilia A and B, respectively. The classic description of two pathways of coagulation leaves it unclear why either type of hemophiliac could not simply clot via the unaffected pathway. Such observations suggest that the classic description represents an incomplete description of *in vivo* coagulation and have prompted some additional development of these theories.

The Single Tissue Factor Pathway

The current view is that the distinct classic intrinsic and extrinsic pathways are interlinked at several levels (Fig. 10-8). In contrast to the original conception that the intrinsic pathway was primarily responsible for coagulation *in vivo*, it is now thought that *tissue factor* is the usual *in vivo* trigger. This tissue factor has now been identified as a protein embedded in phospholipid in the surface membrane of pericytes in blood vessel walls, fibroblasts, and in a variety of other cells.^{97,98,99} and ¹⁰⁰

Figure 10-8. The tissue factor pathway. This figure depicts the pathway thought to be most relevant to *in vivo* coagulation. It indicates that activated Factor X (Xa) can be synthesized via two different pathways. The first pathway involves direct activation of Factor X by a complex formed by tissue factor (TF) and activated Factor VII (VIIa). Alternatively, activated Factor X (Xa) can be formed indirectly via the activation of Factor IX by this same TF and Factor VIIa complex. The dotted arrows indicate the occurrence of an enzymatically mediated conversion of an inactive factor to its active form. The open-headed arrows indicate the translocation of an activated factor to a phospholipid surface to participate in a reaction complex. The shaded spheroids represent the phospholipid surfaces (usually provided by activated platelets).

Normal hemostasis is now thought to be initiated when endothelial disruption exposes blood to tissue factor (TF) in the subendothelial layers of blood vessels.¹⁰¹ The exposed TF binds circulating Factor VII or VIIa. Although the mechanism is not clear, Factor VII bound to TF becomes an activated Factor VIIa/tissue factor complex in a reaction that probably involves Factors Xa, IXa, XIa, and thrombin.¹⁰² Subsequently, Factor X is activated by two distinct sequences. First, it can be activated directly by the Factor VIIa/tissue factor complex, i.e., the classic extrinsic pathway. Alternatively, the Factor VIIa/tissue factor complex can activate Factor IX. Activated Factor IXa then forms the IXa/VIIIc/platelet phospholipid complex with subsequent activation of Factor X in a reaction previously viewed as a component of the intrinsic pathway.

The Existence of Tissue Factor Pathway Inhibitor (TFPI). The previous description appears incomplete. If Factor Xa can be formed via the direct action of the VIIa/TF complex, why is it that hemophiliacs bleed? Why do they appear dependent on Factors VIII and IX to produce Xa? The answer lies in the existence of a feedback inhibitor known as tissue factor pathway inhibitor (TFPI) (Fig. 10-9). TFPI, which is generated in a Factor Xa-dependent fashion, is a potent inhibitor of the formation of Factor Xa by both VIIa/TF-initiated sequences.⁹⁶ In the presence of TFPI, activation of Factor X becomes entirely dependent upon the reaction sequences of the classic intrinsic pathway. The TF pathway may initiate the first flurry of thrombin generation—enough to activate platelets and stimulate cofactors V and VIII. Thereafter, continued thrombin production appears to require the action of Factors XIa, VIIIc, and IXa.⁹⁶

Figure 10-9. Inhibition of coagulation at three levels. Three important mechanisms that serve to control coagulation are depicted. (1) Thrombin, bound to thrombomodulin (TM) activates protein C which, with protein S as a cofactor, inhibits activated Factors V and VIII. (2) Antithrombin III (ATIII) binds, and thereby inhibits, several activated clotting factors in the classic intrinsic and common pathways (XIIa, XIa, IXa, Xa, IIa). (3) Tissue factor pathway inhibitor (TFPI) inhibits both of the pathways initiated by TF and VIIa that lead to the activation of Factor X (see text).

The existence of TFPI gives rise to the hope that an inhibitor of TFPI could prevent the inhibition of tissue factor–mediated coagulation by TFPI. That inhibitor might allow the TF/factor VIIa pathway to achieve hemostasis in hemophiliacs.

Tissue Factor in Disease States. Abnormal elaboration of TF, perhaps by endothelial cells and monocytes,^{103,104,105,106} and ¹⁰⁷103–107 or abnormal access of TF to the circulation may play a role in the initiation of hypercoagulable states or DIC in some clinical conditions, such as cancer, sepsis, amniotic fluid embolus, eclampsia, and severe cerebral injury.^{96,101,108}

Control of Coagulation

Coagulation must be precisely regulated to prevent rampant, uncontrolled clotting throughout the body such as that which occurs with disseminated intravascular coagulation (DIC). Several mechanisms regulate and control coagulation. The fact that the blood remains fluid despite such intense stimuli for coagulation as massive trauma demonstrates the efficiency of these mechanisms and their effectiveness in localizing clot formation to sites of vascular injury.

Natural Mechanisms That Modulate the Coagulation Process. Many factors serve to limit and localize clot formation. First, the clotting factors themselves circulate in an inactive form. Once they do become activated, normal blood flow dilutes their concentration and washes them away from sites of injury, limiting clot formation. Activated clotting factors are preferentially removed from the circulation by the liver and the reticuloendothelial system. And finally, the fact that some interactions of the coagulation pathway require the presence of a phospholipid surface localizes clot formation to these phospholipid surfaces.

Control of Coagulation via Anticoagulants or Inhibitors. Several specific anticoagulant inhibitor systems exist. Many of these systems work *via* thrombin which is truly the “master” coagulation enzyme (see below). It has a critical position in the coagulation cascade and orchestrates most of the positive and negative feedback loops that control coagulation. Thrombin plays a central role in primary hemostasis by activating platelets and stimulating their release of ADP, which promotes platelet aggregation and platelet plug formation. But the role of thrombin in control of the coagulation process is even more prominent because of thrombin's interaction with several naturally occurring circulating anticoagulants.

THROMBIN, THROMBOMODULIN, AND PROTEINS C AND S. Thrombin modulates the activity of the cofactors V and VIII directly, and indirectly *via* protein C and protein S (see Fig. 10-9). Thrombin, when present in low concentrations, can directly increase its own production by accelerating the activity of the two cofactors, Factors V and VIII. Thrombin can also decrease its own synthesis by inhibition of these same two cofactors. Its inhibition of V and VIII, however, occurs indirectly *via* protein C, a naturally occurring, vitamin K–dependent anticoagulant protein. Protein C circulates in plasma as an inactive precursor until it is activated by thrombin.¹⁰⁹ The rate of thrombin-induced protein C activation can be greatly enhanced if thrombin first binds to thrombomodulin, a protein located on the vascular endothelial cell surface. The binding of thrombin to thrombomodulin alters the thrombin molecule such that it can no longer directly activate clotting factors V and VIII and cannot catalyze the conversion of fibrinogen to fibrin. Instead, the thrombin/thrombomodulin complex rapidly converts protein C to active protein C (APC) and APC proteolytically cleaves Factors Va and VIIIa. In this way, thrombin indirectly inhibits its own synthesis.¹¹⁰ The location of thrombomodulin on the endothelial surface is strategic. Where the endothelium is intact, the thrombomodulin–thrombin–protein C interaction will inhibit coagulation and maintain the “nonthrombogenic” property of the endothelial lining. Where the endothelium has been stripped away or damaged, this anticoagulant mechanism will be absent and clotting can continue unopposed.

Protein S is also an anticoagulant protein. Like protein C, it is vitamin K–dependent. Protein S acts as a cofactor in the protein C–catalyzed inactivation of Factors Va and VIIIa.¹¹⁰

The role of protein C is characteristic of that played by many participants in the hemostatic mechanism. Protein C in its native form is inactive. For its enzymatic function, it must be activated by thrombin. Protein C interacts with more than one hemostatic process. It serves as an anticoagulant (degrading cofactors Va and VIIIa) and also promotes fibrinolysis (causing the release of t-PA from endothelial cells). Its actions require the presence of a phospholipid surface to degrade factors Va and VIIIa.

THROMBIN AND ANTITHROMBIN III. Antithrombin III (ATIII) is a circulating anticoagulant that binds to thrombin to inactivate this master coagulation enzyme. Similarly, ATIII can bind and inactivate each of the activated clotting factors of the classic intrinsic coagulation cascade—Factors XIIa, XIa, IXa, and Xa¹¹¹ (see Fig. 10-9). By virtue of its broad inhibitory action, ATIII plays a central role in the regulation of hemostasis *in vivo*.

Heparin and antithrombin III. The ATIII molecule has two critical binding sites, one of which reacts with thrombin (and the other activated clotting factors), and a second to which heparin can bind. In the absence of heparin, ATIII has a relatively low affinity for thrombin. However, when heparin is bound to ATIII, the rate of binding of ATIII to thrombin is accelerated 100–1000 times. Likewise, heparin is able to accelerate dramatically the binding of ATIII to the other activated clotting factors—Factors IXa, Xa, XIa, and XIIa. The action of ATIII, which in the absence of heparin slowly inactivates thrombin, is referred to as the “progressive activity” of ATIII, while the rapid, heparin-dependent inactivation is termed the “heparin cofactor activity” of ATIII.¹¹² Once the ATIII/heparin complex has neutralized thrombin, heparin is released from the complex and can catalyze another ATIII inactivation.

Naturally occurring heparan sulfate and heparin. The endothelial surface is coated with a mucopolysaccharide referred to as the glycocalyx.¹¹³ One of the constituents of this glycocalyx is a naturally occurring heparin-like component called “heparan” sulfate. Much like heparin, this naturally occurring heparan sulfate has the ability to accelerate the binding of ATIII to thrombin and the other activated clotting factors of the classic intrinsic pathway. This heparan sulfate is well positioned because it is at this blood–endothelial interface that activated factors of the coagulation cascade are being generated.¹¹⁴ The presence of heparan sulfate on the endothelial surface further helps to promote the “antithrombotic” property of the endothelial lining.¹¹⁴

ATIII deficiencies. Congenital ATIII deficiency (levels 40–50% of normal) can lead to dangerous thrombotic events. Among patients with a history of deep vein thrombosis or pulmonary embolism, 2–3.5% have ATIII deficiency.¹¹² Arterial thromboses are reported less commonly with this deficiency.

Acquired deficiencies of ATIII may occur in a number of conditions, including liver disease, nephrotic syndrome, DIC, sepsis, pre-eclampsia, fatty liver of pregnancy, and following surgery.¹¹⁵ Plasma ATIII levels are sometimes depressed by oral contraceptive use. The role of ATIII replacement therapy in acquired deficiency states remains controversial.¹¹⁶

Other antithrombins. Several other circulating proteins share the property of progressive inactivation of thrombin but are not influenced by heparin.¹¹² These include α_2 -macroglobulin and α_1 -proteinase inhibitor. These proteins are collectively called serine protease inhibitors or serpins.

TISSUE FACTOR PATHWAY INHIBITOR—AN INHIBITOR THAT DOES NOT WORK *VIA* THROMBIN. Fibrin can be generated *via* several different coagulation sequences and inhibitors exist to control each of these (see Fig. 10-9). The sequence of reactions initiated by activated Factor XII (XIIa) (the classic intrinsic pathway) can be inhibited by the thrombin–thrombomodulin–protein C interaction which inactivates Factors Va and VIIIa. The two TF-initiated sequences (the classic extrinsic pathway) which

generate activated Factor X (Xa) are inhibited by TFPI. Finally, Xa and thrombin (the classic common pathway) can be inhibited by the action of ATIII.

Step 3: Fibrinolysis

The process of fibrinolysis leads to the dissolution of fibrin clots and is necessary to restore normal blood flow. Fibrinolysis can also remodel fibrin clots and “recanalize” vessels which have been occluded by thrombosis.

The Formation of Plasmin

Fibrinolysis involves primarily the production of plasmin, an active fibrinolytic enzyme capable of lysing fibrin clots. Plasmin is formed by the conversion of plasminogen to plasmin by plasminogen activator enzymes (Fig. 10-10). Plasmin does not circulate freely because it would rapidly be degraded by antiplasmins, which are present in the bloodstream in concentrations 10 times that of plasmin. Instead, plasminogen, the precursor to plasmin, circulates; and when it comes into contact with fibrin, it binds to it. In fact, when a fibrin clot is forming, plasminogen is incorporated into the growing fibrin clot together with tissue plasminogen activator (t-PA). Once bound to the fibrin surface, plasminogen is converted to plasmin by t-PA. The bound plasmin is protected from attack by circulating antiplasmins because the binding site by which the plasmin binds to the fibrin is the same site to which the antiplasmins bind.⁸⁹

Figure 10-10. Control of fibrinolysis. Normal endothelial cells release tissue plasminogen activator (t-PA) which activates plasminogen, converting it to plasmin. This fibrinolytic enzyme then degrades fibrin and fibrinogen to their various degradation products (FDPs). The action of t-PA can be inhibited by plasminogen activator inhibitor (see text).

As soon as plasmin is released into the bloodstream (with its binding site exposed), α_2 -antiplasmin neutralizes the plasmin in a matter of 0.1 sec. Thus, like the coagulation cascade, the fibrinolytic system relies upon surface-mediated reactions both for the production of plasmin and for the localization of fibrinolysis to the site of vascular injury.

Tissue Plasminogen Activator

t-PA, which converts plasminogen to plasmin, is produced by vascular endothelial cells. This site of synthesis is important to the maintenance of the “nonthrombogenic” endothelial surface. If a clot should begin to form on the normal endothelial surface, several mechanisms, including the elaboration of t-PA from endothelial cells, will rapidly inhibit clot formation or lead to its dissolution.

t-PA release from endothelial cells can be stimulated by several factors. If sufficient thrombin has been synthesized, thrombin will form a complex with thrombomodulin and activate protein C. Activated protein C (APC) then stimulates the release of t-PA from endothelial cells. t-PA is also released from the endothelium into the blood in response to certain stimuli, such as venous occlusion, physical activity, stress, or vasoactive drugs (such as epinephrine, vasopressin, and DDAVP).¹¹⁷ Once released from endothelial cells, t-PA selectively binds to fibrin, much like plasminogen, which also selectively binds to fibrin. Bound to fibrin, the t-PA converts plasminogen to plasmin.

t-PA does not activate circulating plasminogen. This has important implications. Because t-PA activates only plasminogen bound to fibrin, the process of fibrinolysis by plasmin is localized to the fibrin clot. Therefore, under normal circumstances, widespread, uncontrolled fibrinolysis is prevented.

Recently, a new, stable, fast-acting inhibitor of t-PA has been identified. Inhibition of t-PA reduces the amount of plasmin formed and serves to slow the fibrinolytic process (see Fig. 10-10). This t-PA inhibitor is synthesized by endothelial cells and is present in both plasma and platelets. This inhibitor plays a major role in the control and regulation of fibrinolysis. Some patients with thrombotic disorders have been found to have increased levels of this inhibitor.^{117,118} A similar inhibitor is found in placental tissue. It may be that the progressive “hypercoagulable state” associated with pregnancy is related to increased levels of this t-PA inhibitor.¹¹⁷

Plasminogen Activators

There are plasminogen activators in addition to t-PA. Urokinase is present in the urine but, unlike t-PA, it has no affinity for fibrin and is not present in circulating blood.⁸⁹ Physiologic activators of the fibrinolytic system include vigorous exercise, anoxia, and stress, in addition to Factor XIIa and thrombin. Exogenous plasminogen activators include streptokinase, urokinase, and recombinant t-PA. These fibrinolytic agents all differ with respect to their action, clot specificity, systemic fibrinolytic effect, antigenic effect, and efficacy.⁸⁹ Proteins derived from streptococci and staphylococci have also been found to be activators of the fibrinolytic system. The therapeutic fibrinolytic agents, streptokinase and urokinase, differ from t-PA in that they will activate circulating plasminogen, leading to more widespread fibrinolysis. Fibrinolytic therapy has been used in the treatment of unstable angina, acute peripheral arterial occlusions, deep vein thrombosis, and pulmonary embolism and in occluded indwelling catheters and arteriovenous shunts.⁸⁹

Fibrin Degradation Products

The primary action of plasmin is to degrade fibrin clots. The degradation products produced are called fibrin degradation products (FDPs) or fibrin split products (FSPs). Their structure varies according to whether plasmin cleaves fibrinogen and whether or not fibrin is crosslinked.¹¹⁹ Under normal circumstances, FDPs are removed from the blood by the liver, kidney, and reticuloendothelial system. They normally have half-lives of ~9 hours. However, if the FDPs are produced at a rate that exceeds their normal clearance, they will accumulate. This happens when the fibrinolytic system is excessively active. In high concentrations, FDPs impair platelet function, inhibit thrombin, and prevent the crosslinking of fibrin strands.⁹² The defective polymerization of the fibrin monomers results in a clot that is more readily degraded by plasmin.¹¹⁷ In such high concentrations, FDPs lead to bleeding because FDPs are “inhibitors” of both primary hemostasis and coagulation.

Excess Circulating Plasmin

Under normal circumstances, once plasmin has degraded fibrin clot and escapes from the fibrin surface, it is rapidly inactivated by antiplasmins. Deficiency of α_2 -antiplasmin leads to a bleeding tendency because, with reduced levels of antiplasmin in the circulation, plasmin can circulate. In addition, in pathologic conditions in which the fibrinolytic system produces large quantities of plasmin (primary fibrinolysis), the antiplasmin capacity may be exceeded and plasmin may circulate. This can also happen when fibrinolysis is stimulated in response to disseminated intravascular coagulation (secondary fibrinolysis). Excess plasmin can lead to a coagulopathy. This is primarily because plasmin degrades fibrin; but because it is a serine protease, it can also degrade other coagulation factors, such as fibrinogen, Factors V, VIII, and XIII, and also vWF.¹¹⁷ Plasmin can even digest the platelet receptor GPIb. When plasmin circulates in the bloodstream (unneutralized by antiplasmins), it not only dissolves fibrin clots but also inhibits platelet function and disrupts coagulation. Widespread bleeding can occur.

Summary of the Control of Fibrinolysis

Just as the control of coagulation is multifactorial, so is the control of fibrinolysis. The mechanisms already described assure that, under normal conditions, plasmin is generated only at the site of clot formation, that it is protected from degradation while attached to fibrin, and that it is destroyed rapidly once released into the

circulation.

The Complexities of the Hemostatic Mechanism

The preceding sections reveal that many mechanisms interact to maintain the liquid state of the blood under normal circumstances and to transform blood into a solid clot when injury occurs. These mechanisms include numerous feedback processes. The complexity is revealed by the occurrence of “double agents” which act, at times, as procoagulants and, at other times, as anticoagulants. Thrombin is at the heart of many of these complexities. Thrombin is primarily a procoagulant. Under normal circumstances, it promotes primary hemostasis by activating platelets, and promotes coagulation by direct activation of Factors V, VIII, and XIII. Thrombin, in the final step of the coagulation cascade, cleaves fibrinogen to fibrin. However, it also has anticoagulant effects. As described earlier, when thrombin is first synthesized, it stimulates production of tissue factor pathway inhibitor (TFPI) which slows coagulation *via* the tissue factor pathway and makes continued coagulation dependent upon the reaction complex formed by Factors VIII and IXa. Thrombin has an additional mechanism by which it can inhibit coagulation. Thrombin can bind to thrombomodulin on the surface of the endothelium, and this complex activates protein C. Activated protein C (APC) then cleaves the cofactors Va and VIIIa and inhibits coagulation. Protein C can also promote fibrinolysis. Activated protein C stimulates the release of t-PA from endothelial cells. t-PA binds to any fibrin that has formed and begins degradation of the clot. This helps to preserve the pristine “nonwettable” surface of the endothelial lining.

The Critical Role of the Vascular Endothelium

In the absence of vascular injury, the intact endothelial lining has many antithrombotic properties that serve to limit both primary hemostasis and coagulation and to induce fibrinolysis should a clot begin to form on normal endothelium.⁸⁸ These have been mentioned above and are summarized in [Table 10-6](#).

| Endothelial control of fibrinolysis |
| t-PA |

Table 10-6. ENDOTHELIAL INVOLVEMENT IN THE THREE STAGES OF HEMOSTASIS

The Hemostatic Mechanism: Summary

Under normal circumstances, the hemostatic mechanism is quiescent with many of the potential participants in hemostasis circulating in an inactive form. Only when the endothelial lining is breached, is the hemostatic mechanism set in motion. With collagen and tissue factor exposed, the intertwined processes of platelet mediated primary hemostasis and factor mediated coagulation begin and rapidly the vascular injury is sealed by a platelet mass into which is incorporated fibrinogen, thrombin, plasminogen and t-PA. The completion of the coagulation process converts fibrinogen into fibrin and the platelet plug is transformed into a fibrin clot. Simultaneously, several properties of adjacent intact endothelium (elaboration of ADPases, prostacyclin, thrombomodulin, heparans, and t-PA) serve to prevent extension of the clot beyond the site of injury. Within the clot, plasmin, generated from the trapped plasminogen and t-PA, begins the process of fibrinolysis. Over time, the entire fibrin clot dissolves, new endothelial cells line the vessel and flow is restored.

LABORATORY EVALUATION OF THE HEMOSTATIC MECHANISM

Laboratory Evaluation of Primary Hemostasis

Platelet Count

A platelet count should be the first test ordered in the evaluation of primary hemostasis. The advantages of a platelet count include the fact that it is easy to perform, quick, accurate, and reproducible. However, it reveals only platelet numbers and gives no information regarding their function.

Normal platelet counts range between 150,000 and 440,000/mm³. Counts below 150,000/mm³ are defined as thrombocytopenia. Spontaneous bleeding is likely in patients with platelet counts of <20,000/mm³. With counts of 40,000–70,000/mm³, bleeding that is induced by surgery may be severe.

Bleeding manifestations can vary substantially from patient to patient, similar platelet counts notwithstanding. This occurs because some platelets are more effective than others. When thrombocytopenia results from peripheral destruction of platelets, the bone marrow continues to produce normal, young, large platelets that are hemostatically very effective. A patient with these platelets may have more effective primary hemostasis than a patient whose platelet count is similar but whose platelets were produced by a less active, less healthy bone marrow.

Bleeding Time

The Ivy bleeding time (BT) is the most widely accepted clinical test of platelet function. Both poor platelet function and thrombocytopenia can prolong the bleeding time. A blood pressure cuff is placed around the upper arm and inflated to 40 mm Hg. A cut is made on the volar surface of the forearm and the wound blotted at 30-sec intervals until bleeding stops. In 1977 the Simplate Bleeding Time device, which utilizes a spring loaded lancet, was introduced to standardize the size and depth of the cut. The normal range for the Ivy BT is 2–9 m. Variations in venous pressure, blotting technique, and patient cooperation result in a lack of precision and reproducibility that make this test somewhat less reliable than other coagulation tests.

The bleeding time is purported to evaluate the time necessary for a platelet plug to form following vascular injury. This requires a normal number of circulating platelets, platelets with normal function (which can adhere and aggregate), and an appropriate platelet interaction with the blood vessel wall. A prolongation of the BT may be due to (1) thrombocytopenia, (2) platelet dysfunction (adhesion, aggregation), and (3) vascular abnormalities such as scurvy or the Ehlers-Danlos syndrome.

BTs are prolonged in patients with many conditions that cause platelet dysfunction, such as use of aspirin or uremia. However, prolonged BTs have been observed with numerous disorders that are not associated with platelet dysfunction, including vitamin K deficiency of the newborn, amyloidosis, congenital heart disease, and the presence of Factor VIII inhibitors.¹²⁰ Whether or not the BT test represents a specific measure of *in vivo* platelet function is debated. The test is unpleasant for the patient and leaves a small scar. In spite of the correlation of BT with conditions known to influence platelet function, there are no convincing data to confirm that bleeding time is a reliable predictor of the bleeding that will occur in association with surgical procedures.

Platelet Function

The ability of platelets to aggregate can be assessed quantitatively by observing the response to stimulation with ADP, epinephrine, collagen, or ristocetin. The platelet aggregometer is designed to measure platelet aggregation spectrophotometrically. Clot retraction is another function of platelets that can be assessed grossly. When maintained at 37°C, a clot should begin to retract within 2–4 hours. This test is difficult to quantify and only qualitative results (retraction vs. no retraction) are usually reported.

Laboratory Evaluation of Coagulation

Evolution of the Prothrombin Time (PT) and the Partial Thromboplastin Time (PTT)

When blood is placed in a glass test tube, clot formation occurs in response to contact with the foreign surface. No exogenous reagents are required because all of the factors necessary for contact initiated coagulation are “intrinsic” to blood. The time to formation of a clot *via* this pathway can be prolonged by deficiencies of any factors in the classic intrinsic pathway. However, the observation that, even in hemophiliacs, the addition of thromboplastin (now more commonly called tissue factor) to the test tube could shorten the time to clot formation suggested the presence of an alternative pathway of fibrin formation. That pathway required the addition of something “extrinsic to blood” and did not require the presence of Factors VIII or IX. In 1936, when Quick introduced the prothrombin time (PT) to clinical medicine, sufficient “thromboplastin” was used to yield a clotting time of ~12 sec. Under these circumstances, even patients lacking Factors VIII or IX showed normal clotting times.¹²¹ However, when “dilute” thromboplastin (or a “partial” thromboplastin) was used in lieu of the “12-second reagent,” hemophiliacs showed much longer clotting times than did healthy controls. The two different pathways could be tested individually simply by varying the amount and type of thromboplastin added to blood. If the “complete thromboplastin” were added, coagulation could proceed *via* reactions that were independent of Factors VIIIa and IXa. With a lesser thromboplastin stimulus, coagulation would proceed *via* a sequence of reactions that required the presence of Factors VIIIa and IXa.

Basic Elements of the PT and PTT

The two common tests of coagulation, the prothrombin time (PT) and the partial thromboplastin time (PTT), differ primarily by the type of thromboplastin that is used—a standardized tissue thromboplastin (the “complete thromboplastin”) or a phospholipid component that serves as a platelet substitute (“partial thromboplastin”), respectively. Calcium must also be added because of the chelating agent in the blood specimen container. The time to fibrin strand formation is then measured.

The Prothrombin Time

The PT evaluates the coagulation sequence initiated by tissue factor (TF) and leading to the formation of fibrin without the participation of Factors VIII or IX. The PT measures the time to fibrin strand formation *via* a short sequence of reactions involving only TF, Factors VII, X, V, II (prothrombin), and I (fibrinogen). Tissue factor forms a complex with VIIa and together this complex activates Factor X. From that point, coagulation proceeds *via* the common pathway of coagulation. The test evaluates neither the coagulation process initiated by the classic intrinsic pathway nor the sequence of reactions initiated by tissue factor that generate Xa *via* the reaction complex formed by factors IXa and VIIIa (see [Fig. 10-8](#)).

The normal PT is 10–12 seconds. The PT will be prolonged if deficiencies, abnormalities, or inhibitors of Factors VII, X, V, II, or I are present. The PT test has limitations. First, it is not very sensitive to deficiencies of any of these factors. In fact, the coagulant activity of these factors must drop to 30% of normal before the PT is prolonged. The PT is most sensitive to a decrease in Factor VII and least sensitive to changes in prothrombin (Factor II). When prothrombin levels are only 10% of normal, the increase in the PT may be just 2 sec. Also, PT will not be prolonged until the fibrinogen level is below 100 mg · dl⁻¹. A prolonged PT does not define the exact hemostatic defect. However, when looking at coagulation profiles, if the aPTT (“activated” partial thromboplastin time; see below) is normal, then a prolonged PT is most likely to represent a deficiency or abnormality of Factor VII. Because it has the shortest half-life of the clotting factors synthesized in the liver, Factor VII is the clotting factor that first becomes deficient with liver disease, vitamin K deficiency, or coumadin therapy. Prolongation of the PT may also be due to deficiencies of multiple factors. However, when multiple factor deficiencies coexist, the aPTT will usually be prolonged as well.

The International Normalized Ratio. Another difficulty with the PT test is that many different thromboplastin reagents are used. This results in wide variation in normal values, rendering comparison of PT results between laboratories difficult. The International Normalized Ratio (INR) was introduced to circumvent this difficulty.¹²² Each thromboplastin is compared with an internationally accepted standard thromboplastin and assigned an International Sensitivity Index (ISI). If the test thromboplastin is equivalent to the international standard, it will have an ISI index of 1. Once the ISI number has been determined, PT test times obtained with that reagent are normalized and reported as an INR.¹²³

The Partial Thromboplastin Time

The PTT assesses the function of the intrinsic and final common pathways. It entails the addition of a “partial thromboplastin” (usually a chloroform extract of rabbit brain tissue phospholipid) and calcium to citrated plasma. The PTT reflects the time to fibrin strand formation *via* the classic intrinsic pathway of coagulation.

The PTT will reveal deficiencies, abnormalities, or inhibitors to one or more coagulation factors, including high-molecular-weight kininogen (HMWK), prekallikrein, and Factors XII, XI, IX, VIII, X, V, II, and I. The normal values for PTT vary widely. Times between 40 and 100 sec are usual, and the result is not considered abnormal until PTT is >1120 sec.

The PTT can be made more reproducible and the range of normal values narrower by the addition of contact activator in addition to the partial thromboplastin. This test, called an “activated” partial thromboplastin time (aPTT), is the test that is most commonly used.¹²⁴ Surface activation in the laboratory parallels the contact activation phase involving Factors XII and XI, prekallikrein, and HMWK that is thought to initiate the intrinsic pathway *in vivo*. Diatomaceous earth, kaolin, celite, and ellagic acid are used as surface activators. The aPTT is much faster than the PTT because it eliminates the lengthy “natural” contact activation phase. Normal aPTT values are between 25 and 35 sec.¹²⁵ The aPTT is prolonged when there is a deficiency, abnormality, or inhibitor of Factors XII, XI, IX, VIII, X, V, II, and I (*i.e.*, all factors except VII and XIII). The aPTT is most sensitive to deficiencies of Factors VIII and IX, but, as is the case with the PT, levels of these factors must be reduced to ~30% of normal values before the test is prolonged. As with the PT, the level of fibrinogen must also be reduced to 100 mg · dl⁻¹ before the aPTT is prolonged. aPTT results (like those of the PT) vary from laboratory to laboratory because of nonstandardization of the phospholipids and activators.

The Activated Clotting Time

The activated clotting time (ACT) is similar to the aPTT in that it tests the ability of blood to clot in a test tube and is dependent on factors that are all “intrinsic” to blood (the classic intrinsic pathway of coagulation). Fresh whole blood is added to a test tube that contains a particulate surface activator of Factors XII and XI. The time to clot formation is measured. Partial thromboplastin or a platelet phospholipid substitute is not added. Coagulation is therefore dependent upon the presence of adequate amounts of platelet phospholipid in the blood sample. The automated ACT is widely used to monitor heparin therapy in the operating room. Normal values are in the range of 90–120 sec.¹²⁴ The ACT is far less sensitive than the aPTT to factor deficiencies in the classic intrinsic coagulation pathway. In fact, the ACT may not be prolonged until the coagulant activity of some of the factors is reduced to 1% of normal.

The Thrombin Time

Thrombin time (TT), which is also called the “thrombin clotting time” (TCT), is a measure of the ability of thrombin to convert fibrinogen to fibrin. This test, which is performed by adding exogenous thrombin to citrated plasma, bypasses all the preceding reactions. The thrombin time may be prolonged due to conditions which affect the substrate, fibrinogen, or the action of the enzyme thrombin. The TT is prolonged when the amount of fibrinogen is inadequate (<100 mg · dl⁻¹) or when the fibrinogen molecules that are present are abnormal (dysfibrinogenemia), as in advanced liver disease. Thrombin's enzymatic function can be inhibited by inhibitors such as heparin (complexed to ATIII) or FDPs, or by inhibitors seen in patients with plasma cell myeloma and other immunoproliferative conditions.¹²⁶ The normal TT is <30 sec.

The Reptilase Time. When the thrombin time is prolonged, the reptilase time (RT) can be used to differentiate between the effects of heparin and FDPs. Reptilase, which is derived from a snake venom, converts fibrinogen to fibrin. The action of reptilase is unaffected by heparin but is inhibited by FDPs. A prolonged TT with a normal RT suggests the presence of heparin. Prolongation of both TT and RT will occur in the presence of FDPs, or when fibrinogen level is low. The normal RT is 14–21 sec.

Fibrinogen Level

Fibrinogen concentration is determined by adding large quantities of Factor IIa (thrombin) to citrated plasma and comparing the time to fibrin formation in the patient's plasma with plasma specimens of known fibrinogen levels. Normal values are between 160 and 350 mg%. Below 100 mg%, fibrinogen may be inadequate to produce a clot. Fibrinogen is rapidly depleted during DIC. Less well appreciated is the marked increase in fibrinogen that occurs following surgery and trauma. Levels in excess of 700 mg% may occur. Because of this increase, half of the fibrinogen can be consumed during a hypercoagulable state such as DIC, and the fibrinogen level may still appear to be “normal.”

Laboratory Evaluation of Fibrinolysis

Fibrin Degradation Products and D-Dimer

The test to detect fibrin degradation products (FDPs) employs latex particles coated with antibodies that bind the breakdown products of fibrin (crosslinked or uncrosslinked), the breakdown products of fibrinogen, and fibrinogen itself. The particles are added to the patient's plasma and serial dilutions are made until no visible clumping is seen. The D-dimer assay is specific for a breakdown product of crosslinked fibrin. FDPs will be increased in any state of accelerated fibrinolysis, including advanced liver disease, fibrinolysis associated with cardiopulmonary bypass, administration of exogenous thrombolytics (e.g. streptokinase), and DIC. D-Dimer is specific to conditions in which extensive lysis of the crosslinked fibrin of mature thrombus is occurring, that is, DIC.

The Thromboelastogram

Thromboelastography provides a measure of the mechanical properties of evolving clot as a function of time. A principal advantage of this test is that the processes it measures require the integrated action of all the elements of the hemostatic process: platelet aggregation, coagulation, and fibrinolysis. The thromboelastogram (TEG) is obtained by placing a specimen of blood in a rotating cuvette into which a "piston" is lowered. As clot formation begins, the piston rotates as function of the adherence of the evolving fibrin clot to the piston. The piston is connected to a recorder and the rotation of the piston results in a to-and-fro excursion of the stylus, the amplitude of which is proportional to the speed of piston rotation. [Figure 10-11](#) depicts a normal TEG.

Figure 10-11. The normal thromboelastogram and the variables commonly derived from it. See text for explanation. (Reprinted with permission from Kang Y, Lewis JH, Navalgund A *et al*: >e-Aminocaproic acid for treatment of fibrinolysis during liver transplantation. *Anesthesiology* 66:766, 1987.)

Several parameters are derived from the TEG. The most commonly used ones are listed below, together with their interpretation:¹²⁷

r , the reaction time, is the interval until initial clot formation. It requires thrombin formation, and prolongation is usually indicative of an intrinsic pathway factor deficiency.

k , the clot formation time, is the interval required after r for the TEG to achieve a width of 20 mm. Prolongation occurs with deficiencies of thrombin formation or generation of fibrin from fibrinogen.

α° , the alpha angle is, like k , a measure of the speed of clot formation. A decrease of α° is similar in significance to a prolongation of k .

MA, the maximum amplitude, is a measure of the strength of the fully formed clot. It reflects primarily platelet number and function, although it also requires proper fibrin formation to achieve normal values. MA typically occurs between 30 and 60 m.

$(MA + x)/MA$, the amplitude at a specific time interval (x) after MA divided by MA, is a ratio used as a measure of the rate of fibrinolysis. The $(MA + 60)/MA$ ratio has been used most widely.¹²⁸ A ratio of <0.85 is evidence of abnormal fibrinolysis.¹²⁹ In clinical practice, particularly in liver transplantation, a nonquantitative appreciation of the typical teardrop shape ([Fig. 10-12](#)) is used more often to support a diagnosis of increased fibrinolysis than are specific numerical values. F , the interval from MA to return to a zero amplitude, is a measure of the rate of fibrinolysis. In normal subjects F is sufficiently long that the test is usually terminated before this time elapses.

The TEG has been employed in cardiac surgery, major trauma, and hepatic transplantation. It is in the latter that it is used most frequently. Commonly, in that context, an increased r prompts the administration of FFP, a decreased MA leads to platelet administration, and the teardrop configuration of fibrinolysis leads to the administration of antifibrinolytics. The use of the TEG in liver transplantation has been shown to decrease the amount of RBCs and FFP transfused as compared with transfusion guided by routine coagulation tests.¹³⁰

Interpretation of Tests of the Hemostatic Mechanism

The interpretation of coagulation tests requires a knowledge of the common bleeding disorders. An effective approach to the interpretation of coagulation tests is to appreciate in advance the constellation of test results (the coagulation "profile") that is likely to occur with each of the common bleeding disorders ([Table 10-7](#)).¹³¹ The most commonly ordered coagulation tests are a platelet count, aPTT, and PT and occasionally a bleeding time. When a greater disruption of the hemostatic mechanism is suspected, further tests, including fibrinogen level, TT, and assays for fibrin degradation products and the D-dimer, may be ordered.

| Platelet Count | Bleeding Time | aPTT | PT | Fibrinogen | FDPs | Health-Cases | Examples |

Table 10-7. INTERPRETATION OF COAGULATION TESTS

Common Coagulation Profiles

Platelet Count Decreased (normal aPTT and PT)

Thrombocytopenia may be caused by inadequate platelet production, sequestration in the spleen, excess tissue consumption, dilution by massive transfusions, or by platelet destruction (see Bleeding Disorders, Thrombocytopenia).

Prolongation of Bleeding Time (normal platelet count, aPTT, PT)

Although the BT may be useful for evaluating primary hemostasis, it is rarely used in the intraoperative or postoperative period. As noted earlier, the BT has not been shown to be a reliable predictor of perioperative blood loss.

When the BT is prolonged and the platelet count is normal, von Willebrand's disease (vWD) should be considered. Note that when the BT is prolonged, a normal aPTT does not exclude a diagnosis of vWD. This is because although the Factor VIII:C levels may be decreased with vWD (Type 1), only 25–30% of VIII:C coagulant activity is necessary to produce a normal aPTT. Therefore, it is not uncommon for Type 1 patients with vWD to have a normal aPTT.

There are many acquired conditions that cause platelet dysfunction which can prolong the BT in the presence of a normal platelet count. These include antiplatelet drug ingestion (NSAIDs, ASA, ticlopidine, clopidogrel, etc.), uremia, liver dysfunction, the presence of FDPs (DIC or fibrinolytic therapy), and cardiopulmonary bypass. Liver disease, the presence of FDPs, and cardiopulmonary bypass, however, alter other coagulation tests as well and produce a different coagulation testing profile. Drug ingestion and uremia are the common causes of an isolated prolonged BT. The diagnosis of platelet dysfunction however, is often a diagnosis of exclusion.

Prolonged aPTT (normal platelet count and PT)

The bleeding disorders that produce this combination of test results are limited to those that affect the classic intrinsic pathway of coagulation. The clotting factors that are unique to the intrinsic pathway include prekallikrein, HMWK, and Factors XII, XI, IX, and VIII; and in the common pathway, Factors X, V, II, and I. When the coagulant activity of any of these factors falls to 30% of normal or less, the aPTT may be prolonged.

1. *Deficiency of Factor XII, HMWK, or prekallikrein:* Deficiencies of these factors are not usually associated with a significant hemostatic defect.
2. *Hemophilia A or B:* Hemophilia A (VIII:C) or B (IX) is associated with significant coagulopathies.
3. *von Willebrand's disease:* A deficiency of the von Willebrand factor, which serves as a carrier protein for the coagulant portion of Factor VIII, may prolong the aPTT. However, vWD will also affect platelet function and the patient may demonstrate problems with both primary hemostasis and coagulation.
4. *Heparin therapy:* Heparin therapy is monitored with the aPTT. Initially, only the aPTT is prolonged. At higher doses, both the aPTT and PT are prolonged.
5. *Presence of acquired Factor VIII inhibitors, circulating anticoagulants.*
6. *The lupus anticoagulant:* The lupus "anticoagulant" is an antiphospholipid antibody. It is a common cause of a prolonged aPTT. That prolongation is the result of the binding of the phospholipid used to initiate coagulation *in vitro*. The patients do not have a bleeding diathesis. In fact, they have a prothrombotic tendency that is unexplained. That tendency may occur because of activation of platelets by antibody attack directed at their surface phospholipids. This laboratory abnormality is not corrected when the patient's plasma is mixed with normal plasma because of the presence of inhibitors.
7. *Poor blood collection technique:* Poor blood collection technique can prolong just the aPTT. This is because Factors V and VIII, the labile factors, may be consumed if the blood is partially clotted prior to delivery to the laboratory.¹³² The aPTT is very sensitive to Factor VIII deficiencies.

Summary. When only the PTT is prolonged, it is less likely to be due to a bleeding disorder that involves multiple factor deficiencies (such as liver disease, vitamin K deficiency, the administration of coumadin, or the coagulopathy associated with massive transfusion or DIC). Heparin therapy or congenital disorders of hemostasis are more probable.

Prolonged PT Only (normal platelet count and aPTT)

1. *Factor VII deficiency:* Deficiencies of Factor VII will prolong the extrinsic pathway.
2. *Vitamin K deficiency or coumadin administration.* Because Factor VII has the shortest half-life of the vitamin K–dependent factors, depletion of the vitamin K–dependent factors (either due to vitamin K deficiency or coumadin administration) will first prolong the PT and later prolong the aPTT as well.
3. *Liver disease:* Similarly, the development of liver disease will lead to deficiencies of Factor VII first and initially prolong only the PT. With further deterioration of liver function, both the PT and the aPTT will be prolonged. Liver disease can also lead to thrombocytopenia and platelet dysfunction.
4. *Acquired coagulation factor inhibitors:* These rare conditions can occur in patients with lymphoma or collagen vascular disease.
5. *Amyloidosis:* Patients with amyloidosis will occasionally have decreased levels of factor X with prolongation of PT.

Prolonged aPTT and PT (normal platelet count)

This coagulation profile suggests that multiple factor deficiencies exist or that there is a deficiency of one of the factors in the common pathway, such as fibrinogen. Combined prolongation of the aPTT and PT without thrombocytopenia occurs most commonly with vitamin K deficiency, coumadin therapy, or heparin therapy. With heparin therapy, the aPTT will be prolonged first, but with higher doses, both PT and aPTT will be prolonged. It is important that platelet counts be followed in patients receiving heparin because of the possibility of a heparin-induced thrombocytopenia. Although liver disease can produce multiple factor deficiencies, the platelet count is usually decreased with increasing severity of the disease, and often FDPs will also be elevated (see next page).

Prolonged PT, aPTT, and TT (normal platelet count)

The presence of "thrombin inhibitors" such as heparin or FDPs can prolong the PT, aPTT and TT simultaneously. These tests can also be prolonged by hypofibrinogenemia, *i.e.*, a fibrinogen level less than 100 mg · dl⁻¹.

Prolongation of the TT makes the diagnosis of simple vitamin K deficiency or coumadin therapy unlikely. The thrombin time is very sensitive to even minute levels of heparin and the thrombin time is also prolonged in the presence of FDPs. FDPs may be elevated with fibrinolytic therapy, DIC, or liver disease. However, DIC and liver disease usually result in a coagulation profile that includes thrombocytopenia as well. A normal platelet count makes heparin or fibrinolytic therapy more likely.

Prolonged aPTT, PT, TT; Decreased Platelet Count

The patient with a low platelet count and prolongation of all coagulation tests has a global disruption of the hemostatic mechanism. This clinical picture can be produced by DIC, the dilutional effects of massive transfusion, and by heparin. To differentiate DIC from the dilutional effects of massive transfusion and the effects of excess heparin, a fibrinogen level and an assay for FDPs and D-dimer is helpful. Both DIC and the dilutional effects of massive transfusion will reduce fibrinogen levels. DIC, however, results in the production of the D-dimer.

Fibrinogen Levels Decreased

Fibrinogen levels are decreased most commonly with hypercoagulable states such as DIC and with the coagulopathy produced by massive transfusion. Fibrinogen levels may be decreased with liver disease as well due to the decreased synthesis of this factor. Conversely, fibrinogen levels are increased with stress and pregnancy.

Fibrinogen Levels Decreased in the Presence of Circulating FDPs

An assay for FDPs is helpful in the differential diagnosis of the patient who has a low platelet count and prolonged aPTT, PT, and TT. The presence of FDPs may differentiate the coagulopathy due to massive transfusion from that produced by DIC or severe liver disease. Because FDPs are the byproduct of fibrinolysis, often their presence is used as "circumstantial evidence" that DIC is ongoing. However, elevated levels of FDPs are also seen with severe liver disease.¹³² Positive tests for fibrin monomers (D-dimer) are more specific for DIC.

Summary

The interpretation of coagulation tests is best done by identifying which elements of the hemostatic mechanism have been disrupted and then attempting, in the context of the patient's medical condition, to determine the probable cause of that coagulation profile (see [Table 10-7](#)). Platelet number and platelet function disorders can be evaluated with a platelet count and bleeding time, respectively. Defects of coagulation are evaluated with the PT, aPTT, TT, and fibrinogen level. The presence of DIC is evaluated by tests for fibrin degradation products and the D-dimer. Systemic fibrinolysis is reflected by the presence of FDPs, a shortened euglobulin clot lysis time, or an abnormal TEG. Bleeding disorders which are first diagnosed in the hospitalized patient are usually acquired and often involve multiple factor deficiencies. The most common bleeding disorders include vitamin K deficiency, liver disease, DIC, systemic fibrinolysis, dilutional coagulopathy, and heparin excess. Therefore, understanding the coagulation profile produced by each of these bleeding disorders will be valuable. The interpretation of coagulation tests is made difficult by the fact that patients who develop a bleeding diathesis in the perioperative period may have more than one bleeding disorder (*e.g.*, DIC and coagulopathy due to massive transfusion) and may also have a surgical cause for bleeding.

DISORDERS OF HEMOSTASIS: DIAGNOSIS AND TREATMENT

The hemostatic mechanism involves an intricate balance that serves to limit blood loss in the event of vascular injury while maintaining the liquid character of blood at

other times. Under normal circumstances, an equilibrium between clotting and bleeding is maintained with the help of multiple activators, inhibitors, cofactors, and feedback loops, both positive and negative. Under pathologic circumstances, that equilibrium may be lost, leading to either hemorrhagic or thrombotic complications. Accordingly, disorders of hemostasis can be broadly classified into those that lead to abnormal bleeding and those that lead to abnormal clotting. The disorders may be further categorized according to whether they involve platelets, clotting factors, and/or the presence or absence of inhibitors (such as FDPs). Finally, disorders may be hereditary or acquired. These organizational frameworks will be helpful in reaching a diagnosis on the basis of the results of coagulation tests. The treatment that follows from diagnosis may require administration of hemostatic agents (platelets and/or clotting factors) or the use of pharmacologic agents. The latter may be chosen for effects on platelets (desmopressin, antiplatelet drugs), on clotting factors (vitamin K, coumadin, heparin) or on naturally occurring inhibitors (antifibrinolytic agents, protamine, fibrinolytics).

The preoperative history is invaluable in the identification of disorders of hemostasis. History will also commonly reveal whether an abnormality is one of primary hemostasis, one of coagulation, or a combined disorder. Abnormalities of primary hemostasis, usually caused by reduced platelet number or function, will be revealed by evidence of “superficial” (skin and mucosal) bleeding, including easy bruising, petechiae, prolonged bleeding from minor skin lacerations, recurrent epistaxis, and menorrhagia. Coagulation abnormalities are associated with “deep” bleeding events, including hemarthroses or hematomas after blunt trauma. [Table 10-8](#) lists the common entities associated with these two groups of abnormalities. In the absence of a disease state or pharmacologic agent known to be associated with a bleeding disorder (discussed below), a suspicious history should lead to consideration of hereditary abnormalities of hemostasis.

Hereditary Disorders of Hemostasis

von Willebrand's Disease

von Willebrand's disease (vWD) is the most common hereditary bleeding disorder. The incidence in the general population is approximately 1%.¹³³ The disorder was first identified by Eric von Willebrand in 1926 among the inhabitants of the Aland Islands near the coast of Finland.¹³⁴ von Willebrand's disease is the result of abnormal synthesis of a protein, the von Willebrand factor (vWF), which is important for both primary hemostasis and coagulation. That protein is a large polymeric molecule with numerous distinct binding domains responsible for its several hemostatic functions. Those domains include sites that are specific for collagen (for adherence to the subendothelium), the platelet GPIb receptor (for platelet adhesion to collagen), the platelet GPIIb/IIIa receptor (for platelet aggregation), and Factor VIII:C (for its carrier protein function). The many different mutations of vWF lead to several quantitative and functional alterations and hence to various clinical presentations of the disease. Because of the role that vWF plays in primary hemostasis, the disease is often discussed in the context of platelet disorders. Without vWF, platelet function is impaired and tests of platelet function, most notably the bleeding time, are often abnormal. However, treatment of this disease does not usually involve platelet transfusion, but rather restoration of the vWF with FFP, cryoprecipitate, or the administration of desmopressin.

SYNTHESIS OF vWF. vWF is synthesized by endothelial cells, megakaryocytes, and platelets. Platelet vWF is stored in the platelet alpha granules. There is evidence that estrogens, corticosteroids, and thyroid hormones may influence the rate of vWF synthesis.^{135,136} While the mechanisms that regulate plasma vWF are not well understood, it is known that ABO blood group status relates to vWF plasma levels. People with blood group O have 20–30% less vWF antigen than those with other blood types.¹³⁷

ENDOTHELIAL SECRETION OF vWF. Release of vWF from endothelial cells at sites of vascular injury can be induced by several agonists including thrombin, histamine, oxidative stress, and other mediators of thrombosis and/or inflammation.¹³⁴ These agonists, however, are thought not to influence plasma levels of vWF. Plasma levels of vWF increase in response to epinephrine and other catecholamines, vasopressin, and DDAVP (1-deamino-8-D-arginine vasopressin or desmopressin) as well as pregnancy, physical activity, and other stresses.¹³⁸ The stress-related increases in the plasma vWF level may be mediated by epinephrine.

THE ROLE OF vWF IN PRIMARY HEMOSTASIS. vWF is essential for platelet plug formation. It mediates platelet adhesion to the subendothelial surface of blood vessels and promotes platelet-to-platelet aggregation.¹³⁹ vWF, probably principally vWF synthesized by the endothelium, is “translocated” to the subendothelium, in part in response to epinephrine and DDAVP. After binding to the subendothelium, the vWF undergoes a conformational change that allows platelets to adhere *via* their glycoprotein GPIb receptors. This binding can occur only after the conformational change, and in solution, platelets will not spontaneously bind to vWF. The antibiotic ristocetin can induce the platelet GPIb–vWF interaction and, accordingly, is the basis for one laboratory test of platelet function.

vWF also participates in platelet aggregation. Aggregation occurs by binding of vWF molecules to the GPIIb/IIIa receptors on the surface of several platelets. The vWF has multiple well-spaced binding sites for the platelet receptors as well as for binding to the subendothelial matrix. Fibrinogen and fibrin can also crosslink platelets by binding to the same GPIIb/IIIa sites.

CARRIER PROTEIN FOR FACTOR VIII:C. The vWF also acts as a carrier protein for the coagulant activity of Factor VIII, referred to as VIII:C, with which it circulates in a complexed form that prolongs VIII:C's circulation time.

vWD HAS MANY PHENOTYPES. Numerous possible mutations result in several clinical presentations. Three broad categories of the disease exist. Some patients have merely a quantitative deficiency of the factor. Others produce a vWF which is qualitatively abnormal. A third category of patients have a total vWF deficiency. The various phenotypes of the disease were classified in 1994 by a subcommittee of the International Society for Thrombosis and Hemostasis.¹⁴⁰

In the most common variant of vWD (70–80% of vWD), the plasma levels of vWF are decreased, but there is no demonstrable structural or functional alteration of the protein. Patients with this form of vWD (Type 1) present with a pattern of bleeding that is characteristic of abnormalities of primary hemostasis.

Twenty to thirty percent of patients with vWD have Type 2 disease. These patients have normal or low vWF antigen levels but the vWF is structurally and functionally abnormal. There are many Type 2 subtypes. Some mutations affect the platelet interactions of vWF while others affect the Factor VIII interaction. In subtype 2B, the vWF is constitutively active and has a high affinity for the platelet GPIb receptor without the necessity for a conformational change. The bleeding diathesis is probably the result of formation and clearance of vWF–platelet complexes and the resultant thrombocytopenia. DDAVP, which is therapeutic for other vWD variants, may aggravate this form of the disease by causing severe thrombocytopenia. In the subtype 2N (Normandy) vWD, the vWF has a markedly reduced affinity for Factor VIII. These patients demonstrate normal platelet function, but bleed because of decreased Factor VIII coagulant activity. These patients are readily misdiagnosed as having mild hemophilia A.

Type 3 vWD is characterized by a prolonged bleeding time and low to undetectable levels of vWF, resulting in a severe abnormality of both primary hemostasis and coagulation. The prevalence of this variant is very low (~1 per million).¹³³

History reveals easy bruising, mucosal bleeding (epistaxis), and oozing or bleeding following prior surgery. The first line of treatment (detailed below) is DDAVP.

Diagnosis and Treatment. History will commonly reveal abnormal bleeding from mucosal surfaces. Sixty percent of the patients will report epistaxis, 50% report menorrhagia, and 35% acknowledge gingival bleeding, easy bruising, and hematomas.¹³⁴ von Willebrand's disease should be considered in patients who give a history of unexplained postoperative bleeding, particularly following tonsillectomy or dental extraction. Although this is a hereditary disease, a clear family history is not always evident because disease severity varies substantially.

Multiple specialized laboratory tests may be required to confirm the diagnosis of vWD. What is important for the anesthesiologist to appreciate is that the results of the most commonly ordered coagulation tests—the platelet count, the aPTT, and the PT—may be normal in the patient with vWD. While the half-life of VIII:C is diminished in vWD, there is generally sufficient VIII:C to yield a normal aPTT in basal conditions. If, in fact, the aPTT is very prolonged, it is likely that the patient has a severe form of vWD. Quantitative assays of vWF are available, but interpretation can be difficult because normal values are not well established and many variables influence levels. A single normal or abnormal value for vWF cannot be viewed as definitive. The response to the infusion of plasma can be used to distinguish vWD from hemophilia A. With hemophilia A, Factor VIII level is maximal immediately after plasma or cryoprecipitate infusion. Patients with vWD demonstrate the same immediate rise in factor VIII levels, but the increase is sustained for 48 hours because the patient with vWD is able to produce factor VIII:C.¹⁴¹

DDAVP (1-deamino-8-D-arginine vasopressin), which promotes release of vWF, is effective first-line therapy for the large majority of patients with vWD, including those with Type 1 and Type 2A disease. However the recognition of subtype 2B (see above) is important because DDAVP will cause thrombocytopenia in these patients.¹⁴² DDAVP, given intravenously in a dose of 0.3 $\mu\text{g} \cdot \text{kg}^{-1}$, increases Factor VIII:C and vWF two- to fivefold in most patients. Its effect is maximal after 30 minutes and elevated levels persist for 6–8 hours¹³⁴ (see Pharmacologic Therapy: [Desmopressin](#) below). The antifibrinolytic agents *e*-aminocaproic acid and tranexamic acid are sometimes used in combination with DDAVP to manage these patients during the perioperative period. They may be given intravenously, or orally. They have also been administered topically, as mouthwashes, in patients with vWD undergoing dental extractions. Oral contraceptives (estrogens) have been used to treat patients with vWD and menorrhagia or who are undergoing elective surgery. The mechanism of action of the estrogens is not well understood, although a connection with vWF synthesis is suspected.

Cryoprecipitate contains vWF and will correct the hemostatic defect. However, its use entails exposure to multiple donors, with the associated infectious risk. Therefore, cryoprecipitate is no longer the standard form of replacement therapy. Instead virus-inactivated Factor VIII concentrates, which have significant levels of both Factor VIII and the vWF, are preferred in emergency situations if DDAVP therapy is inadequate. In situations that are less emergent, virally attenuated vWF concentrates can be used to supply vWF.¹⁴³ Over time, the infusion of vWF will increase Factor VIII levels. In those patients who do not respond to Factor VIII concentrates, platelets are sometimes administered in an attempt to correct the platelet defect caused by the deficient or abnormal vWF. Antiplatelet drugs should be avoided in patients with vWD.

The Hemophilias

The hemophilias are among the oldest disorders for which genetic counseling has been offered. Hemophilia A results from mutations that lead to either deficient or functionally defective Factor VIII:C. Hemophilia B (Christmas disease) and hemophilia C are caused by deficiency or abnormality of Factors IX and XI, respectively. The relative frequencies of the three hemophilias are: Factor VIII:C, 85%; Factor IX, 14%; and Factor XI, 1%. Both hemophilia A and B are sex-linked recessive disorders, which therefore occur almost exclusively in males. Hemophilia C is an autosomal recessive disorder that occurs almost exclusively in Ashkenazi Jews.¹⁴⁴ About 50% of operations in hemophiliacs are orthopedic procedures required for treatment of the arthritic consequences of hemarthroses.

Hemophilia A. Factor VIII is a very large macromolecule with two components, the coagulant Factor VIII (VIII:C) and the von Willebrand factor. The VIII:C molecule circulates bound to and protected by vWF. In hemophilia A, patients have normal levels of vWF, but exhibit reduced or defective Factor VIII:C. More than 600 abnormal Factor VIII genes have been identified.¹⁴⁵ Hemophilia A occurs in approximately 1 in 5000 males.¹³³

Hemophiliacs experience deep tissue bleeding, hemarthroses, and hematuria most commonly. Clinically, hemophilia A can be classified as mild, moderate, and severe. Patients with mild disease have factor levels of 5–30% of normal and usually bleed abnormally only following trauma. Patients with moderate disease have factor levels of 1–5% and occasionally bleed spontaneously as well as following trauma. The great majority of hemophiliacs have the severe form of the disease. Their Factor VIII:C levels are less than 1% of normal and they frequently experience spontaneous bleeding episodes. The severity of clinical symptoms usually correlates with the level of clotting factor activity. Like the patient with von Willebrand's disease, hemophiliacs should avoid aspirin and other platelet-inhibiting agents.

DIAGNOSIS AND TREATMENT. Patients with hemophilia A will commonly report a history that reveals the X-linked recessive pattern of disease inheritance. Diagnosis of hemophilia A is made on the basis of a prolonged aPTT and specific factor assays demonstrating a deficiency of Factor VIII coagulant activity with normal levels of vWF, Factor IX, and Factor XI. The patient will have a normal prothrombin time and a normal bleeding time.

Hemophilia A is treated with plasma-derived concentrates that have been treated by viral attenuation procedures (heat-treated) or with recombinant Factor VIII. The recombinant Factor VIII is thought to provide the greatest safety from viral transmission. In the 1980s, the use of lyophilized Factor VIII concentrates made from pooled plasma from as many as 20,000 donors led to the transmission of HIV to many hemophiliacs. Recombinant factor VIII became available in 1992.

If a hemophiliac presents for elective surgery, the patient's hematologist should be consulted. Questions can also be directed to the regional hemophilia center. The National Hemophilia Foundation has listings of the regional centers. The required factor replacement will be dependent upon (1) the patient's plasma volume and (2) the desired procoagulant activity. The patient's plasma volume can be assumed to be equal to 40 ml of plasma per kilogram of body weight. A 60-kg person has a plasma volume of 2400 ml. One unit of Factor VIII procoagulant activity is defined as the amount of Factor VIII present in one milliliter of plasma in an individual with 100% of the normal level. A procoagulant level of 25% is a common target for achieving control of a bleeding episode. This would mean that a total of 600 units (25% × 2400 ml) of Factor VIII:C would be required. For elective surgery, the level of Factor VIII:C activity is usually raised to 50–100% of normal. The number of units of Factor VIII:C contained in the Factor VIII concentrates is usually noted on each bag. Cryoprecipitate contains Factor VIII:C as well, but carries a greater risk of virus transmission. Unfortunately, many hemophiliacs develop inhibitors to Factor VIII:C. The presence of the inhibitor increases the amount of Factor VIII:C that must be administered to manage a given hemostatic challenge.

DDAVP will also increase plasma Factor VIII:C and vWF concentrations. DDAVP is thought to cause the release of Factor VIII:C from liver endothelial cells. There is a large variation in patient response to DDAVP, and it is most effective in patients with Factor VIII:C levels greater than 5%.¹⁴⁶ It is given iv in a dose of 0.3 µg · kg⁻¹ in 50 ml of saline over 15–30 min. It causes a prompt increase in Factor VIII:C.

The antifibrinolytics ε-aminocaproic acid and tranexamic acid have been used to treat hemophiliac patients prior to dental procedures. The agents are contraindicated in bleeding episodes involving joints or the urinary tract because the clots that do form may not be lysed for a long time.

Hemophilia B. Factor IX deficiency is also an X-linked recessive disorder that produces a bleeding diathesis that is clinically indistinguishable from hemophilia A. The management of this disorder is similar to that of hemophilia A. Bleeding is controlled with fresh frozen plasma or prothrombin complex, which contains Factor IX (as well as II, VII, and X). Prothrombin complex conveys a very substantial infectious risk and also entails a risk of thrombosis and DIC because of the presence of activated factors. Virus-inactivated Factor IX concentrates, which have been developed recently, should supplant the use of prothrombin complex.¹⁴⁴

Protein C and Protein S Deficiency

Hereditary deficiency of proteins C and S is associated with thromboembolic events originating on the venous side of the circulation, including deep vein thromboses, pulmonary embolus, and stroke as a consequence of paradoxical embolization. The complete absence of protein C is associated with death in infancy. Patients who experience thromboembolic events and have decreased levels of protein C or S should remain on anticoagulant therapy indefinitely.

Acquired Disorders of Hemostasis

For mnemonic purposes, it is helpful to classify bleeding disorders according to which of the three hemostatic processes is involved: primary hemostasis (platelet disorders); coagulation (clotting factor disorders); fibrinolysis (production of inhibitors such as FDPs); or some combination of the three. Similarly, it is useful to use the results of coagulation tests to determine whether the clinical problem involves primary hemostasis (decreased platelet count, increased bleeding time, etc.), coagulation (prolonged PT and aPTT, decreased factor levels, etc.), fibrinolysis (increased FDPs, increased D-dimer), or some combination of the three. Ultimately, therapeutic decisions (e.g., administration of platelets, FFP, or an antifibrinolytic agent) will similarly be oriented to treatment of one or more of these processes.

Acquired Disorders of Platelets

The clinical conditions that cause an isolated disorder of primary hemostasis typically involve abnormalities of either platelet number or function.

Thrombocytopenia. Platelets are derived from megakaryocytes in the bone marrow in response to thrombopoietin, which is synthesized by the liver. The causes of thrombocytopenia may be categorized as follows: (1) inadequate production by the bone marrow, (2) increased peripheral consumption or destruction (non-immune-mediated), (3) increased peripheral destruction (immune-mediated), (4) dilution of circulating platelets, and (5) sequestration (Fig. 10-13).

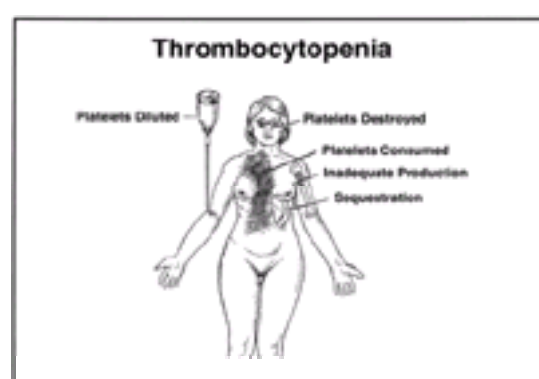

Figure 10-13. Thrombocytopenia. The figure depicts the five processes that can lead to thrombocytopenia. They include platelet destruction, as occurs immunologically in lupus erythematosus; platelet consumption, as occurs with burns or other massive tissue injury conditions; inadequate production, as can occur with marrow infiltration, chemotherapy, or radiation; sequestration as can occur in the presence of splenomegaly, and dilution occurring during massive transfusion.

1. Bone marrow production of platelets can be impaired in many ways. Physical and chemical agents (radiation and chemotherapy), various drugs (thiazide diuretics, sulfonamides, diphenylhydantoin, alcohol), infectious agents (hepatitis B, TB, overwhelming sepsis), and chronic disease states (uremia, liver disease) can all cause bone marrow suppression. Infiltration of the bone marrow by cancer cells or replacement by fibrosis will also result in inadequate platelet production.
2. Accelerated non-immunologically mediated consumption can occur in many conditions that cause extensive activation of coagulation with or without the occurrence of DIC. After extensive tissue damage (burns or massive crush injuries that denude vascular endothelium), the normal process of hemostasis activates platelets, leading to their consumption and to thrombocytopenia. In a similar fashion, the interaction of platelets with nonendothelialized structures such as large vascular grafts can also lead to a transient thrombocytopenia. Platelets are consumed in patients with an extensive vasculitis such as occurs with toxemia of pregnancy. The many conditions that cause DIC (see below) will also cause platelets to be consumed or destroyed faster than they can be produced.
3. Immunologically mediated consumption can be caused by various drugs (heparin, quinidine, cephalosporins) and autoimmune disorders (systemic lupus erythematosus, rheumatoid arthritis, thrombotic thrombocytopenic purpura). Alloimmunization resulting from previous blood transfusions or pregnancy can cause refractoriness to platelet transfusions.
4. Dilution of platelets will occur in the context of massive transfusion (see below and [Risks of Blood Product Administration](#) above).
5. Under normal conditions approximately one third of platelets are sequestered in the spleen. When the spleen enlarges, an increasing number are sequestered and thrombocytopenia may result. This may occur in splenomegaly associated with myelodysplastic syndromes and cirrhosis of the liver, although in the latter condition decreased production also contributes to thrombocytopenia.

Disorders of Platelet Function.

UREMIA. Platelet dysfunction is common in uremic patients.¹⁴⁷ The accumulation of compounds (guanidine, succinic acid, and hydroxyphenolic acid) is thought to contribute to this dysfunction through interference with the platelet's ability to expose the PF3 phospholipid surface. These compounds are dialyzable and, accordingly, dialysis frequently improves the hemostatic defect associated with uremia. An additional abnormality involving the interaction of von Willebrand factor with platelet receptors is also suspected. DDAVP (desmopressin), which among other effects induces immediate release of vWF from endothelial cells, rapidly improves platelet adhesiveness.¹⁴⁸ However, the mechanism of this effect is not understood. It is not simply a matter of restoring vWF levels, because circulating vWF is typically present in normal levels in uremia. Administration of erythropoietin and conjugated estrogens has also been observed to cause gradual improvement of the hemostatic defect associated with uremia. The mechanisms of these effects are similarly not known. Cryoprecipitate will also improve the platelet dysfunction of uremia but, given the efficacy of DDAVP, the associated risks are not justified. When life-threatening bleeding occurs in the uremic patient, platelet concentrates should be administered.

ANTIPLATELET AGENTS. Anesthesiologists will encounter patients receiving medications that are administered expressly for the purpose of platelet inhibition. These agents are given to reduce the risk of myocardial infarction, stroke,¹⁴⁹ and other thromboembolic complications. They induce platelet dysfunction by several mechanisms which include inhibition of cyclo-oxygenase, inhibition of phosphodiesterase, adenosine receptor antagonism, and blockade of the glycoprotein IIb/IIIa receptor. A variety of drugs given for other indications may also impair platelet function, including amitriptyline, imipramine, chlorpromazine, cocaine, diltiazem, lidocaine, various penicillins, and beta blockers.¹⁵⁰

Cyclo-oxygenase inhibitors. Aspirin is the prototype. Aspirin produces irreversible inhibition of platelet cyclo-oxygenase (cox), which results in inhibition of synthesis of thromboxane A₂, a potent platelet proaggregant and vasoconstrictor. In moderate doses, there is selective sparing of the synthesis of prostacyclin (antiaggregant, vasodilator), which results in "tilting" the balance substantially in favor of platelet inhibition. Indomethacin, phenylbutazone, and all the nonsteroidal anti-inflammatory agents similarly inhibit cyclo-oxygenase. However, their inhibition is promptly reversible with clearance of the drug. The recently introduced Cox-2 inhibitors selectively inhibit the cox isoform responsible for generating the mediators of pain and inflammation, while sparing the cox-1 isoform, whose inhibition causes gastric damage, decreased renal blood flow, and inhibition of platelet thromboxane A₂. Accordingly, platelet function should not be impaired. In fact there is concern that Cox-2 inhibitors, which should reduce prostacyclin generation by vascular endothelial cells, may actually tilt the natural balance toward platelet aggregation.¹⁵¹

Phosphodiesterase inhibitors. Cyclic AMP is an inhibitor of platelet aggregation and levels are increased by inhibition of phosphodiesterase. Dipyridamole, which is used for stroke prophylaxis alone or more commonly in combination with aspirin, appears to act primarily by this mechanism.¹⁵² Caffeine, aminophylline, and theophylline will also similarly produce mild, reversible platelet inhibition.

Adenosine receptor antagonists. Ticlopidine and clopidogrel, which are administered for stroke prophylaxis, are antagonists of the P2 purinoceptor. They noncompetitively inhibit ADP-induced platelet aggregation and their effect is probably irreversible.¹⁵³

Glycoprotein IIb/IIIa receptor antagonists. These newly introduced agents block platelet aggregation by blocking the GPIIb/IIIa site to which fibrinogen and vWF bind. Used principally for the management of acute coronary syndromes, these agents include abciximab (a monoclonal antibody), tirofiban, and eptifibatide. These agents all require iv administration. Their effect is reversible. Platelet function recovers rapidly (4 hours after discontinuation of tirofiban and eptifibatide) but is somewhat delayed (48 hours) after abciximab.

OTHER CONDITIONS. Myeloproliferative and myelodysplastic syndromes produce intrinsic defects in platelets. In these disorders, the platelets may be abnormal both in morphology and function. Platelet dysfunction occurs in conjunction with conditions that also cause other hemostatic abnormalities (liver disease, fibrinolytic states including DIC, storage defects) and are discussed below.

Acquired Disorders of Clotting Factors

Vitamin K Deficiency. Hepatic synthesis of clotting Factors II, VII, IX, and X as well as protein C and protein S requires the presence of vitamin K. When synthesized in the absence of vitamin K, the factors are structurally abnormal and are called PIVKAs (proteins induced by vitamin K absence or antagonists). Vitamin K is necessary for the enzymatic carboxylation of the four vitamin K-dependent clotting factors. The carboxyl group enables these factors to bind via a calcium bridge to phospholipid surfaces (PF3) during the coagulation process. When vitamin K deficiency occurs, these factors are depleted in an order determined by their individual half-lives. Factor VII has the shortest half-life and is the first to be depleted, then Factors IX and X, and finally Factor II.

"Vitamin K" actually refers to a group of vitamins.¹⁵⁴ Vitamin K₁ (phylloquinone) is found in leafy green vegetables. The greatest quantities occur in brussels sprouts. Vitamin K₂ (menaquinone) is synthesized by the normal intestinal flora. It is rare for patients to develop vitamin K deficiency solely because of dietary deficiency, but it may occur in patients who are receiving parenteral nutrition without vitamin K supplementation and who are being treated concurrently with broad-spectrum antibiotics that destroy the gut flora. Because the body has no appreciable stores of vitamin K, deficiencies can develop in roughly one week. Newborns, who have a sterile gut at birth, have been noted to develop vitamin K deficiency.

Vitamin K is a fat-soluble vitamin, and therefore requires bile salts for absorption from the jejunum. Patients with biliary obstruction, pancreatic insufficiency, malabsorption syndromes, GI obstruction, or rapid GI transit can develop vitamin K deficiency due to inadequate absorption.

DIAGNOSIS AND TREATMENT. Vitamin K deficiency will cause prolongation of the PT. This occurs because Factor VII is depleted first. With more prolonged deficiency, the aPTT will also be increased because of declining levels of Factors IX and X. Platelet count will be normal. Vitamin K may be administered orally, intramuscularly (im), or intravenously. Urgent treatment of vitamin K deficiency is best accomplished by im or iv administration of vitamin K (Aquamephyton) in doses of 10–20 mg. Vitamin K should be administered slowly to avoid the occurrence of hypotension. Improvement of the coagulation disturbance will be apparent within 6–8 hours.

Coumadin therapy. Coumadin produces its anticoagulant effect by competition with vitamin K for binding sites in the liver. Administration of coumadin leads to the depletion of functional vitamin K-dependent factors (II, VII, IX, X, protein C and protein S). As with vitamin K deficiency, Factor VII is the first factor to be depleted. Subsequently, Factors IX and X are depleted, and then Factor II. Accordingly, initially only the PT will be prolonged. With higher doses of coumadin, the aPTT will be affected as well.

Coumadin is administered for the prevention of deep venous thrombosis and pulmonary embolism, and to patients with atrial fibrillation, some prosthetic heart valves, and ventricular mural thrombi in the setting of acute myocardial infarction.¹⁵⁵ Patients with protein S or protein C deficiency are also treated with long-term anticoagulation with coumadin. Coumadin therapy is adjusted according to the INR (see Tests of the [Hemostatic Mechanism](#)). The primary untoward effect of coumadin therapy is bleeding. Rapid reversal of coumadin effect can be accomplished by administration of vitamin K, 10–20 mg iv. INR should be rechecked at 6-hour intervals. Vitamin K administration may have to be repeated at 12-hour intervals. In situations of greater urgency FFP administration will be required.

Heparin therapy. Heparin is used widely for anticoagulation in vascular surgery and in procedures requiring cardiopulmonary bypass (CPB). It inhibits coagulation principally through its interaction with one of the body's natural anticoagulant proteins, antithrombin III (ATIII). Heparin of higher molecular weight binds to ATIII and in

so doing causes a conformational change that greatly increases ATIII's inhibitory activity. In spite of its name, anti-"thrombin" III, ATIII inhibits several activated factors, including Xa, IXa, XIa, and XIIa, in addition to IIa (thrombin). It is most active against thrombin and Xa. Heparin also increases the activity of a second native antithrombin, heparin cofactor II. Heparin cofactor II inhibits thrombin and not the other activated factors. Its contribution to the clinical effects of heparin is not clear. Resistance to heparin can occur in patients who are deficient in ATIII on either a hereditary or an acquired basis. The latter may occur in patients on sustained heparin therapy or in the presence of depletion by a consumptive coagulopathy. Heparin responsiveness can be restored by administration of ATIII (ATIII concentrates or FFP).

Heparin-induced thrombocytopenia. Up to 5% of patients who receive heparin therapy for 5 days will develop thrombocytopenia as a result of antibodies (probably IgG) directed against platelet-heparin complexes. Onset requires several days in the heparin-naïve patient, but can occur much more quickly in those who have been previously exposed.¹⁵⁶

Heparin in cardiopulmonary bypass. A comprehensive discussion of the use and monitoring of heparin therapy in CPB is beyond the scope of this chapter. Extensive reviews are available.^{157,158} In brief, the common practice is to maintain activated clotting time of >480–500 sec for the duration of bypass. There is a substantial variation in the heparin–ACT dose–response relationship, probably because of variability in heparin binding to many native surfaces including platelets, WBCs, endothelium, and plasma proteins including the vWF and ATIII.¹⁵⁷ While there is controversy, it appears that there is greater hazard in allowing ACT to be on the "low side" than in maintaining more complete heparinization.¹⁵⁹ Evidence of platelet activation is less apparent when longer ACTs are maintained. Whether this is a function of direct inhibition of platelets, which are subject to contact activation by the CPB circuit, binding of vWF, or the result of reduced formation of thrombin and inhibition of platelets by its breakdown products (FDPs) is not apparent to the authors of this review. Protamine is administered for reversal of heparin effect. Many clinicians employ a "cc for cc" technique. However, a more careful titration of protamine against ACT is ideal to avoid excessive administration of protamine, which has inherent anticoagulant effects including platelet inhibition, stimulation of t-PA release from endothelium, and inhibition of fibrinogen cleavage by thrombin.¹⁶⁰

Various alternatives have been considered for the patient with heparin-induced thrombocytopenia who requires CPB.^{161,162} Plasmapheresis prior to surgery with subsequent use of heparin has been employed.¹⁵⁶ The nonheparin alternatives for anticoagulation include specific inhibitors of thrombin (hirudin, hirulog, argatroban) and the defibrinogenating agent Ancrod (a snake venom). There are limitations. The contact activation of platelets is not inhibited and platelet inhibitors should probably be administered simultaneously. Experience is very limited and well-defined protocols are not established.

Low-molecular-weight heparins. LMW fractions of heparin have been employed principally for deep vein thrombosis prophylaxis. These agents, which also act *via* ATIII, have greater activity against Factor Xa than thrombin. Because of more consistent absorption after subcutaneous injection and less variability in binding to plasma proteins, they have more predictable dose–response characteristics than unfractionated heparin. A longer half-life allows once per day dosing. They also appear to cause less platelet inhibition and are associated with a lower incidence of heparin-induced thrombocytopenia.¹⁶³ Protamine neutralization of LMW heparins is reported to be incomplete.¹⁶⁴

Acquired Combined Disorders of Platelets and Clotting Factors

Massive Transfusion. The various hazards of massive transfusion, as reviewed earlier, include two potential consequences with implications for coagulation: (1) dilutional deficiencies of factors and platelets and (2) hypothermia. Isovolemic exchange of blood with packed RBCs or other factor- and platelet-free fluids will lead to potentially significant reductions first of fibrinogen, then of Factors V and VIII, and finally platelets. These occurrences should be suspected when exchanged volumes reach 140%, 200%, and 230% of original blood volume, respectively.³⁰ However, as noted previously, administration of hemostasis-promoting blood products should be based on clinical and laboratory evidence of coagulopathy and not on exchange volume estimates.

Hypothermia slows coagulation (as it does all enzymatically mediated reactions) and causes sequestration of platelets. At 29°C (at which temperature the risk of cardiac dysrhythmias is critical), PT and aPTT will increase ~50% over normothermic values and platelet count will decrease by ~40%.¹⁴⁴ Notwithstanding a general conviction that "cold patients bleed," there have been no quantitative correlations of temperature and bleeding in the clinical setting. Temperatures of 33°C are commonly used in elective neurosurgery without clinically apparent coagulopathy. However, Ferrara *et al*⁹ reviewed the clinical course of 45 patients who received massive transfusion following trauma. The duration of hypotension was similar in patients who survived and those who did not. However, the degree of acidosis and hypothermia was more extreme in the nonsurvivors, and the nonsurvivors developed coagulopathies despite adequate blood, plasma, and platelet replacement. In studies of this nature, it is difficult to separate the effects of the common clinical concomitants of hypothermia—acidosis, shock, massive transfusion, massive tissue injury—from those of hypothermia *per se*. Furthermore, the significance of hypothermia may lie in the interaction with other variables. In spite of the ambiguity, hypothermia should be carefully avoided and aggressively corrected in the patient receiving massive transfusion.

Citrate intoxication, another potential complication of massive transfusion, can cause diminished calcium (Factor IV) availability. However, critical cardiac consequences occur before hypocalcemia has significant implications for coagulation.

Acquired Combined Disorders of Platelets and Clotting Factors with Increased Fibrinolysis

Liver Disease. Chronic liver disease is associated with abnormalities of all three phases of hemostasis: primary hemostasis, coagulation, and fibrinolysis.¹⁴⁷ Table 10-8 (see page 224) provides an overview of these abnormalities.

| |
|--|
| Thrombocytopenia |
| • decreased production |
| • hypersplenism |
| • increased consumption (DIC) |
| Impaired platelet function |
| • decreased FDP clearance |
| Decreased factor synthesis |
| • decreased hepatocyte function |
| • vitamin K deficiency (diet, malabsorption) |
| Increased factor consumption |
| • decreased clearance of activated factors |
| • decreased synthesis of inhibitors (protein C, protein S) |
| Increased fibrinolysis |
| • decreased synthesis of α_2 -antiplasmin |
| • decreased clearance of t-PA |

Table 10-8. ETIOLOGY OF HEMOSTATIC ABNORMALITIES IN LIVER DISEASE

IMPAIRED PRIMARY HEMOSTASIS. Impaired primary hemostasis occurs as a result of both thrombocytopenia and impaired platelet function. The former is largely the result of decreased production which in turn is probably the result of decreased thrombopoietin secretion by the liver. Hypersplenism may also contribute but its role has been overemphasized. Platelet dysfunction can occur when liver disease is sufficiently advanced that clearance of FDPs is impaired or when DIC complicates the coagulation disturbance. The FDPs coat the surface of platelets and impair aggregation.³⁹ Ethanol can also directly contribute to platelet dysfunction by inhibition of the synthesis of ADP, ATP, and thromboxane A₂. Accordingly, when faced with a patient with liver disease who is bleeding, a normal platelet count cannot be assurance of intact primary hemostasis. DDAVP may be helpful, but transfusion of platelet concentrates may be necessary.⁹²

DISTURBANCES OF COAGULATION. Disturbances of coagulation may occur because of both decreases in factor production and increases in factor consumption. The liver synthesizes all of the clotting factors (with the probable exception of Factor VIII). As with vitamin K deficiency, hepatic disease first leads to a deficiency of Factor VII since it has the shortest half-life. Thereafter, deficiencies will develop in Factors II, IX, and X. Dietary deficiency of vitamin K, as may occur in alcoholics, with diminished secretion of bile salts leading to malabsorption, will exaggerate these deficiencies. If impaired coagulation is the result of vitamin K deficiency and not hepatic damage, then parenteral vitamin K may be helpful in restoring factor levels of II, VII, IX, and X. Further deterioration of hepatic function will affect the remaining factors, I, V, XI, and XII. Impaired liver function can also cause a thrombotic tendency, which leads to increased consumption of clotting factors. This occurs for two reasons. First, synthesis of the natural anticoagulants—antithrombin III, protein C, and protein S—may be diminished, thereby altering the balance of pro- and anticoagulant forces; second, clearance of activated clotting factors from the circulation may be impaired, thereby allowing persistent activation of the coagulation cascade.

INCREASED FIBRINOLYSIS. Increased fibrinolysis occurs as a result of decreased clearance of t-PA from the circulation by the impaired liver and decreased hepatic synthesis of α_2 -antiplasmin.¹⁶⁵ The combination of accelerated coagulation and increased fibrinolysis in patients with advanced liver disease can lead to a persistent, low-grade DIC. The release into the circulation of the breakdown products of necrotic hepatocytes may contribute to the development of DIC.¹⁵⁴ Diagnosis of DIC is

often difficult because the laboratory tests used to identify DIC are already abnormal in patients with liver dysfunction. Thrombocytopenia, prolonged PT and aPTT, decreased fibrinogen level, and circulating FDPs will commonly occur in the absence of DIC. The D-dimer test is the most specific for the occurrence of DIC.

Diagnosis and Treatment.

COAGULATION ABNORMALITIES ASSOCIATED WITH LIVER DISEASE. The initial laboratory evaluation should include platelet count, PT, aPTT, fibrinogen level, and D-dimer. In the event of thrombocytopenia and clinical bleeding or pending surgery, platelet transfusions are appropriate. If the PT is prolonged (>11.5 times control), vitamin K should be administered speculatively. In the absence of a response to vitamin K (which requires a minimum of 8 hours), factor deficiencies should be treated with fresh frozen plasma (FFP) with attention to the possibility of volume overload. Cryoprecipitate is appropriate in the event of hypofibrinogenemia (fibrinogen <100–125 g · dl⁻¹). However, cryoprecipitate does not contain the vitamin K–dependent factors. While antifibrinolytics have been applied in the context of liver transplantation, they should not otherwise be used for bleeding associated with liver disease because of the catastrophic consequences of administering these agents in the face of an unrecognized DIC.¹⁶⁶

Disseminated Intravascular Coagulation. Thorough and detailed reviews of DIC are available.^{167,168} DIC is characterized by excessive formation of thrombin throughout the vascular tree. It is triggered by the appearance of tissue factor (TF; formerly called thromboplastin) activity in the circulation in amounts sufficient to overwhelm the mechanisms that normally restrain and localize clot formation. That appearance may be the result of either extensive endothelial injury, which exposes TF of fibroblastic origin, or the release of TF into the circulation as occurs with amniotic fluid embolus, extensive soft tissue damage, or severe head injury. [Table 10-9](#) lists the numerous clinical conditions that can generate this TF activity. The accelerated process of clot formation causes both tissue ischemia and, ultimately, critical depletion of platelets and factors. Simultaneously, the fibrinolytic system is intensely activated and plasmin is generated to lyse the extensive fibrin clots. The mechanisms that normally serve to localize plasmin are similarly overwhelmed and plasmin circulates freely. Fibrinolysis and circulating plasmin result in extensive degradation of both fibrin and fibrinogen. The fibrin degradation products that result inhibit platelet aggregation and prevent the normal crosslinking of fibrin monomers. Depleted of platelets and clotting factors and inhibited by FDPs, the coagulation system fails and the patient bleeds.

| |
|---------------------------------------|
| Sepsis |
| Malignancies |
| Obstetric conditions |
| Amniotic fluid embolus |
| Fetal death <i>in utero</i> |
| Abruptio placentae |
| Pre-eclampsia |
| Extensive tissue damage |

| Liver failure |
| Extensive cerebral injury |
| Head injury |
| Stroke |
| Extensive vascular endothelial damage |
| Vasculitis |
| Pre-eclampsia |
| Hemolytic transfusion reactions |
| Snake venoms |

Table 10-9. CLINICAL CONDITIONS ASSOCIATED WITH DISSEMINATED INTRAVASCULAR COAGULATION

[Table 10-9](#) reveals that several clinical entities that are encountered frequently in anesthetic and critical care practice are associated with the development of DIC. Sepsis is the most common cause. Endotoxins or lipopolysaccharide breakdown products from bacteria incite an inflammatory response which includes the generation of cytokines (tumor necrosis factor α , various interleukins). These cytokines in turn stimulate the release or expression of TF by endothelial cells, macrophages, and monocytes and the DIC sequence is initiated.

Several obstetric conditions can cause DIC. These include amniotic fluid embolism, placental abruption, and fetal death *in utero*. Each of these conditions can cause the direct release of TF-equivalent material into the circulation, leading to a rapid and extensive activation of the coagulation system and fulminant DIC. Pre-eclampsia is characterized by a systemic vasculitis. The associated endothelial damage causes an initially low-grade DIC which accelerates as vasculitis-related damage leads to release of TF from ischemic tissues, in particular placenta.

Large burns, extensive traumatic soft tissue injuries, severe brain injury, and hemolytic transfusion reactions can also liberate TF-equivalent material into the circulation and incite DIC. Certain malignancies, most notably promyelocytic leukemia and adenocarcinomas, are associated with DIC. However, with malignancy-associated DIC, thrombotic manifestations are more likely to appear first, whereas with the others mentioned above, the hemorrhagic diathesis is often the first clinical manifestation. A few general conditions such as acidosis, shock, and hypoxia are associated with DIC.¹⁶⁹ Shock which is associated with low blood flow promotes coagulation because one of the control mechanisms (rapid blood flow) is compromised. Clearance of activated clotting factors is reduced when blood flow is decreased. Acidosis and hypoxia may contribute to both tissue and endothelial damage.

The clinical manifestations of DIC are a consequence of both thrombosis and bleeding. Bleeding is a more common clinical presentation in patients with acute, fulminant DIC. Petechiae, ecchymoses, epistaxis, gingival/mucosal bleeding, hematuria, and bleeding from wounds and puncture sites may be evident. With the chronic forms of DIC, thrombotic manifestations are more likely. Organs with the greatest blood flow (e.g., kidney and brain) typically sustain the greatest damage. Pulmonary function may deteriorate as a consequence of microthrombus accumulation.

DIAGNOSIS OF DIC. The typical constellation of laboratory findings includes increased PT and aPTT, thrombocytopenia, a decreased fibrinogen level, and the presence of FDPs and D-dimers. The peripheral smear may reveal schistocytes (fragmented RBCs reflecting the microangiopathy that occurs as a consequence of widespread fibrin deposition). Fibrinogen level may not be decreased initially. Fibrinogen is an “acute-phase reactant” which increases in response to stress, and the early consumption of fibrinogen may simply reduce its levels to “normal.” FDPs are a sensitive measure of fibrinolytic activity although they are not specific for DIC. FDPs appear as a result of the breakdown of fibrin in any stage of clot maturation or fibrinogen itself. D-dimer (which is a breakdown product of the crosslinked fibrin in a mature clot) is much more specific for DIC and should be measured when that diagnosis is suspected.

Various other laboratory assays have been employed to support a diagnosis of DIC, but should probably not be considered part of the anesthesiologist's routine. They include levels of ATIII, α_2 -antithrombin, and protein C (all decreased because of binding to thrombin); plasminogen (decreased); thrombin–ATIII (TAT) complexes (increased); and Factor VIII (decreased in DIC but normal with hepatic failure without DIC).

TREATMENT OF DIC. Treatment should focus on management of the underlying condition. Septicemia will require antibiotic therapy. The obstetric conditions are frequently self-limited, although evacuation of the uterus or hysterectomy may be warranted. Hypovolemia, acidosis, and hypoxemia should be corrected to prevent their contribution to the DIC process.¹⁷⁰

When bleeding is or may become life-threatening, the consumptive coagulopathy must be treated. Platelets will be required for thrombocytopenia, e.g., <50,000/mm³. FFP will replace the clotting factor deficiencies. Fibrinogen level should be increased to >100 mg · dl⁻¹. When hypofibrinogenemia is severe (<50 mg · dl⁻¹), it will not be corrected by the limited amounts of fibrinogen present in FFP, and cryoprecipitate should be administered. Six units of cryoprecipitate will increase fibrinogen level by approximately 50 mg · dl⁻¹ in a 70-kg patient.¹⁶⁸

Heparin has been advocated. However, the contemporary practice is to restrict its use to situations in which thrombosis is clinically problematic, principally DIC associated with malignancies. There is no proven benefit in situations in which bleeding is the predominant manifestation.^{167,168} Although antifibrinolytics have been considered, their administration in the face of widespread thrombosis is potentially disastrous so they should not be used. Antithrombin III concentrates have been administered. ATIII is a natural anticoagulant that binds both thrombin and the activated factors of the “intrinsic process” and is typically depleted during DIC. The hope is that its administration will serve to slow the runaway coagulation process. However, a beneficial effect on outcome from DIC has not been confirmed,¹⁷¹ and its use should be viewed as experimental.

Cardiopulmonary Bypass and Coagulation. The management of anticoagulation and postcardiopulmonary bypass (CPB) bleeding are addressed in [Chapter 32](#).

Blood Component Therapy

After observation of a clinical coagulopathy and laboratory testing, the clinician must determine which, if any, hemostatic blood products or pharmacologic agents are

warranted. Brief descriptions of the preparation of and the indications for the various hemostatic blood components follow. For the collection and preparation of whole blood and packed RBCs, see the section entitled [Collection and Preparation of Blood Products for Transfusion](#) (above).

Platelets

Platelets are separated from plasma by centrifugation. They are commonly supplied as single-donor units with the platelets suspended in a small quantity of residual plasma. One unit of platelets will increase the platelet count of a 70-kg recipient by 5000–10,000/mm³. When platelets are indicated, a common practice is to administer one unit per 10 kg of body weight. Accordingly, platelet transfusion will often entail exposure to multiple donors. Donor exposure can be minimized by the use of single-donor “platelet pheresis packs,” which contain the platelet equivalent of approximately six single units. These are obtained by serial blood withdrawals from a single donor followed by centrifugation and return of the RBCs to the donor.

Platelet viability is optimal at 22°C but storage is limited to 4–5 days. The short shelf time means that platelets are usually administered before the results of the newly introduced nucleic acid amplification test (NAT) for viral agents are available. Platelets bear both ABO and human leukocyte (HLA) antigens. ABO compatibility is ideal. But even though incompatibility shortens the life span of the platelet, ABO compatibility is not absolutely necessary. Not all institutions ABO-match platelets. The HLA antigens are responsible for the platelet refractoriness exhibited in some patients who develop antibodies after multiple transfusions containing either platelets or white blood cells. Platelets do not carry the Rh antigen. However, administration of platelets from an Rh-positive donor to an Rh-negative recipient should be avoided in order to prevent sensitization as a result of passenger RBCs in the platelet preparation. This is especially important in females who may subsequently become pregnant.

Platelets should be administered to correct clinical coagulopathy associated with deficiencies in platelet number or platelet function. When platelet count falls acutely below 75,000/mm³, bleeding is often evident in the surgical patient. However, platelets should not be given unless a clinical coagulopathy is apparent. In other patient populations, a clinical coagulopathy may not occur until much lower platelet counts are reached, e.g., 10,000/mm³ in ITP (idiopathic thrombocytopenic purpura), 20,000/mm³ in bone marrow depression,¹⁷² and 40,000/mm³ during massive transfusion. Platelet dysfunction may occur and platelet administration may be warranted in situations in which platelet counts exceed 100,000/mm³, e.g., after cardiopulmonary bypass, in the presence of platelet-inhibiting drugs (ASA, ticlopidine), and uremia. Again, it is the presence of a clinical coagulopathy that justifies their administration.

Fresh Frozen Plasma (FFP)

Plasma is separated from the RBC component of whole blood by centrifugation. One unit has a volume of 200–250 ml. It will contain the preservative added at the time of collection, usually CPD-adenine. To preserve the two labile clotting factors (V and VIII), it is frozen promptly and thawed only immediately prior to administration. FFP must be ABO-compatible. Rh-positive plasma can be given to an Rh-negative recipient, but ideally this should be avoided in young females because of the possibility of alloimmunization to the Rh antigen on passenger RBCs in the FFP. Indications for FFP administration¹⁷³ include: (1) replacement of factor deficiencies indicated by a clinical coagulopathy and laboratory evidence, e.g., PT >18 sec, aPTT >145 sec, fibrinogen <100 mg · dl⁻¹; (2) immediate reversal of coumadin effect; (3) deficiency of antithrombin III, protein C, protein S, or C1-esterase inhibitor; (4) treatment of thrombotic thrombocytopenic purpura and the hemolytic uremic syndrome; and (5) clinical coagulopathy associated with massive blood transfusion. FFP should not be used as a volume expander or to treat nutritional deficiency in the absence of coagulation disorders. An empirical dose of 5–10 ml of FFP per kilogram of body weight may be used.¹⁷⁴

Solvent Detergent Plasma

One of the principal hazards of FFP administration has been virus transmission. Three procedures—pasteurization, photochemical treatment, and solvent detergent (SD) treatment—have been used to inactivate viruses. The SD technique is now the most widely applied, largely because it is highly effective in inactivating all of the lipid-encapsulated viruses (HIV, HCV, HGBV, HTLV). The disadvantage of the SD technique is that the process involves pooling of large numbers of single FFP units (>1000) and is not effective against nonlipid-enveloped viruses (HAV, parvovirus) or the agent of Creutzfeldt-Jacob disease. The concern with SD plasma is that the pooling process might result in wide dissemination of an infectious agent. The incidence of parvovirus viremia among donors is estimated to be between 0.03 and 0.6%.¹⁷⁵ Parvovirus infection has been reported as a consequence of transfusion. While the disease is usually self-limited, significant morbidity (e.g., red cell aplasia, meningitis) can occur, especially in immunocompromised patients.¹⁷⁵ The future of SD plasma is not clear at the time of this review.

Cryoprecipitate

Cryoprecipitate can be recovered from FFP thawed at 4°C.^{176,177} It is a concentrated source of Factor VIII, Factor XIII, vWF, and fibrinogen. It is stored at –20°C and thawed immediately prior to use. Indications include (1) hypofibrinogenemia (<100 mg · dl⁻¹), (2) hemophilia A (if a virus-inactivated Factor VIII concentrate is not available), (3) von Willebrand's disease, (4) Factor XIII deficiency, (5) preparation of fibrin “glue,” and (6) uremia with active bleeding.

One unit of cryoprecipitate (the yield from one unit of FFP) contains sufficient fibrinogen to increase fibrinogen level 5–7 mg · dl⁻¹.¹⁷⁶ Accordingly, it is usually provided in bags that contain 10 or 20 units. ABO compatibility is not essential because of the limited antibody content of the associated plasma vehicle (10–20 ml). Viruses can be transmitted with cryoprecipitate.

Factor VIII and Factor IX Concentrates

Plasma concentrates of Factors VIII and IX are available. Because they are “pooled” donor products, they have an inherent risk of virus transmission. However, contemporary methods of virus inactivation have made these preparations relatively safe.¹⁷⁸ Factor VIII concentrate is indicated for the treatment of hemophilia A. Factor IX concentrate is indicated in hemophilia B (Christmas disease) and for deficiencies of Factors II, VII, and X, which it also contains in substantial concentrations.

Antithrombin III

Virus-treated ATIII concentrates are available. They have been employed in the treatment of congenital and acquired ATIII deficiencies.¹⁷⁹ The latter include DIC and fulminant hepatic failure.

Pharmacologic Therapy

Desmopressin (1-deamino-8-D-arginine vasopressin; DDAVP) is a synthetic analog of the natural hormone vasopressin. The actions of vasopressin are thought to be mediated by two general classes of receptors: those that mediate smooth muscle contraction in the peripheral vasculature (V1 receptors), and those that regulate water reabsorption in the collecting ducts of the nephron (V2 receptors). Desmopressin has no activity at the V1 receptors and accordingly has virtually no vasoconstrictor effect. It does, however, act at V2 receptors. In fact, desmopressin is a more potent antidiuretic than vasopressin and has a more prolonged activity. Desmopressin was used primarily for clinical conditions such as diabetes insipidus until its hemostatic effects were recognized.

The hemostatic effects of desmopressin are thought to be mediated by “low-affinity, extra-renal V2-like” receptors.¹⁴⁸ Desmopressin causes release of coagulation factor VIII:C, vWF, and tissue plasminogen activator. Desmopressin is thought to release VIII:C from the sinusoidal liver endothelial cells, and the vWF from endothelial cells. Desmopressin also increases platelet adhesiveness and shortens the bleeding time, though the mechanism of these effects is not fully understood. It appears to entail more than a simple increase in the plasma vWF level.

Desmopressin

Indications: Desmopressin has proven an effective treatment for certain types of vWD, mild hemophilia, and various conditions associated with platelet dysfunction.¹⁴⁸

von Willebrand's Disease. The most common form of vWD (Type 1) involves a simple quantitative decrease in the plasma levels of vWF. Desmopressin is extremely effective in these patients. It can effectively normalize the plasma levels of vWF. However, patients with Type 2 vWD synthesize an abnormal protein, and increased release of the abnormal factor does not usually improve their bleeding defect. Patients with the 2B subtype of vWD, who produce a factor that binds spontaneously to the platelet GPIIb receptor (without the need for a conformation change) may actually become thrombocytopenic following desmopressin administration. Patients with Type 3 vWD who produce virtually no vWF also do not benefit from desmopressin.¹⁴⁸

Mild Hemophilia. Desmopressin is useful in patients with mild to moderate hemophilia A who synthesize enough Factor VIII:C that desmopressin can effectively liberate the needed clotting factor into the blood. In these patients, desmopressin can increase the circulating factor VIII:C concentration 2- to 6-fold.

Conditions Associated with Platelet Dysfunction. Desmopressin has been shown to reduce the bleeding time in a variety of conditions associated with platelet dysfunction. It produces rapid and temporary correction of prolonged bleeding times in uremic patients following intravenous or intranasal administration. In cirrhotics, desmopressin increases the concentrations of larger vWF multimers and shortens prolonged bleeding times. Desmopressin also decreases the prolonged bleeding times caused by many drugs including aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), dextran, ticlopidine, and heparin.¹⁴⁸

Use in Cardiac Surgery. The prophylactic use of desmopressin in cardiac surgical patients has been controversial. Because one of the most common and clinically relevant hemostatic changes during CPB is the occurrence of both platelet dysfunction and thrombocytopenia, numerous studies have been performed to assess the use of desmopressin in these patients. Those that have revealed decreased blood loss or blood product administration have involved principally patients who were predisposed to blood loss, *e.g.*, redo procedures^{180,181,182} and ¹⁸³ and patients receiving aspirin.¹⁸⁴ The latter observation suggests that patients at risk can safely continue aspirin up to the time of surgery.

Dosage Recommendations. Desmopressin is commonly administered iv in a dose of 0.3 $\mu\text{g} \cdot \text{kg}^{-1}$. The effect of desmopressin is almost immediate. Peak levels of Factor VIII:C and vWF are achieved within 30–60 min and the effect lasts for several hours.¹⁴⁸ Desmopressin administration may be repeated after 8–12 hours. When used in cardiac surgery, the drug should be administered after termination of cardiopulmonary bypass. Water balance should be monitored. However, while congestive cardiac failure and hyponatremia and seizures in children have been reported, clinically significant water retention is relatively uncommon. Desmopressin may be administered as a nasal spray and is available for home use for both mild hemophiliacs and patients with vWD (Type 1). Intravenous administration causes a more rapid rise in VIII:C levels and is therefore preferable for acute hemostatic challenges.

Tachyphylaxis. There has been concern that tachyphylaxis to repeated doses might occur as a result of depletion of endogenous stores of Factor VIII:C and vWF. This has not been a problem clinically. There is a decrement in the Factor VIII:C and vWF plasma levels achieved with second and subsequent doses of desmopressin, but the response plateaus at a clinically useful level. In addition, multiple doses are rarely warranted.

Antifibrinolytics

Antifibrinolytic agents have been used frequently in situations in which exaggerated fibrinolysis is suspected of contributing to intraoperative bleeding. These situations include cardiopulmonary bypass procedures, hepatic transplantation, and prostate surgery. The use of antifibrinolytic mouthwashes in the context of dental procedures in patients with hemophilia has been mentioned elsewhere in this chapter. There are three commonly available antifibrinolytics. They are the lysine analogs ϵ -aminocaproic acid (EACA) and tranexamic acid (TXA) and the serine protease inhibitor aprotinin.

ϵ -Aminocaproic Acid and Tranexamic Acid. EACA and TXA bind to both plasminogen and plasmin molecules to produce a structural change. That structural change blocks the conversion of plasminogen to plasmin and also prevents plasmin from degrading fibrinogen and fibrin. The dual action of these agents results in two effects on the hemostatic mechanism. First, decreased synthesis of plasmin from plasminogen results in reduced fibrinolysis (clot lysis). The second effect of these drugs, the inactivation of plasmin, decreases the formation of degradation products of fibrinogen and fibrin. These FDPs have anticoagulant effects, including the inhibition of platelet aggregation and the inhibition of the crosslinking of fibrin strands, which are thereby avoided.

Aprotinin. Aprotinin produces its antifibrinolytic effect by a different mechanism. It is an inhibitor of numerous serine protease enzymes including plasmin and kallikrein. The latter participates in the process of contact activation of Factor XII. As a consequence of its inhibition of plasmin, aprotinin, like EACA and TXA, prevents degradation of fibrinogen and fibrin. As is the case with EACA and TXA, the reduction in FDPs should improve both platelet and coagulation function. However, aprotinin is believed to have an additional beneficial effect on platelets. The mechanism of that effect is not known. Better preservation of the GP1b receptor (which is necessary for initial platelet adhesion to vascular defects) has been reported during cardiopulmonary bypass in patients who received aprotinin.¹⁸⁵ The relevance of any platelet specific effect remains controversial.¹⁸⁶

Use of Antifibrinolytics in Cardiac Surgery. A meta-analysis of the many studies of these agents that have been performed in the context of cardiopulmonary bypass confirms that, overall, blood loss and the administration of allogeneic blood is diminished by the use of all three agents.¹⁸⁷ Concern has been expressed that antifibrinolysis might lead to an increased rate of graft occlusion and myocardial infarction. A recent meta-analysis did not bear out that concern.¹⁸⁷ There does not appear to be a clear consensus as to which of the three agents is most appropriate in the context of cardiopulmonary bypass. Various authors have argued that EACA and TXA are preferable to aprotinin because they are less expensive and have apparently similar efficacy.^{188,189}

The patterns of use of antifibrinolytic agents in cardiac surgery vary substantially among institutions. Few appear to use these agents routinely for all cardiopulmonary bypass procedures. Some reserve their use for situations more likely to be associated with post-CPB bleeding (*e.g.*, redo procedures, circulatory arrest procedures). Still others appear to reserve antifibrinolytics for refractory bleeding post-CPB. The latter seems less logical because much of the activation of the hemostatic mechanism occurs during cardiopulmonary bypass.

There is a small but finite rate of allergic responses to aprotinin. Accordingly, a test dose has been recommended for patients who have had prior exposure to aprotinin. The potential for developing sensitivity has been used as a rationale for avoiding administration of aprotinin in circumstances where it is not clearly indicated (*e.g.*, first-time CABG), so that it may be used safely in the event of a redo procedure.

Use of Antifibrinolytics in Hepatic Transplantation. Accelerated fibrinolysis occurs commonly in patients undergoing hepatic transplantation. This is probably, in part, the consequence of decreased clearance of activated clotting factors by the diseased liver. More importantly, hepatic clearance ceases entirely during the anhepatic phase. In addition, with reperfusion of the donor liver, there is an “explosive” release of t-PA into the systemic circulation.¹⁹⁰ Aprotinin, EACA, and TXA have all been used and reported to reduce blood loss in hepatic transplantation.^{190,191,192} and ¹⁹³ However, not all studies have demonstrated a reduction in transfusion requirements.¹⁹⁴ In some instances, these agents have been administered prophylactically.¹⁹⁰ However, the more commonly used and advocated approach is to administer these agents only in response to the demonstration, typically by thromboelastography (see Fig. 10-12), of hyperfibrinolysis.^{192,195}

Figure 10-12. Thromboelastogram patterns seen in normal subjects and in subjects with four abnormalities of hemostasis. New York, Praeger, 1986.)

CONCLUSION

The approach to the bleeding patient requires a knowledge of the basic hemostatic mechanism, common bleeding disorders, an ability to interpret coagulation tests, and an appreciation of the risks involved with blood component therapy.

More than 30 years ago, Dr. E. M. Papper¹ emphasized the importance of understanding the pharmacology of anesthetics:

Clinical anaesthetists have administered millions of anaesthetics during more than a century with little precise information of the uptake, distribution, and elimination of inhalational and non-volatile anaesthetic agents. Considering how serious is the handicap of not knowing those fundamental and important facts about the drugs they have used so often, the record of success and safety in clinical anaesthesia is an extraordinary accomplishment indeed. It can in some measure be attributed to the accumulated experience and successful teaching of a highly developed sense of intuition from generation to generation of anaesthetists. It can also be attributed in part to the ability to learn by error after observing patients come uncomfortably close to injury and even to death.

In the last few years, however, sufficient fundamental information has become available to explain these clinical successes. The empirical process of giving an anaesthetic can be better understood because of the specific data provided by the studies reported in this symposium and by the work of others which has preceded them.

Understanding the principles of pharmacology and knowledge of the specific properties of individual drugs are even more important today. New anesthetics, opioids, and neuromuscular blockers have recently become available. We do not have the benefit of decades of experience with these new drugs, so we must depend on carefully conducted investigations for the information needed to use them optimally. As Dr. Papper wrote,

If the anaesthetist studies the pharmacology of these agents and understands their pharmacokinetic properties, he can with reasonable certainty predict which of these newer anaesthetic agents will hold promise for clinical utility . . . the clinician can spare his patients much danger and his own work many hardships if he is aware of the physicochemical and pharmacological [properties] of new agents.

Our patients are also changing. Many have concomitant diseases that were once considered contraindications to anesthesia and surgery. Therefore, we must consider the impact of chronic diseases, and of the drugs used to treat them, on the responses to drugs administered during the perioperative period. Comprehensive knowledge of clinical pharmacology is a prerequisite to the practice of anesthesiology.

The first sections of this chapter discuss the biologic and pharmacologic factors that influence drug absorption, distribution, and elimination. Quantitative analysis of these processes is discussed in the section on pharmacokinetics. The next section presents the fundamentals of pharmacodynamics—those factors that determine the relationship between drug concentration and pharmacologic effects. Clinical application of pharmacokinetics and pharmacodynamics is then reviewed. The final section briefly presents the mechanisms of drug interactions. Although specific properties of drugs are used to illustrate basic pharmacologic principles, detailed information regarding the pharmacology of drugs used in anesthesiology is presented in succeeding chapters.

TRANSFER OF DRUGS ACROSS MEMBRANES

Absorption, distribution, metabolism, and excretion of drugs require their transfer across cell membranes. Most drugs must also traverse cell membranes to reach their sites of action. Biologic membranes consist of a lipid bilayer with a nonpolar core and polar elements on their surfaces. Proteins are embedded in the lipid bilayer and are oriented similarly, with ionic, polar groups on the membrane surfaces and hydrophobic groups in the membrane interior. The nonpolar core hinders the passage of water-soluble molecules, so that only lipid-soluble molecules easily traverse cell membranes.

Transport Processes

Drugs can cross cell membranes either by passive processes or by active transport through the membrane. *Passive diffusion* occurs when a concentration gradient exists across a membrane. The rate of passive transfer is directly proportional to the concentration gradient and the lipid solubility of the drug. Passage of water-soluble drugs is restricted to small aqueous channels through the membrane. These channels are so narrow that only molecules smaller than 200 D pass through them readily. Capillary endothelial cells, except those in the central nervous system (CNS), permit transfer of much larger molecules, such as albumin (molecular weight ~67,000 D). Because of these unique features, diffusion of drugs across capillary membranes outside the CNS is limited by blood flow, not by lipid solubility.²

Some drugs are transferred through cell membranes of hepatocytes, renal tubular cells, and others by *active transport*. This is an energy-requiring process that is both specific and saturable. Active transport can pump compounds against their concentration gradients. *Facilitated diffusion* shares some characteristics with active transport. It is also carrier-mediated, specific, and saturable, but does not require energy and cannot overcome a concentration gradient.²

Effects of Molecular Properties

Most drugs are too large to pass through cellular membrane channels and must traverse the lipid component of membranes. Almost all drugs are either weak acids or weak bases, and are present in both ionized and nonionized forms at physiologic pH. The nonionized form is more lipid-soluble and able easily to traverse cell membranes. The nonionized fraction of weak acids, such as salicylates and barbiturates, is greater at low pH values, so acidic drugs become more lipid-soluble as pH

decreases. The nonionized fraction of weak bases like opioids and local anesthetics increases as the pH becomes more alkaline. The pK_a is the pH at which exactly 50% of a weak acid or base is present in each of the ionized and nonionized forms. The closer the pK_a is to the ambient pH, the greater the change in the degree of ionization for a given change in pH. If there is a pH gradient across a membrane, drug will be trapped on the side that has the higher ionized fraction, because only the nonionized drug is diffusible. This phenomenon is known as *ion trapping*. The total drug concentration is greater on the side of the membrane with the higher ionized fraction. However, at equilibrium, the concentration of nonionized drug will be the same. In most situations, the range of pH values is too small to cause major changes in the degree of ionization. However, there are major pH changes in the upper gastrointestinal (GI) tract, which can affect drug absorption.

DRUG ABSORPTION

Except after intravenous (iv) injections, drugs must be absorbed into the circulation before they can be delivered to their sites of action. Therefore, absorption is an important determinant of both the intensity and duration of drug action. Incomplete absorption limits the amount of drug reaching the site of action, reducing the peak pharmacologic effect. Rapid absorption is a prerequisite for rapid onset of action. In contrast, slow absorption permits a sustained duration of action because of the "depot" of drug at the absorptive site. The speed of absorption depends on the solubility and concentration of drug. All drugs must dissolve in water to reach the circulation. Consequently, drugs in aqueous solutions are absorbed faster than those in solid formulations, suspensions, or organic solvents, such as propylene glycol. A high concentration of drug facilitates absorption. Increased blood flow to the site of injection increases the rate of absorption. Decreased blood flow secondary to hypotension, vasoconstrictors, or other factors slows drug absorption. Vasoconstrictors added to local anesthetics delay absorption after subcutaneous injection. This prolongs the duration of action at the site of injection and lessens the chance of systemic toxicity.

Route of Administration

In general medical practice, drugs are most commonly administered orally. The advantages of oral administration are convenience, economy, and safety. Disadvantages include the requirement for a cooperative patient, incomplete absorption, and metabolism of the drug in the GI tract and liver before it reaches the systemic circulation.² In anesthesia, drugs are most frequently administered *via* iv and inhalational routes. Both permit rapid and reasonably predictable attainment of the desired blood concentration.

Oral Administration

Absorption from the GI tract is highly variable because of the multiple factors involved. Tablets and capsules must disintegrate before the drug can dissolve in the GI lumen. The drug must then cross the GI epithelium and pass into the portal circulation. The most important site of absorption of all drugs is the small intestine, because of its large surface area and the anatomic characteristics of its mucosa. The nonionized fraction of weak acids such as barbiturates is higher at low pH values, which favors absorption from the stomach. However, the effect of pH on ionization of acidic drugs in the stomach is offset by the small surface area and thickness of the gastric mucosa, and the rapidity of gastric emptying. Basic drugs are highly ionized at low pH, so they cannot cross the gastric mucosa. The more alkaline pH of the small intestine increases the nonionized fraction of basic drugs such as opioids, facilitating their absorption.

Once drugs enter the portal circulation, they must traverse the liver before reaching the systemic circulation. Some drugs are extensively metabolized during this initial pass through the liver, so that only a small fraction of the drug reaches the systemic circulation. This is called the *first-pass effect*. Depending on the magnitude of the first-pass effect, the oral dose must be proportionately larger than the iv dose to achieve the same pharmacologic response. Metabolism of some drugs by the GI mucosa also contributes to the first-pass effect.³

Sublingual Administration

Drug absorbed from the oral mucosa passes directly into the systemic circulation, eliminating the first-pass effect. Because of the small surface area for absorption, this route is efficacious only for nonionized, highly lipid-soluble drugs, such as nitroglycerin.

Rectal Administration

The first-pass effect is less evident after rectal administration because much of the drug is absorbed into the systemic circulation. Unfortunately, absorption from the rectum is often erratic and incomplete.²

Transcutaneous Administration

Only lipid-soluble drugs can penetrate intact skin sufficiently to produce systemic effects. Drug "patches" applied to the skin are now widely used. These systems consist of an adhesive containing a reservoir of drug that is slowly released after the patch is applied, producing a stable pharmacologic effect. Drugs currently administered in this fashion include scopolamine (for motion sickness) and nitroglycerin. Opioid patches are used for treatment of chronic pain. Transcutaneous absorption of drugs from patches is passive, so the onset time is delayed. This disadvantage can be overcome by using an electric current to "drive" ionized drugs into the skin, a process is called *iontophoresis*. Transcutaneous iontophoretic administration of fentanyl has been described.⁴

Intramuscular and Subcutaneous Injection

Absorption of drugs from subcutaneous tissue is relatively slow, permitting a sustained effect. The rate of absorption can be altered by changes in the drug formulation. Examples of such manipulations are the various preparations of insulin and the addition of vasoconstrictors to local anesthetic solutions. Uptake of drugs after intramuscular injection is more rapid than after subcutaneous administration because of greater blood flow. Drugs in aqueous solution are very readily absorbed. The effect of drugs in nonaqueous solutions, such as diazepam in propylene glycol, is less predictable because of erratic absorption.⁵

Intrathecal, Epidural, and Perineural Injection

Intrathecal injection of local anesthetics or other drugs close to their sites of action in the spinal cord permits the use of very low doses, eliminating the risk of adverse systemic drug effects. This is not an advantage of epidural anesthesia or major perineural regional anesthesia because of the greater total dose required. The major disadvantage of these routes of injection is the expertise they require.

Inhalational Administration

Uptake of inhalational anesthetics from the pulmonary alveoli to the blood is exceedingly rapid because of their low molecular weight and high lipid solubility, the large total alveolar surface area and because alveolar blood flow is almost equal to cardiac output.

Intravenous Injection

Intravenous injection eliminates the need for absorption, so that therapeutic blood concentrations are rapidly attained. This is especially advantageous when rapid onset of action is desired. It also simplifies titration of the dose to individual patients' responses. Unfortunately, rapid onset also has its hazards; should an adverse drug reaction or overdose occur, the effects are immediate and potentially severe.

Bioavailability

Bioavailability is defined as the fraction of the total dose that reaches the systemic circulation. Bioavailability is reduced by factors such as incomplete absorption from the site of injection or GI tract, the first-pass effect, or pulmonary uptake of drugs.

Even after iv injection, the bioavailability of drugs formulated in lipid suspensions may be less than 100%. These suspensions contain small lipid droplets. Some, but not all, of the drug diffuses from the lipid droplets into the plasma. These droplets are taken up by the liver and metabolized. Presumably, some drug is also metabolized before it is released back into the circulation. The bioavailability of the lecithin suspension of diazepam is 30% less than that of diazepam in propylene glycol, even with direct iv injection.⁶

DRUG DISTRIBUTION

After absorption or injection into the systemic circulation, drugs are distributed throughout the body. Highly perfused organs, such as the brain, heart, lungs, liver, and kidneys, receive most of the drug soon after injection. Delivery to muscle, skin, fat, and other less well perfused tissues is slower, and equilibration of distribution into these tissues may take several hours or even days.

Capillary membranes are freely permeable in most tissues, so drugs quickly pass into the extracellular space. Subsequent distribution varies according to the physicochemical properties of the drug. Distribution of highly polar, water-soluble drugs such as the neuromuscular blockers is essentially limited to extracellular fluid. Lipid-soluble drugs like propofol easily cross cell membranes and are therefore distributed much more extensively.

Distribution of drugs into the CNS is unique. Brain capillaries do not have the large aqueous channels typical of capillaries in other tissues. Consequently, diffusion of water-soluble drugs into the brain is severely restricted. In contrast, distribution of highly lipid-soluble drugs into the CNS is limited only by cerebral blood flow. For more polar compounds, the rate of entry into the brain is proportional to the lipid solubility of the nonionized drug.

Drugs accumulate in tissues because of binding to tissue components, pH gradients, or uptake of lipophilic drugs into fat. These tissue stores can act as reservoirs that prolong the duration of drug action, either in the same tissue, or by delivery to the site of action elsewhere after reabsorption into the circulation.

Binding of drugs to plasma proteins and erythrocytes influences distribution to other tissues. Only free, unbound drug can cross capillary membranes. The extent of tissue uptake of drugs depends on the affinity of drug binding to blood constituents, relative to the overall affinity of binding to tissue components.

Redistribution

The rapid entry and equally rapid egress of lipophilic drugs from richly perfused organs such as the brain and heart is referred to as *redistribution*. This phenomenon is illustrated by the events that follow an injection of thiopental. The brain concentration of thiopental peaks within 1 minute because of high blood flow to the brain and the high lipid solubility of thiopental. As the drug is taken up by other, less well perfused tissues, the plasma level rapidly decreases. This creates a concentration gradient from cerebral tissue to the blood, so that thiopental quickly diffuses back into the blood, where it is redistributed to other tissues that are still taking up drug. Ultimately, adipose tissue contains most of the drug remaining in the body because of the high lipid solubility of thiopental. However, recovery from a single dose of thiopental depends predominantly on redistribution of thiopental from the brain to muscle, because of the larger mass and greater perfusion of muscle compared to adipose tissue.^{7,8}

A single moderate dose of thiopental (<5–6 mg · kg⁻¹) has a very short duration of action because of redistribution. If repeated injections are given, the concentration of thiopental builds up in the peripheral tissues, and termination of drug action becomes increasingly dependent on the much slower process of drug elimination. Termination of the pharmacologic effects of other lipophilic drugs, such as fentanyl and its derivatives, and propofol, is also governed by these factors.

Placental Transfer

Most drugs cross the placenta by simple diffusion, so thiopental and other lipid-soluble drugs with low molecular weights are most readily transferred. Highly polar, water-soluble compounds such as the neuromuscular blocking drugs do not cross the placenta to a significant extent. Fetal pH is slightly lower than maternal pH. This pH gradient causes the ionized fraction of weak bases, such as opioids and local anesthetics, to be higher in the fetus. Therefore, the fetal total drug level may be higher than predicted from the maternal total drug level because of ion trapping.⁹ Different total drug concentrations can also result from differences between mother and fetus in the extent of drug binding to plasma proteins. However, regardless of the effects of pH and protein binding, the concentration of free, nonionized drug is the same on both sides of the placenta once equilibrium is reached. For most drugs, this is the most important form, because it has the most pharmacologic activity.

DRUG ELIMINATION

Elimination is an inclusive term referring to all the processes that remove drugs from the body. Elimination occurs either by excretion of unchanged drug or by metabolism (biotransformation) and subsequent excretion of metabolites. The liver and kidneys are the most important organs for drug elimination. The liver eliminates drugs primarily by metabolism to less active compounds and, to a lesser extent, by hepatobiliary excretion of drugs or their metabolites. The primary role of the kidneys is the excretion of water-soluble, polar compounds. Drugs having these properties, such as most nondepolarizing neuromuscular blockers, undergo renal excretion intact.¹⁰ The kidneys are also the primary route for excretion of water-soluble metabolites of drugs that initially undergo hepatic biotransformation. Pulmonary excretion is the major route for elimination of anesthetic gases and vapors.

The term *drug clearance*, or *elimination clearance*, describes the ability to remove drug from the blood. Drug clearance is the theoretical volume of blood from which drug is completely and irreversibly removed in a given time interval. It is analogous to creatinine clearance, which quantitatively describes the ability of the kidneys to eliminate creatinine. Like creatinine clearance, drug clearance has units of flow, milliliters per minute (mL · min⁻¹). Many drugs are cleared by more than one route, and multiple elimination pathways are additive. Consequently, total drug clearance is equal to the sum of the clearances of all of the elimination pathways.

Total drug clearance can be calculated with pharmacokinetic models of blood concentration *versus* time data. However, clearance by individual organs and the biologic factors influencing drug elimination cannot be estimated from blood concentration data alone. Additional data, such as the hepatic arteriovenous drug concentration difference or the rate of urinary excretion of the drug, are needed to determine the contribution of a specific organ to total drug clearance.

Hepatic Drug Clearance

Drug clearance by the liver is dependent on three biologic factors: (1) hepatic blood flow, (2) the intrinsic ability of the liver to irreversibly eliminate the drug from the blood, and (3) the extent of drug binding to plasma proteins or other blood constituents. The interrelationships between these factors have been described with the *venous equilibration model* of hepatic drug clearance.^{11,12} According to this model, the unbound concentration of drug in hepatic venous blood is in equilibrium with the unbound concentration in hepatocytes. The unbound drug within the liver is the drug that can be eliminated by biotransformation or biliary excretion.

The venous equilibration model is based on two assumptions: that hepatic drug clearance is limited by delivery of drug to the liver, and that elimination is a first-order process.¹¹ By definition, *first-order* means that a constant fraction of the drug is eliminated per unit time. The fraction of the drug removed from the blood passing through the liver is the hepatic extraction ratio, *E*:

$$E = \frac{C_a - C_v}{C_a}, \quad (11-1)$$

where *C_a* is the mixed hepatic arterial–portal venous drug concentration and *C_v* is the mixed hepatic venous drug concentration. The total hepatic drug clearance, *Cl_H*, is:

$$Cl_H = Q \cdot E, \quad (11-2)$$

where *Q* is hepatic blood flow. Therefore, hepatic clearance is a function of hepatic blood flow and the ability of the liver to extract drug from the blood. The ability to extract drug depends on the activity of drug-metabolizing enzymes and the capacity for hepatobiliary excretion.

The concept of *intrinsic clearance* was developed to account for the effects of blood flow and drug binding in the blood on elimination.¹¹ Intrinsic clearance represents the ability of the liver to remove drug from the blood in the absence of any limitations imposed by blood flow or drug binding. The relationship of total hepatic drug clearance to the extraction ratio and intrinsic clearance, *Cl_i*, is:

$$Cl_H = Q \cdot E = Q \left(\frac{Cl_i}{Q + Cl_i} \right) \quad (11-3)$$

The right-hand side of [Equation 11-3](#) indicates that if intrinsic clearance is very high (many times larger than hepatic blood flow), total hepatic clearance approaches hepatic blood flow. On the other hand, if intrinsic clearance is very small, hepatic clearance will be similar to intrinsic clearance. These relationships are shown in [Figure](#)

11-1.

Figure 11-1. The relationship between hepatic extraction ratio, intrinsic clearance, and hepatic clearance at the normal hepatic blood flow of $1.5 \text{ L} \cdot \text{min}^{-1}$. For drugs with high intrinsic clearance ($>25 \text{ L} \cdot \text{min}^{-1}$), increasing intrinsic clearance has little effect on hepatic extraction and total hepatic clearance. The inset demonstrates the relationship at low values of intrinsic clearance on an expanded scale. (Reprinted with permission from Wilkinson GR, Shand DG: A physiologic approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Thus, hepatic drug clearance and extraction are determined by two independent variables, intrinsic clearance and hepatic blood flow. Changes in either will change hepatic clearance. However, the extent of the change depends on the initial intrinsic clearance. If the inherent ability of the liver to eliminate a drug (intrinsic clearance) is doubled, then the extraction ratio also increases, but not necessarily to the same extent. The extraction ratio and intrinsic clearance do not have a simple, linear relationship:

$$E = \frac{Cl_i}{Q + Cl_i} \quad (11-4)$$

If the initial intrinsic clearance is small relative to hepatic blood flow, then the extraction ratio is also small, and Equation 11-4 indicates that doubling intrinsic clearance will produce an almost proportional increment in the extraction ratio, and, consequently, clearance. However, if intrinsic clearance is much greater than hepatic blood flow, a twofold change in intrinsic clearance has a negligible effect on the extraction ratio and drug clearance. In nonmathematical terms, high intrinsic clearance indicates efficient hepatic elimination. It is hard to enhance an already efficient process, whereas it is relatively easy to improve on inefficient drug clearance due to low intrinsic clearance.

The effect of changes in hepatic blood flow also depends on the magnitude of intrinsic clearance. If extraction and intrinsic clearance are high, a decrease in hepatic blood flow causes a small increase in the extraction ratio (Fig. 11-2) that is insufficient to offset the effects of reduced hepatic flow (Eq. 11-4). Consequently, changes in hepatic blood flow produce virtually proportional changes in clearance of drugs with high extraction ratios (Fig. 11-3). For a drug with a low intrinsic clearance, a decrease in hepatic blood flow is associated with a larger, almost proportional increase in the extraction ratio (see Fig. 11-2). This largely offsets the effects of changes in blood flow, so that clearance of drugs with low extraction ratios is essentially independent of hepatic blood flow (see Fig. 11-3).

Figure 11-2. The effect of changes in hepatic blood flow on extraction of drugs with different extraction ratios. The extraction ratios at the normal hepatic blood flow of $1.5 \text{ L} \cdot \text{min}^{-1}$ are above the corresponding curves. (Reprinted with permission from Wood JJ: Drug disposition and pharmacokinetics. In Wood M, Wood AJJ [eds]: Drugs and Anesthesia—Pharmacology for Anesthesiologists, p 27. Baltimore, Williams & Wilkins, 1990. After Wilkinson GR, Shand DG: A physiologic approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Figure 11-3. The effect of changes in hepatic blood flow on hepatic clearance of drugs with different extraction ratios. The extraction ratios for each curve at $1.5 \text{ L} \cdot \text{min}^{-1}$ flow are indicated. The arrows indicate the normal physiologic range of hepatic blood flow. (Reprinted with permission from Wood AJJ: Drug disposition and pharmacokinetics. In Wood M, Wood AJJ [eds]: Drugs and Anesthesia—Pharmacology for Anesthesiologists, p 27. Baltimore, Williams & Wilkins, 1990. After Wilkinson GR, Shand DG: A physiologic approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Hepatic clearance of drugs with extraction ratios $\leq 30\%$ is independent of changes in liver blood flow, but very sensitive to the liver's ability to metabolize the drug, which can vary as a result of pathologic conditions, inhibition or induction of drug-metabolizing enzymes, or interindividual differences. In contrast, hepatic clearance of drugs with high extraction ratios ($>70\%$) is determined primarily by liver blood flow rather than the activity of drug-metabolizing enzymes. Drugs with intermediate extraction ratios, between 30% and 70%, share characteristics with both the other groups. Drugs can be classified as having either high, intermediate, or low extraction ratios (Table 11-1). Comparing drugs with high versus low extraction ratios reveals easily discernible differences in disposition.¹¹

| Low | Intermediate | High |
|--------------|--------------|-------------|
| Diazepam | Alfentanil | Alprenolol |
| Lorazepam | Methohexital | Bupivacaine |
| Methadone | Midazolam | Diltiazem |
| Phenytoin | Rapacuronium | Fentanyl |
| Rocuronium | Vecuronium | Ketamine |
| Theophylline | | Lidocaine |
| Thiopental | | Maprotiline |
| | | Metoprolol |
| | | Morphine |
| | | Naloxone |
| | | Nifedipine |
| | | Propofol |
| | | Propranolol |
| | | Sufentanil |
| | | Verapamil |

Drugs eliminated primarily by other organs are not included in this table.

Table 11-1. CLASSIFICATION OF SOME DRUGS ENCOUNTERED IN ANESTHESIOLOGY ACCORDING TO HEPATIC EXTRACTION RATIOS

Binding of drugs to plasma proteins and other blood constituents can also affect drug clearance. Whether drug binding influences drug clearance depends on the extraction ratio and the extent of binding. Three classes of hepatic clearance can be defined by integrating the effects of drug binding in the blood and the extraction ratio.¹³ Clearance of drugs with high extraction ratios is *flow-limited* because it depends only on hepatic perfusion and is not affected by changes in drug binding or intrinsic clearance. The combination of a low extraction ratio and a high free fraction results in *capacity-limited, binding-insensitive* clearance, which is affected by changes in intrinsic clearance but is not significantly influenced by binding or hepatic perfusion. Drugs with low extraction ratios and low free fractions have capacity-limited, binding-sensitive clearance, which is not greatly affected by changes in hepatic blood flow but depends on both intrinsic clearance and the free drug concentration. Elimination of drugs with intermediate extraction ratios and binding is influenced by all three biologic factors—hepatic blood flow, intrinsic clearance, and the free drug concentration in the blood. The relative importance of these three factors cannot be predicted unless the extraction ratio and the unbound fraction in the blood are known.

Physiologic, Pathologic, and Pharmacologic Alterations in Hepatic Drug Clearance

At rest, approximately 30% of cardiac output perfuses the liver. The hepatic artery provides roughly 25% of total hepatic flow, with the remainder supplied *via* the portal vein. Many physiologic and pathologic conditions alter hepatic blood flow, but there is little information regarding the effect of these changes in blood flow on hepatic drug clearance. The splanchnic circulation responds to a variety of stimuli, and splanchnic flow is often sacrificed to meet the demands of other tissues.

Moving from the supine to the upright position decreases cardiac output, which produces a reflex increase in systemic vascular resistance. The splanchnic circulation participates in this generalized vasoconstriction, which decreases hepatic blood flow by 30–40%.¹² Clearance of aldosterone, which has a high hepatic extraction ratio, is decreased in the upright position.¹² Postural changes probably also influence clearance of drugs with high hepatic extraction ratios, but this has not been systematically investigated.

Exercise, heat stress, and hypovolemia all decrease splanchnic blood flow in proportion to the associated increase in heart rate, which suggests that these responses are mediated by the sympathetic nervous system.¹² As expected, these conditions decrease clearance of indocyanine green, which has a high hepatic extraction ratio. In contrast, the clearance of antipyrine, a drug with a low extraction ratio, is not affected by these conditions.¹⁴

Decreases in cardiac output cause reflex splanchnic vasoconstriction, which reduces hepatic blood flow in proportion to the reduction in cardiac output.¹⁵ Lidocaine clearance is reduced in patients with congestive cardiac failure.¹⁶ Consequently, if usual doses of lidocaine are given to patients with heart failure, the risk of lidocaine toxicity is increased. Marked reduction in hepatic blood flow causes hepatocellular dysfunction; therefore, severe congestive heart failure decreases drug clearance by reducing both intrinsic clearance and hepatic blood flow.¹⁷ Cardiovascular collapse severely compromises both liver blood flow and hepatocellular function.¹² In experimental hemorrhagic shock, clearance of lidocaine was decreased by 40%, whereas hepatic blood flow declined by 30%.¹⁸ The reduction in clearance is too large to be caused solely by decreased hepatic perfusion, implying a concomitant reduction in intrinsic clearance secondary to hepatic ischemia.

Liver disease can decrease drug clearance because of hepatocellular dysfunction, altered hepatic blood flow, or both.¹² Cirrhosis reduces clearance of drugs with high extraction ratios, including lidocaine,¹⁶ meperidine,^{19,20} and propranolol.²¹ This is secondary to decreased hepatic perfusion, which can be the result of reduced total liver blood flow, intrahepatic shunting, or extrahepatic shunting of portal venous blood.¹² Portosystemic shunting increases the bioavailability of orally administered drugs with high extraction ratios.¹² Cirrhosis also decreases clearance of drugs with low extraction ratios, such as diazepam,^{22,23} because of impaired hepatocellular function, which decreases intrinsic clearance. Acute viral hepatitis reduces the clearance of drugs with both high (meperidine,²⁴ lidocaine²⁵) and low (diazepam²²) hepatic extraction ratios. These observations indicate that both acute and chronic liver diseases affect liver function and blood flow in a parallel fashion. Consequently, in chronic therapy, doses of any drug cleared by the liver should be reduced in patients with hepatic disease.

Drugs that alter splanchnic hemodynamics affect clearance of highly extracted drugs. Propranolol decreases hepatic blood flow, thus decreasing its own clearance¹² and the clearance of concomitantly administered lidocaine.²⁶ The volatile anesthetics all decrease hepatic blood flow, although isoflurane does so to a lesser extent than halothane or enflurane.^{27,28} Intra-abdominal surgery causes a further decrease in hepatic perfusion.²⁷ Hypotension produced by spinal anesthesia reduces splanchnic blood flow.²⁹ In contrast to the volatile anesthetics, nitrous oxide, opioids, and barbiturates have little effect on hepatic blood flow.¹² Although they are potentially of great clinical importance, the effects of these hemodynamic alterations have not been thoroughly investigated. It is logical to assume that the clearance of drugs with high hepatic extraction ratios will be reduced during anesthesia and surgery.

Renal Drug Clearance

Although the kidneys do metabolize drugs, their major function in drug elimination is to excrete drugs, and metabolites produced elsewhere (primarily the liver), into the urine. Renal clearance of drugs is determined by the net effects of three processes: glomerular filtration, tubular secretion, and tubular reabsorption.^{30,31}

Glomerular filtration cannot eliminate drugs efficiently. The glomerular filtration rate is approximately 20% of renal plasma flow.³² Consequently, even if none of the drug is bound to plasma proteins, only about 20% can be removed by glomerular filtration. Drug binding to plasma proteins and erythrocytes reduces the amount filtered, because only unbound drug can pass through the glomerular membrane into the renal tubule. If a drug is neither secreted nor reabsorbed by the renal tubules, then renal drug clearance will be equal to glomerular clearance. Drugs and metabolites excreted in this fashion have low renal extraction ratios, and their renal clearance depends on the degree of binding to blood constituents. Therefore, protein binding is a major determinant of both hepatic and renal clearance of drugs with low extraction ratios.

Proximal renal tubular cells have two discrete mechanisms for secreting acidic and basic organic compounds.³⁰ These processes are carrier-mediated, so they are saturable. Drugs with similar physicochemical characteristics compete for available carrier molecules and interfere with each other's secretion. If a drug is very avidly secreted by tubular cells and not subsequently reabsorbed, it will have a high renal extraction ratio. Renal clearance of such drugs is largely determined by the magnitude of renal blood flow.³⁰ This is analogous to the importance of liver blood flow in the clearance of drugs with high hepatic extraction ratios.

Clearance of drugs filtered by the glomeruli or secreted by the proximal renal tubule may be decreased by subsequent reabsorption from the renal tubule. If this is extensive, the drug will have a very low renal extraction ratio and negligible renal clearance. Tubular reabsorption occurs by active, carrier-mediated transport that is similar to active secretion. Drugs can also be reabsorbed by passive diffusion across the tubular epithelium. The progressive reabsorption of water from the renal tubule facilitates passive reabsorption of drugs by creating a tubule-to-plasma concentration gradient for the drug. Consequently, oliguria can decrease renal drug clearance.³¹ Passive reabsorption is determined by the lipid solubility and degree of ionization of a drug. Highly lipophilic drugs like thiopental are almost completely reabsorbed and have virtually no renal clearance. For less lipophilic drugs, the degree of ionization is a major determinant of the extent of passive reabsorption because only the nonionized drug readily diffuses across the renal tubular epithelium. Urine pH can range from 4.5 to 8.0, which can cause large changes in the ionized fraction of weak acids and bases, particularly if the pK_a is close to or within this range. Urine pH can be manipulated to increase renal drug clearance after overdoses.

Physiologic, Pharmacologic, and Pathologic Alterations in Renal Drug Clearance

In adults, renal blood flow is approximately $1200 \text{ mL} \cdot \text{min}^{-1}$, so renal plasma flow is approximately $700 \text{ mL} \cdot \text{min}^{-1}$. About one-fifth of the plasma is filtered by the

glomerulus, resulting in an average glomerular filtration rate of $125 \text{ mL} \cdot \text{min}^{-1}$. Renal blood flow and glomerular filtration rate are autoregulated, so they remain fairly constant as long as mean arterial pressure is between 70 and 160 mm Hg.³² Consequently, renal drug clearance is more constant than hepatic clearance, because renal blood flow is more closely autoregulated than hepatic blood flow.

The capacity for excreting endogenous and exogenous compounds depends on the number of functionally intact nephrons. Decreased glomerular filtration is accompanied by a parallel loss of renal tubular function. Therefore, clearance of endogenous creatinine, which is essentially equivalent to the glomerular filtration rate, can be used to estimate overall renal function. It follows that renal drug clearance is proportional to creatinine clearance, even for drugs eliminated primarily by tubular secretion. This principle has been used to develop nomograms for reducing drug doses according to the creatinine clearance in the presence of renal dysfunction.³³ Many drugs, including lidocaine,³⁴ pancuronium,³⁵ and meperidine,³⁶ have pharmacologically active metabolites that are excreted by the kidneys. Therefore, both parent drugs and their metabolites can contribute to drug toxicity in patients with renal failure.

Renal function decreases progressively with age. By age 80 years, creatinine clearance is reduced by about 50%.³⁷ Despite the age-related decrease in glomerular filtration rate, serum creatinine is not elevated in healthy elderly patients because muscle mass, the source of creatinine, also decreases with age. Therefore, even if serum creatinine is normal, renal clearance of drugs is reduced in elderly patients.

Many drugs encountered in anesthetic practice are eliminated primarily by the kidneys (Table 11-2). In renal failure, doses of these drugs must be reduced to avoid adverse effects. In addition to renal disease, other pathologic processes can impair kidney function. Low cardiac output states reduce renal blood flow, glomerular filtration, and, consequently, renal drug clearance.³⁰ Advanced hepatic cirrhosis also interferes with renal function,³⁰ and this combination, the *hepatorenal syndrome*, reduces elimination of almost all drugs.

Table 11-2. DRUGS WITH SIGNIFICANT RENAL EXCRETION ENCOUNTERED IN ANESTHESIOLOGY

DRUG METABOLISM

Unless tolerance* develops, termination of drug action depends on removal of the drug from its sites of action. Most operations are completed within a relatively short period (duration of anesthesia <2–3 hours). In such cases, drug redistribution is the primary mechanism responsible for reducing drug concentrations in the blood. This, in turn, establishes the concentration gradient required for removal of drugs from their sites of action. Drug metabolism is more important in terminating effects of drugs that are not extensively redistributed, or when larger, or repeated, doses are administered. This could occur after prolonged anesthesia (>4–5 hours). Consideration of drug metabolism is also important in the therapeutics of critical care and pain therapy.

Drugs must usually cross biologic membranes to reach their sites of action, so most are relatively lipid-soluble. This property makes their excretion difficult, because lipophilic compounds are readily reabsorbed from the gut and the distal renal tubule. Metabolism, or *biotransformation* of drugs to more polar, water-soluble compounds, facilitates the ultimate excretion of metabolites in the bile and urine. Biotransformation is a protective mechanism for preventing the accumulation and resultant toxic effects of various lipophilic compounds acquired from the environment.

Metabolites are usually less active pharmacologically than the parent drug. However, this is not always true. Many benzodiazepines have metabolites that have similar pharmacologic effects.⁵ The analgesic effects of codeine are due to its biotransformation to morphine. Metabolites can also be toxic. The major metabolite of meperidine is normeperidine, which can cause seizures.³⁶ If metabolites are pharmacologically active or toxic, further biotransformation or excretion is required for termination of their effects.

Metabolism of drugs and other exogenous compounds, known collectively as *xenobiotics*, occurs primarily in the liver. Other organs, including the kidneys, lungs, gut, and skin, also metabolize drugs, but extrahepatic biotransformation is quantitatively unimportant in most instances.

Biotransformation Reactions

Biotransformation reactions have classically been divided into two groups. *Phase I* reactions alter the molecular structure of xenobiotics by modifying an existing functional group of the drug, by adding a new functional chemical group to the compound, or by splitting the original molecule into two fragments. These changes in molecular structure result from oxidation, reduction, or hydrolysis of the parent compound. *Phase II* reactions consist of the coupling, or conjugation, of a variety of endogenous compounds to polar chemical groups. The polar chemical group at which conjugation occurs is frequently the result of a previous Phase I reaction, hence the “Phase I–Phase II” nomenclature. However, not all drugs are eliminated by this sequential pathway of biotransformation. Oxidation of thiopental produces its major metabolite, thiopental carboxylic acid,³⁸ which undergoes renal excretion without undergoing a Phase II biotransformation. Morphine is directly conjugated to form morphine glucuronide without first undergoing a Phase I reaction.

Phase I Reactions

Phase I reactions may hydrolyze, oxidize, or reduce the parent compound. *Hydrolysis* is the insertion of a molecule of water into another molecule, which forms an unstable intermediate compound that subsequently splits apart. Thus, hydrolysis cleaves the original substance into two separate molecules. Hydrolytic reactions are the primary way amides, such as lidocaine and other amide local anesthetics, and esters, such as succinylcholine, are metabolized.

Many drugs are biotransformed by oxidative reactions. *Oxidations* are defined as reactions that remove electrons from a molecule. The common element of most, if not all, oxidations is an enzymatically mediated reaction that inserts a hydroxyl group (OH) into the drug molecule.³⁹ In some instances, this produces a chemically stable, more polar hydroxylated metabolite. However, hydroxylation usually creates unstable compounds that spontaneously split into separate molecules. Many different biotransformations are effected by this basic mechanism. Dealkylation (removal of a carbon-containing group), deamination (removal of nitrogen-containing groups), oxidation of nitrogen-containing groups, desulfuration, dehalogenation, and dehydrogenation all follow an initial hydroxylation.³⁹ Hydrolysis and hydroxylation are comparable processes. Both have an initial, enzymatically mediated step that produces an unstable compound which rapidly dissociates into separate molecules.

Some drugs are metabolized by *reductive reactions*, that is, reactions that add electrons to a molecule. In contrast to oxidations, where electrons are transferred from NADPH to an oxygen atom, the electrons are transferred to the drug molecule. Oxidation of xenobiotics requires oxygen, but reductive biotransformation is inhibited by oxygen, so it is facilitated when the intracellular oxygen tension is low.⁴⁰

The Cytochrome P450 System. The complex of enzymes and pigmented hemoproteins that catalyzes most oxidative and some reductive biotransformations is known collectively as the *cytochrome P450 system*. These hemoproteins, when reduced by carbon monoxide, have an absorption spectrum with a peak at the 450-nm wavelength, hence their name. This system is incorporated into the smooth endoplasmic reticulum of hepatocytes. The endoplasmic reticulum is an intracellular network of tubules similar in ultrastructure to cellular membranes. Other tissues, including the kidneys, lungs, and skin, also contain cytochrome P450, but in much smaller amounts.³ Upper intestinal enterocytes contain high concentrations of cytochrome P450, which contributes to the first-pass effect by metabolizing drugs absorbed from the GI tract before they reach the systemic circulation.⁴¹ The cytochrome P450 complex is capable of metabolizing hundreds of compounds, including endogenous substances such as steroids and amines, as well as drugs and other exogenous compounds acquired from the environment.⁴² The cytochrome P450 system oxidizes its substrates primarily by the insertion of an atom of oxygen in the form of a hydroxyl group, while another oxygen atom is reduced to water.

Cytochrome P450 is not a single entity; rather, it is a superfamily of related enzymes.⁴³ More than 150 cytochrome P450s have been identified.⁴² More than 25 different human cytochrome P450s in 14 different families have been characterized.^{44,45} There are “constitutive” forms of cytochrome P450 that are involved in the metabolism of various endogenous compounds, such as steroids, thyroxine, prostaglandins, and amines. In addition to the constitutive forms, production of cytochrome P450s can be induced by a wide variety of xenobiotics.⁴⁶ Cytochrome P450 drug-metabolizing activity increases after exposure to various exogenous chemicals, including many drugs.⁴⁷ The number and type of cytochrome P450s present at any time depends on exposure to different xenobiotics. The cytochrome P450 system is able to protect the organism from the deleterious effects of accumulation of exogenous compounds because of its two fundamental characteristics—broad substrate specificity and the capability to adapt to exposure to different substances by induction of different cytochrome P450 enzymes.

Biotransformations can be inhibited if different substrates compete for the drug-binding site on the same cytochrome P450. The effect of two competing substrates on each other's metabolism depends on their relative affinities for the enzyme. Biotransformation of the compound with the lower affinity is inhibited to a greater degree. This is the mechanism by which the H₂ receptor antagonist cimetidine inhibits the metabolism of many drugs, including meperidine, propranolol, and diazepam.^{48,49} and ⁵⁰ The newer H₂ antagonist ranitidine has a different structure and causes fewer clinically significant drug interactions.⁵¹ Other drugs, notably calcium channel blockers and antidepressants, also inhibit oxidative drug metabolism in humans.^{52,53} During the last decade, information regarding both induction and inhibition of different cytochrome P450 isoenzymes by specific drugs has become available.⁵³ This information allows clinicians to predict which combinations of drugs are more likely to lead to clinically significant interactions due to altered drug metabolism by the cytochrome P450 system.

Induction and inhibition of hepatic drug-metabolizing enzyme systems change the intrinsic hepatic clearance of drugs. This is most important for drugs with low hepatic extraction ratios, because intrinsic clearance is the primary determinant of their hepatic clearance. Altered drug-metabolizing enzyme activity has little effect on drugs with high hepatic extraction ratios because their clearance depends primarily on hepatic blood flow.

Phase II Reactions

Phase II reactions are also known as *conjugation* or *synthetic reactions*. Many drugs do not have a polar chemical group suitable for conjugation, so conjugation occurs only after a Phase I reaction. Other drugs, such as morphine, already have a polar group that serves as a “handle” for conjugation, and they undergo these reactions directly. Various endogenous compounds can be attached to parent drugs or their Phase I metabolites to form different conjugation products.⁵⁴ These endogenous substrates include glucuronic acid, acetate, and amino acids. Mercapturic acid conjugates result from the binding of exogenous compounds to glutathione. Other conjugation reactions produce sulfated or methylated derivatives of drugs or their metabolites. Like the cytochrome P450 system, the enzymes that catalyze Phase II reactions are inducible.⁴⁷ Phase II reactions produce conjugates that are polar, water-soluble compounds. This facilitates the ultimate excretion of the drug *via* the kidneys or hepatobiliary secretion. Like cytochrome P450, there are different families and superfamilies of the enzymes that catalyze Phase II biotransformations.⁵⁴

Factors Affecting Biotransformation

Drug metabolism varies substantially between individuals because of variability in the genes controlling the numerous enzymes responsible for biotransformation. For most drugs, individual subjects' rates of metabolism have a unimodal distribution. However, distinct subpopulations with different rates of elimination of some drugs have been identified. The resulting multimodal distribution of individual rates of metabolism is known as *polymorphism*. For example, different genotypes result in either normal, low, or (rarely) absent plasma pseudocholinesterase activity, accounting for the well-known differences in individuals' responses to succinylcholine, which is hydrolyzed by this enzyme. Many drug-metabolizing enzymes exhibit genetic polymorphism, including cytochrome P450 and various transferases that catalyze phase II reactions.⁵⁵

Drug metabolism also varies with age. The fetus and neonate have less capacity for some biotransformations, especially those catalyzed by cytochrome P450.^{56,57} However, cytochrome P450 activity increases dramatically in early infancy.^{56,57} Neonates also have less capacity for conjugation reactions, especially glucuronidation.^{56,57} Impaired conjugation of bilirubin causes “physiologic jaundice.” Metabolism of some drugs may also be decreased in geriatric patients, although it is difficult to separate the effects of age *per se* from the effects of organ dysfunction, which is more prevalent in the elderly.^{58,59}

Exposure to various foreign compounds can alter drug-metabolizing enzyme activity. Barbiturates, phenytoin, macrolide antibiotics, imidazole antifungal agents, and corticosteroids can cause drug interactions secondary to induction of hepatic drug-metabolizing enzymes.⁴⁷ Chronic ethanol consumption induces enzyme activity, but acute intoxication inhibits the biotransformation of some drugs.⁶⁰ Smoking increases the metabolism of many drugs secondary to enzyme induction by polycyclic hydrocarbons in tobacco smoke.⁶¹

Liver disease profoundly affects drug disposition. It is difficult to distinguish the impact of altered biotransformation *per se* from other effects of liver disease: altered binding of drugs to plasma proteins and decreased liver blood flow. Nonetheless, hepatic disease decreases clearance of drugs with low hepatic extraction ratios,^{13,62} which implies impaired biotransformation. Congestive heart failure decreases metabolism of lidocaine and theophylline.¹⁷ Renal failure has different effects on different biotransformation reactions. Hydrolytic and acetylation reactions are slowed, but conjugations usually are not affected, and some oxidations may actually be enhanced.⁶³

Effects of Anesthesia and Surgery on Biotransformation

Drug disposition is altered in the perioperative period. Although many other factors are probably also involved, biotransformation reactions are affected by anesthesia and surgery. In dogs anesthetized with halothane, the intrinsic hepatic clearance of propranolol is decreased, which implies that hepatic drug-metabolizing ability is impaired.⁶⁴ Halothane inhibits demethylation of aminopyrine in a dose-dependent fashion. Isoflurane has less effect, and enflurane does not affect aminopyrine biotransformation.⁶⁵

Many investigators have studied the effects of anesthesia and surgery on antipyrine clearance. Antipyrine, an antipyretic that is no longer used therapeutically, does not bind to plasma proteins, has a low hepatic extraction ratio, and is not cleared by the kidneys. Therefore, clearance of antipyrine is solely dependent on the activity of hepatic drug-metabolizing enzymes. This permits the use of antipyrine clearance as an indicator of hepatic drug-metabolizing activity.⁶⁶ Clearance of antipyrine is generally increased after surgery conducted with a wide variety of general anesthetic techniques,^{67,68} although there are exceptions to this rule. General anesthesia with enflurane does not appear to increase antipyrine clearance.⁶⁹ After operations lasting more than 4 hours, antipyrine clearance is decreased.⁷⁰ Presumably, major surgical trauma interferes with drug metabolism, although the precise mechanisms are not known. Antipyrine clearance is also increased after spinal anesthesia.⁶⁸ Therefore, general anesthesia is not a prerequisite for increased rates of biotransformation in the postoperative period, and other perioperative factors also affect drug metabolism. For example, the caloric source of iv nutritional regimens influences antipyrine clearance. It is decreased when the only caloric source is 5% dextrose, and increased when amino acids are substituted for dextrose.⁷¹

In addition to altered rates of biotransformation, other factors, such as decreased hepatic blood flow during surgery,^{27,28} can affect drug elimination in the perioperative period. In many patients the magnitude of these changes is too small to cause any clinically evident problems. However, in some patients clinically significant changes in drug elimination could occur. Decreased drug clearance can result in higher concentrations of drugs and increase the risk of adverse effects, especially after prolonged surgery. Clinicians must be aware of the potential for excessive pharmacologic effects and must tailor doses accordingly.

BINDING OF DRUGS TO PLASMA PROTEINS

After injection or ingestion, drugs are transported to their sites of action and to eliminating organs *via* the blood. Drugs are present in the blood in two fractions. Some are simply dissolved in plasma water; the rest is bound to various components of whole blood, such as plasma proteins and red blood cells. Ideally, drug concentrations should be measured in whole blood because drugs are transported in blood, not plasma, and drugs equilibrate between erythrocytes and plasma very quickly.⁷² Unfortunately, measurement of total drug levels and drug binding in whole blood is technically much more difficult than in plasma or serum, so very few investigators have directly measured whole blood binding. As a compromise, the blood:plasma concentration ratio can be used to estimate whole blood binding.

Drugs bind to plasma proteins in a reversible fashion that obeys the law of mass action. The rate constants of the association and dissociation reactions are k_1 and k_2 , respectively. These reactions are very rapid, having half-times of a few milliseconds. Binding of drugs to blood constituents other than proteins, such as erythrocytes, proceeds in an analogous fashion. The equilibrium dissociation constant, K_d , quantifies the affinity of drug-protein binding:

$$K_d = \frac{k_2}{k_1} = \frac{[\text{unbound drug}] \times [\text{protein}]}{[\text{drug-protein complex}]}$$

The dissociation constant has units of moles per liter (mol · L⁻¹), and is the drug concentration at which 50% of the binding sites are occupied. The degree of binding is dependent on the affinity of the protein for the drug, the protein concentration, and the concentration of drug available for binding.

The extent of plasma–drug binding can be expressed as the *percentage of drug bound*, which is the percentage of the total drug present that is bound to plasma proteins. Alternatively, the *free fraction*, which is the percentage of drug not bound to plasma proteins, can be used. For example, approximately 83% of fentanyl is bound to plasma proteins. Therefore, the free fraction of fentanyl is about 17%.^{73,74}

Protein binding is affected by many factors, including temperature and pH.⁷² At high drug concentrations, binding sites become saturated and the free fraction increases. There are also qualitative differences between species in plasma proteins that affect drug binding, and binding to purified human albumin may not correlate with binding in plasma.⁷² Consequently, to provide clinically useful information, *in vitro* measurement of drug binding must be conducted at physiologic temperature and pH, with human plasma, and at concentrations within the usual therapeutic range.

Drug–protein binding has important pharmacologic implications, because only unbound drug can cross cell membranes to reach its sites of action. Also, free drug is more readily available for elimination. This has led to the frequently held misconception that drug bound to plasma proteins and other blood constituents is pharmacologically inert. This is not the case. As soon as unbound drug leaves circulation, the law of mass action dictates that some drug will dissociate from binding sites, which tends to restore the free drug concentration. This occurs almost instantaneously, so that the bound fraction of drug serves as a dynamic reservoir that buffers acute changes in the free drug concentration.

As discussed earlier, clearance of some drugs depends upon the degree of protein binding. The extent of distribution of drugs throughout the body also depends on the degree of binding. At equilibrium, the portion of the total drug in the body that is in extravascular sites is determined by the relative affinity of blood binding *versus* binding to all other tissues. A drug that is highly bound to plasma proteins or erythrocytes cannot be extensively distributed unless it has even greater affinity for extravascular binding sites.

Binding Proteins

Two plasma proteins are primarily responsible for drug binding: albumin and α₁-acid glycoprotein (AAG). Drugs also bind to other plasma proteins, such as globulins or lipoproteins, and to erythrocytes. Drugs can bind to more than one protein. For example, fentanyl and sufentanil bind to albumin, AAG, globulins, and also to red blood cells.⁷⁴

Albumin is the most important drug-binding protein. In addition to a wide range of drugs, including barbiturates, benzodiazepines, and penicillins, albumin binds endogenous compounds such as bilirubin. Many drugs bind to more than one site on the albumin molecule, and most drugs have one or two high-affinity, primary binding sites and a variable number of secondary, low-affinity sites. Studies with radioactively labeled drugs indicate that albumin has at least three discrete, high-affinity drug-binding sites. Diazepam, digitoxin, and warfarin each bind to a different site. The sites at which other drugs bind to albumin and the affinity of the drug–albumin bond can be determined by using these three markers.⁷⁵ This permits prediction of the likelihood of drug interactions due to one drug displacing another. Drugs that compete for the same binding site are more likely to displace one another than drugs that bind at different sites, and the drug with the lower affinity for the binding site will be more easily displaced.

Factors Affecting Drug Binding

The physicochemical properties of drugs influence binding to plasma proteins. Albumin is the major binding protein for organic acids, such as penicillins and barbiturates. Basic drugs also bind to albumin, but to a lesser extent. The primary binding protein for many basic drugs is AAG (Table 11-3). Basic drugs also bind to lipoproteins and globulins. AAG is an acute phase reactant, and its concentration increases in many acute and chronic illnesses.

| | |
|--------------|-------------|
| Alfentanil | Methadone |
| Alprenolol | Proprenolol |
| Bupivacaine | Quinidine |
| Disopyramide | Ropivacaine |
| Fentanyl | Sufentanil |
| Lidocaine | Verapamil |
| Meperidine | |

Table 11-3. DRUGS BINDING TO α₁-ACID GLYCOPROTEIN

In general, the greater the lipid solubility of a drug, the greater the binding to plasma proteins (Table 11-4). Water-soluble drugs, such as neuromuscular blocking agents, are bound to a substantially lesser extent than lipid-soluble drugs, like propofol. This is also true for drugs that belong to the same class. The degree of binding of opioids parallels their lipid solubility: morphine is the least bound, fentanyl and its derivatives are highly bound, and meperidine is intermediate. Similarly, bupivacaine is bound to a greater extent than lidocaine.

| Class/Drug | Percent Bound | Reference |
|----------------------------------|---------------|--------------|
| CARDIOVASCULAR DRUGS | | |
| Ethanol | 10–15 | 1,200 |
| Fentanyl | 70–80 | 1,201 |
| Ketorolac | 90 | 1,202 |
| Propofol | 95–98 | 1,203 |
| Verapamil | 88–91 | 1,204 |
| BENZODIAZEPINES | | |
| Alprazolam | 87–90 | 1,205 |
| Clonazepam | 88–92 | 1,206 |

| Vecuronium | 1.5–2% | 1,214, 1,215 |
| Rocuronium | 1.5 | 1,216 |
| OPIODS | | |
| Alfentanil | 82 | 1,217 |
| Fentanyl | 80 | 1,218 |
| Sufentanil | 75–85 | 1,219 |
| Sufentanil | 80–90 | 1,220 |
| Sufentanil | 80–90 | 1,221, 1,222 |
| Meperidine | 40 | 1,223 |

* At metabolic concentrations. At toxic plasma concentrations, binding of local anesthetic decreases, leading to a marked increase in the free drug concentration.

Table 11-4. PLASMA PROTEIN BINDING OF SOME DRUGS USED IN ANESTHESIOLOGY

Many physiologic and pathologic states cause quantitative and qualitative changes in the primary drug-binding plasma proteins, albumin and AAG. Drug binding may also be affected by acid–base disturbances that alter the degree of ionization of drugs and proteins, and by accumulation of endogenous compounds that compete for drug-binding sites.

Maternal and Neonatal Drug Binding

Binding of drugs in pregnancy and in the fetus or neonate has received much attention because of its impact on placental drug transfer. Pregnant women have reduced

levels of albumin, and the binding of many organic acids, such as phenytoin, is decreased at term.⁷⁶ Although thiopental is also an organic acid, unlike phenytoin, the free fraction of thiopental is not increased in patients undergoing cesarean section,⁷⁷ so that usual doses of thiopental do not result in excessive free drug levels. This is fortunate, because high free drug levels would increase the risk of side-effects and enhance placental transfer of the drug. The free fraction of diazepam, which binds primarily to albumin, is increased at term.⁷⁸ AAG levels are not changed during pregnancy.⁷⁸ However, the free fractions of lidocaine and propranolol are, nonetheless, increased at term.⁷⁸

Neonates have decreased levels of albumin and AAG,^{76,77,78} and neonatal albumin has less affinity for some drugs.^{76,79} Consequently, the free fraction of many drugs, especially those that bind to AAG, is higher in the neonate than in the mother.⁷⁹ Although binding of many drugs is decreased in neonates, this does not affect the unbound concentration of drugs transferred across the placenta. Under near steady-state conditions, maternal and fetal free drug concentrations are the same, although the total fetal level is lower. Because the free drug is the more pharmacologically active species, the decrease in maternal plasma drug binding is of greater consequence as far as placental transfer of drugs is concerned. Decreased drug binding must be considered in neonatal therapeutics.⁵⁷

Age and Sex

The plasma concentrations of the primary drug-binding proteins change with increasing age: albumin decreases slightly, whereas AAG tends to increase.^{80,81} and ⁸² The free fractions of lidocaine, meperidine, and propranolol, all of which bind to AAG, are not changed in the elderly.^{82,83} and ⁸⁴ Similarly, binding of drugs to albumin is minimally altered. The binding of midazolam does not change,⁸⁵ and diazepam binding may decrease slightly.^{22,80,86} The typical magnitude of age-associated decreases in drug binding is illustrated by thiopental. The average free fraction of thiopental of 18% in young adults only increases to 22% in geriatric patients.⁸⁷ Clinically significant changes in drug binding in elderly patients are more often caused by pathologic processes than by age *per se*.

Studies comparing drug binding in men and women have not found any clinically significant differences between the sexes. This is not surprising, because the concentrations of albumin and AAG in men and women do not differ significantly.^{78,81}

Hepatic Disease

The plasma albumin concentration is often decreased in patients with liver disease. Drug binding may also be affected by qualitative changes in the albumin molecule that decrease affinity for drugs, and by accumulation of endogenous substances, such as bilirubin, that compete for drug-binding sites.¹³ Although hepatic diseases vary widely in pathophysiology and severity, it is possible to make some generalizations regarding their impact on drug binding. The free fractions of drugs that bind primarily to albumin are increased. This is true for organic bases such as diazepam^{22,88} and morphine,⁸⁹ and for the organic acids phenytoin⁸⁹ and thiopental.^{90,91} The free fractions of basic drugs, such as lidocaine²⁵ and meperidine,²⁴ are not increased in patients with acute viral hepatitis, which suggests that drug binding to AAG is minimally affected by liver disease.

Renal Disease

Albumin levels tend to decrease in all types of renal disease. However, even when albumin levels are normal, binding of thiopental⁹² and phenytoin⁸⁹ is decreased. The free fraction of phenytoin is correlated with both the albumin concentration and the severity of renal dysfunction.⁸⁹ This indicates that renal failure reduces the affinity of albumin for organic acids. Dialysis does not restore the affinity of albumin for thiopental or phenytoin.^{89,92} The plasma-protein binding of many other organic acids is also decreased in renal failure.⁹³

The effect of renal disease on the binding of basic drugs depends on whether the drug binds primarily to albumin or to AAG, and on the type of renal disease. The free fraction of diazepam, which binds primarily to albumin, is increased in the nephrotic syndrome, renal failure, and after renal transplantation.⁹⁴ Similarly, binding of morphine is decreased in uremia.⁸⁹ Binding of other basic drugs varies according to the changes in AAG in different types of renal disease. Lidocaine binding increases in renal failure and after renal transplantation, conditions associated with increased AAG levels.⁹⁴ Likewise, propranolol binding is increased in patients with renal disease and elevated concentrations of AAG.⁹⁵ Lidocaine binding is not altered in nephrotic patients who have normal levels of AAG.⁹⁰

Other Diseases, Surgery, and Trauma

Patients with inflammatory diseases, such as rheumatoid arthritis and Crohn's disease, have increased levels of AAG and, consequently, decreased free fractions of drugs that bind to this protein.^{95,96} Malignant disease is also associated with elevated levels of AAG, and increased binding of lidocaine, propranolol, and other basic drugs has been demonstrated in patients with cancer.⁹⁷ In contrast, albumin tends to decrease in patients with malignancies, which can decrease binding of acidic drugs.⁹⁶ After acute myocardial infarction, AAG levels double and remain elevated for about 3 weeks.⁹⁸ Consequently, the binding of lidocaine and propranolol is increased.^{98,99}

The catabolic state that follows surgery and trauma decreases plasma albumin levels.¹⁰⁰ In contrast, the concentration of AAG increases after trauma¹⁰¹ and surgery¹⁰² and remains elevated for several weeks. These changes result in alterations in drug binding. The free fraction of phenytoin increases after surgery, probably secondary to decreased levels of albumin, although the contemporaneous increase in free fatty acids may result in competition for binding sites.¹⁰⁰ Higher AAG levels increase binding of basic drugs, such as lidocaine and propranolol, after trauma¹⁰¹ and surgery.^{103,104}

PHARMACOKINETIC PRINCIPLES

The concentration of a drug at its site or sites of action is a fundamental determinant of its pharmacologic effects. Because drugs are transported to and from their sites of action in the blood, the concentration at the active site is in turn a function of the concentration in the blood. The change in drug concentration over time in the blood, at the site of action, and in other tissues is a result of complex interactions of various biologic factors with the physicochemical characteristics of the drug. Together, these factors determine the rate, extent, and pattern of drug absorption, distribution, metabolism, and excretion. The term *pharmacokinetics*, derived from the Greek words *pharmakon* (medicine) and *kinesis* (movement), refers to the quantitative analysis of the relationship between the dose of a drug and the ensuing changes in drug concentration in the blood and other tissues.

Early pharmacokinetics studies of iv and inhalational anesthetics used physiologic, or perfusion models. In these models, body tissues are classified according to similarities in perfusion and affinity for drugs.¹⁰⁵ Highly perfused tissues, including the brain, heart, lungs, liver, and kidneys, make up the vessel-rich group. Muscle and skin comprise the lean tissue group, and fat is considered as a separate group. The vessel-poor group, which has minimal effect on drug distribution and elimination, is composed of bone and cartilage. Physiologic pharmacokinetic models made major contributions to understanding the factors influencing recovery from thiopental. These models established that awakening after a single dose was primarily due to redistribution of thiopental from the brain to muscle and skin.^{7,8} Distribution to other tissues and metabolism played minor roles. This fundamental concept, *redistribution*, also applies to all lipophilic drugs. Physiologic models have also contributed greatly to our understanding of the uptake and distribution of inhalational anesthetics.¹⁰⁶

Physiologic pharmacokinetic models provide much insight into factors affecting drug action. They can predict the effects of physiologic changes, such as altered regional blood flows or reduced cardiac output, on drug distribution and elimination. The disadvantage of perfusion-based models is their complexity. Verification of these models requires measurement of drug concentrations in many different tissues, which is rarely practical.¹⁰⁵ Because of these disadvantages, simpler pharmacokinetic models have been developed. In these models the body is envisaged as composed of one or more *compartments*. Drug concentrations in the blood are used to define the relationship between dose and the time course of changes of the drug concentration.¹⁰⁷ It is critically important to understand that the different "compartments" of a compartmental pharmacokinetic model cannot be equated with the tissue groups that make up physiologic pharmacokinetic models. Compartments are theoretical entities that are used to derive pharmacokinetic parameters, such as clearance, volume of distribution, and half-times. These parameters quantify drug distribution and elimination.

Although the simplicity of compartmental models, compared to physiologic pharmacokinetic models, has its advantages, it also has some disadvantages. For example, cardiac output is not a parameter of compartmental models, and compartmental models therefore cannot be used to predict directly the effect of cardiac failure on drug disposition. However, compartmental pharmacokinetic models can still quantify the effects of reduced cardiac output on the disposition of a drug if a group of patients with cardiac failure is compared to a group of otherwise healthy subjects.

The discipline of pharmacokinetics is, to the despair of many, mathematically based. In the succeeding sections, formulas are used to illustrate the concepts needed to understand and interpret pharmacokinetic studies. Readers are encouraged to concentrate on the concepts, not the formulas.

Pharmacokinetic Concepts

Rate Constants and Half-times

The disposition of most drugs follows *first-order* kinetics. A first-order kinetic process is one in which a constant fraction of the drug is removed during a finite period of time. This fraction is equivalent to the rate constant of the process. Rate constants are usually denoted by the letter k , and have units of “inverse time,” such as min^{-1} or h^{-1} . If 10% of the drug is eliminated per minute, then the rate constant is 0.1 min^{-1} . Because a constant fraction is removed per unit of time in first-order kinetics, the absolute amount of drug removed is proportional to the concentration of the drug. It follows that, in first-order kinetics, the rate of change of the concentration at any given time is proportional to the concentration present at that time. When the concentration is high, it will fall faster than when it is low. First-order kinetics apply not only to elimination, but also to absorption and distribution.¹⁰⁷

Rather than using rate constants, the rapidity of pharmacokinetic processes is often described with half-times—the time required for the concentration to change by a factor of 2. Half-times are calculated directly from the corresponding rate constants with this simple equation:

$$t_{1/2} = \frac{(\ln 2)}{k} = \frac{0.693}{k} \quad (11-6)$$

Thus, a rate constant of 0.1 min^{-1} translates into a half-time of 6.93 minutes. The half-time of any first-order kinetic process, including drug absorption, distribution, and elimination, can be calculated. First-order processes asymptotically approach completion, because a constant fraction of the drug, not an absolute amount, is removed per unit of time. However, after five half-times, the process will be almost 97% complete (Table 11-5). For practical purposes, this is close enough to 100%, and can be considered as such.

| Number of Half-times | Percent of Drug Remaining | Percent of Drug Removed |
|----------------------|---------------------------|-------------------------|
| 0 | 100 | 0 |
| 1 | 50 | 50 |
| 2 | 25 | 75 |
| 3 | 12.5 | 87.5 |
| 4 | 6.25 | 93.75 |
| 5 | 3.125 | 96.875 |

Table 11-5. HALF-TIMES AND PERCENT OF DRUG REMOVED

Volumes of Distribution

The volume of distribution quantifies the extent of drug distribution. The physiologic factor that governs the extent of drug distribution is the overall capacity of tissues *versus* the capacity of blood for that drug. Overall tissue capacity for uptake of a drug is in turn a function of the total volume of the tissues into which a drug distributes and their average affinity for the drug. In compartmental pharmacokinetic models, drugs are envisaged as distributing into one or more “boxes,” or compartments. These compartments cannot be equated with tissues. Rather, they are hypothetical entities that permit analysis of drug distribution and elimination, and description of the drug concentration *versus* time profile.

The volume of distribution is an “apparent” volume because it represents the size of these hypothetical boxes, or compartments, that is necessary to explain the concentration of drug in a reference compartment, usually called the *central* or *plasma compartment*. The volume of distribution, V_d , relates the total amount of drug present to the concentration observed in the central compartment:

$$V_d = \frac{\text{total amount of drug present}}{\text{concentration}} \quad (11-7)$$

This formula is logical. If a drug is extensively distributed, then the concentration will be lower relative to the amount of drug present, which equates to a larger volume of distribution. For example, if a total of 10 mg of drug is present and the concentration is $2 \text{ mg} \cdot \text{L}^{-1}$, then the apparent volume of distribution is 5 L. On the other hand, if the concentration was $4 \text{ mg} \cdot \text{L}^{-1}$, then the volume of distribution would be 2.5 L.

Simply stated, the apparent volume of distribution is a numeric index of the extent of drug distribution that does not have any relationship to the actual volume of any tissue or group of tissues. It may be as small as plasma volume, or, if overall tissue uptake is extensive, the apparent volume of distribution may greatly exceed the actual total volume of the body (Fig. 11-4). In general, lipophilic drugs have larger volumes of distribution than hydrophilic drugs (Fig. 11-4). Because the volume of distribution is a mathematical approximation, it cannot be directly correlated with the anatomic and physiologic factors that influence drug distribution. Determination of the volume of distribution from a compartmental model does not provide any information regarding the tissues into which the drug actually distributes or the concentrations in those tissues. Despite these limitations, the volume of distribution provides useful information. For example, an increase in the volume of distribution means that a larger loading dose will be required to “fill up the box” and achieve the same concentration. Various pathologic conditions can alter the volume of distribution, necessitating therapeutic adjustments.

Figure 11-4. The volume of distribution of some drugs used in anesthesiology.

Total Drug Clearance

In compartmental pharmacokinetic models, the ability of the system as a whole to irreversibly eliminate a drug is quantified by the *total drug clearance* or *elimination clearance*. Elimination clearance is the portion of the volume of distribution from which drug is completely and irreversibly removed during a given time interval. It is analogous to creatinine clearance, and, like creatinine clearance, drug clearance has units of flow. Drug clearance is often corrected for weight or body surface area, in which case the units are $\text{mL} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ or $\text{mL} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ respectively.

Elimination clearance, Cl , can be calculated from the declining blood levels observed after an iv injection, as follows:

$$Cl = \frac{\text{dose}}{\text{area under the concentration versus time curve}} \quad (11-8)$$

Again, this formula is intuitively logical. If a drug is rapidly removed from the plasma, its concentration will fall more quickly than the concentration of a drug that is less readily eliminated. This results in a smaller area under the concentration versus time curve, which equates to greater clearance.

A significant limitation of calculating elimination clearance from compartmental pharmacokinetic models is that the relative contribution of different organs to drug elimination cannot be determined. Nonetheless, estimation of drug clearance with these models has made important contributions to clinical pharmacology. In particular, these models have provided a great deal of clinically useful information regarding altered drug elimination in various pathologic conditions.

Compartmental Pharmacokinetic Models

One-Compartment Model

Although for most drugs the one-compartment model is an oversimplification, it does serve to illustrate the basic relationships between clearance, volume of distribution, and the elimination half-time. In this model, the body is envisaged as a single homogeneous compartment. Drug distribution after injection is assumed to be instantaneous, so there are no concentration gradients within the compartment. The concentration can decrease only by elimination of drug from the system. The plasma concentration *versus* time curve for a hypothetical drug with one-compartment kinetics is shown in [Figure 11-5](#). With the concentration plotted on a logarithmic scale, the concentration *versus* time curve becomes a straight line. The slope of the logarithm of concentration *versus* time is equal to the first-order elimination rate constant.

Figure 11-5. The plasma concentration, plotted on both linear (—, left vertical axis) and logarithmic (- - -, right vertical axis) scales, *versus* time for a hypothetical drug exhibiting one-compartment, first-order pharmacokinetics.

Immediately after injection, before any drug can be eliminated, the amount of drug present is equal to the dose. Therefore, by modifying [Equation 11-7](#), the volume of distribution can be calculated:

$$Vd = \frac{\text{dose}}{\text{initial concentration}} \quad (11-9)$$

In the one-compartment model, drug clearance, Cl , is equal to the product of the elimination rate constant, k_e , and the volume of distribution:

$$Cl = k_e \cdot Vd \quad (11-10)$$

Combining [Equation 11-6](#) and [Equation 11-10](#) yields:

$$Cl = \frac{0.693 \cdot Vd}{t_{1/2}}; \text{ thus: } t_{1/2} = \frac{0.693 \cdot Vd}{Cl} \quad (11-11)$$

Therefore, the greater the clearance, the shorter the elimination half-time, which is easy to understand. Less obvious is the impact of the volume of distribution on the elimination half-time. It is easiest to understand if the physiologic correlate of a large volume of distribution is considered. A large volume of distribution reflects extensive tissue uptake of a drug, so that only a small fraction of the total amount of drug is in the blood and accessible to the organs of elimination. Consequently, the greater the volume of distribution, the longer the elimination half-time. For drugs that exhibit multicompartment pharmacokinetics, the relationship between clearance, volume of distribution, and the elimination half-time is not a simple linear one such as [Equation 11-11](#). However, the same principles apply. All else being equal, the greater the clearance, the shorter the elimination half-time; the larger the volume of distribution, the longer the elimination half-time. Thus, the elimination half-time depends on two other variables, clearance and volume of distribution, that characterize, respectively, the extent of drug distribution and efficiency of drug elimination.

Two-Compartment Model

For many drugs, a graph of the logarithm of the plasma concentration *versus* time after an iv injection is similar to the schematic graph shown in [Figure 11-6](#). There are two discrete phases in the decline of the plasma concentration. The first phase after injection is characterized by a very rapid decrease in concentration. The rapid decrease in concentration during this “distribution phase” is largely caused by passage of drug from the plasma into tissues. The distribution phase is followed by a slower decline of the concentration owing to drug elimination. Elimination also begins immediately after injection, but its contribution to the drop in plasma concentration is initially much smaller than the fall in concentration due to drug distribution.

Figure 11-6. A schematic graph of the plasma concentration, on a logarithmic scale, *versus* time for a drug with a distribution phase preceding the elimination phase (two-compartment or biexponential kinetics). See text for explanation.

To account for this biphasic behavior, one must consider the body to be made up of two compartments, a central (or plasma) compartment and a peripheral compartment (Fig. 11-7). This two-compartment model assumes that it is the central compartment into which the drug is injected and from which the blood samples for measurement of concentration are obtained, and that drug is eliminated only from the central compartment. Drug distribution within the central compartment is considered to be instantaneous. In reality, this last assumption cannot be true. However, drug uptake into some of the highly perfused tissues is so rapid that it cannot be detected as a discrete phase on the plasma concentration versus time curve.

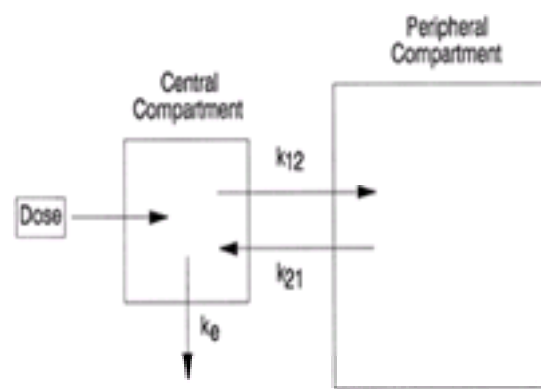

Figure 11-7. A two-compartment pharmacokinetic model. See text for explanation.

The distribution and elimination phases can be characterized by graphic analysis of the plasma concentration *versus* time curve, as shown in Figure 11-6. The elimination phase line is extrapolated back to time zero (the time of injection). At any time, the difference between the total concentration and the concentration on the extrapolated elimination phase line is equal to a corresponding point, at that time, on the distribution phase line. In Figure 11-6, the zero time intercepts of the distribution and elimination lines are points A and B, respectively. The *hybrid rate constants*, a and b, are equal to the slopes of the two lines, and are used to calculate the distribution and elimination half-times; a and b are called hybrid rate constants because they depend on both distribution and elimination processes.

At any time after an iv injection, the plasma concentration of drugs with two-compartment kinetics is equal to the sum of two exponential terms:

$$Cp_{(t)} = Ae^{-at} + Be^{-bt}, \quad (11-12)$$

where t = time, $Cp_{(t)}$ = plasma concentration at time t , A = y -axis intercept of the distribution phase line, a = hybrid rate constant of the distribution phase, B = y -axis intercept of the elimination phase line, and b = hybrid rate constant of the elimination phase. The first term characterizes the distribution phase and the second term characterizes the elimination phase. Immediately after injection, the first term represents a much larger fraction of the total plasma concentration than the second term. After several distribution half-times, the value of the first term approaches zero, and the plasma concentration is essentially equal to the value of the second term (see Fig. 11-6).

In multicompartment models, the drug is initially distributed only within the central compartment. Therefore, the initial apparent volume of distribution is the volume of the central compartment. Immediately after injection, the amount of drug present is the dose, and the concentration is the extrapolated concentration at time $t = 0$, which is equal to the sum of the intercepts of the distribution and elimination lines. The volume of the central compartment, $V1$, is calculated by modifying Equation 11-7:

$$V1 = \frac{\text{dose}}{\text{initial plasma concentration}} = \frac{\text{dose}}{A + B} \quad (11-13)$$

The volume of the central compartment is important in clinical anesthesiology because it is the pharmacokinetic parameter that determines the peak plasma concentration after an iv bolus injection. Hypovolemia, for example, reduces the volume of the central compartment. If doses are not correspondingly reduced, the higher plasma concentrations will increase the incidence of adverse pharmacologic effects.

Immediately after iv injection, all of the drug is in the central compartment. Simultaneously, three processes begin. Drug moves from the central to the peripheral compartment, which also has a volume, $V2$. This intercompartmental transfer is a first-order process, and its magnitude is quantified by the rate constant k_{12} . As soon as drug appears in the peripheral compartment, some passes back to the central compartment, a process characterized by the rate constant k_{21} . The transfer of drug between the central and peripheral compartments is quantified by the *distributional* or *intercompartmental clearance*:

$$\text{Intercompartmental clearance} = V1 \cdot k_{12} = V2 \cdot k_{21} \quad (11-14)$$

The third process that begins immediately after administration of the drug is irreversible removal of drug from the system *via* the central compartment. As in the one-compartment model, the elimination rate constant is k_e . The rapidity of the decrease in the central compartment concentration after iv injection depends on the magnitude of the compartmental volumes, the intercompartmental clearance, and the elimination clearance.

At equilibrium, the drug is distributed among the central and the peripheral compartment, and by definition, the concentrations in the compartments are equal. Therefore, the ultimate volume of distribution, termed the volume of distribution at steady-state (V_{ss}), is the sum of $V1$ and $V2$. Extensive tissue uptake of a drug is reflected by a large volume of the peripheral compartment, which, in turn, results in a large V_{ss} . Consequently, V_{ss} can greatly exceed the actual volume of the body.

As in the single-compartment model, in multicompartment models the elimination clearance is equal to the dose divided by the area under the concentration *versus* time curve. This area, as well as the compartmental volumes, and intercompartmental clearances, can be calculated from the intercepts and hybrid rate constants, without having to reach steady-state conditions.¹⁰⁸

Three-Compartment Model

After iv injection of some drugs, the initial, rapid distribution phase is followed by a second, slower distribution phase before the elimination phase becomes evident. Therefore, the plasma concentration is the sum of three exponential terms:

$$Cp_{(t)} = Ae^{-at} + Be^{-bt} + G^{-gt}, \quad (11-15)$$

where t = time, $Cp_{(t)}$ plasma concentration at time t , A = intercept of the rapid distribution phase line, a = hybrid rate constant of the rapid distribution phase, B = intercept of the slower distribution phase line, b hybrid rate constant of the slower distribution phase, G = intercept of the elimination phase line, and g = hybrid rate constant of the elimination phase. This triphasic behavior is explained by a three-compartment pharmacokinetic model (Fig. 11-8). As in the two-compartment model, the drug is injected into and eliminated from the central compartment. Drug is reversibly transferred between the central compartment and two peripheral compartments, which accounts for two distribution phases. Drug transfer between the central compartment and the more rapidly equilibrating, or "shallow," peripheral compartment is characterized by the first-order rate constants k_{12} and k_{21} . Transfer in and out of the more slowly equilibrating, "deep" compartment is characterized by the rate constants k_{13} and k_{31} . In this model, there are three compartmental volumes: $V1$, $V2$, and $V3$, whose sum equals V_{ss} ; and three clearances: the rapid intercompartmental clearance, the slow intercompartmental clearance, and elimination clearance.

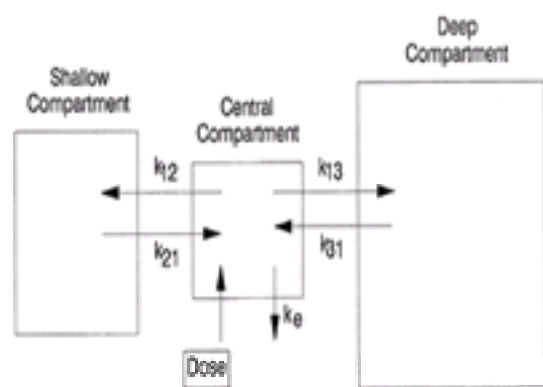

Figure 11-8. A three-compartment pharmacokinetic model. See text for explanation.

The pharmacokinetic parameters of interest to clinicians, such as clearance, volumes of distribution, and distribution and elimination half-times, are determined by calculations analogous to those used in the two-compartment model. Accurate estimates of these parameters depend on accurate characterization of the measured plasma concentration versus time data. A frequently encountered problem is that the duration of sampling is not long enough to define accurately the elimination phase.¹⁰⁹ Similar problems arise if the assay cannot detect low concentrations of the drug. Whether a drug exhibits two- or three-compartment kinetics is of no clinical consequence. In fact, some drugs have two-compartment kinetics in some patients and three-compartment kinetics in others.^{86,110} In selecting a pharmacokinetic model, the most important factor is that it accurately characterize the measured concentrations. In general, the model with the smallest number of compartments or exponents that accurately reflects the data is used.

Effects of Hepatic or Renal Disease on Pharmacokinetic Parameters

As discussed earlier, hepatic and renal disease not only affect the ability to eliminate drugs, but also change the binding of drugs to plasma proteins. Consequently, the effects of altered protein binding and the effects of impaired organ function must be considered to understand fully the impact of hepatic or renal disease on pharmacokinetic variables.

The extent of drug distribution depends on the relative affinity of blood *versus* tissues for the drug. Therefore, if the free fraction in plasma increases, the volume of distribution must also increase. The magnitude of the change depends on the initial free fraction and volume of distribution. An increase in the free fraction will produce the greatest increase in the volume of distribution for drugs that are highly bound to plasma proteins and have small volumes of distribution. In contrast, changes in plasma protein binding of drugs with large volumes of distribution have minimal effects on the volume of distribution, because so little of the total amount of drug is in the plasma.¹¹¹

In theory, a parallel change in tissue binding would cancel the effect of changes in plasma binding. However, this appears to be uncommon. Increased volumes of distribution of propranolol¹¹² and diazepam²² associated with increased free fractions have been observed in patients with hepatic disease. Decreased binding of thiopental in patients with renal failure also increases the volume of distribution.⁹²

The effect of altered protein binding on total drug clearance also depends on the initial magnitude of the clearance. Increases in the free fraction of drugs with low hepatic extraction ratios and drugs eliminated primarily by glomerular filtration cause a proportional increase in clearance. In contrast, altered protein binding has little effect on drugs with high hepatic or renal clearance. The effect of an increased free fraction on elimination depends on the net effect on clearance and the volume of distribution.¹¹¹ The elimination half-time will increase if increased volume of distribution is the paramount change, or decrease if increased clearance predominates.

Diverse pathophysiologic changes preclude precise prediction of the pharmacokinetics of a given drug in individual patients with hepatic or renal disease. However, some generalizations can be made. Binding of drugs to albumin is decreased, so that doses of drugs given as an iv bolus, such as thiopental, should be reduced. In patients with hepatic disease, the elimination half-time of drugs metabolized or excreted by the liver is often increased because of decreased clearance, and, possibly, increased volume of distribution. Repeated doses of such drugs as benzodiazepines, opioids, and barbiturates may accumulate, leading to excessive and prolonged pharmacologic effects. Recovery from small doses of drugs such as thiopental and fentanyl is largely the result of redistribution, so recovery from conservative doses will be minimally affected. In patients with renal failure, similar concerns apply to the administration of drugs excreted by the kidneys. It is almost always better to underestimate a patient's dose requirement, observe the response, and give additional drug if necessary.

Nonlinear Pharmacokinetics

The physiologic and compartmental models thus far discussed are based on the assumption that drug distribution and elimination are first-order processes. Therefore, their parameters, such as clearance and elimination half-time, are independent of the dose or concentration of the drug. However, the rate of elimination of a few drugs is dose-dependent, or *nonlinear*.

Elimination of most drugs involves interactions with protein molecules, either enzymes catalyzing biotransformation reactions or carrier proteins for transmembrane transport. If sufficient drug is present, the capacity of the drug-eliminating systems can be exceeded. When this occurs, it is no longer possible to excrete a constant fraction of the drug present to the eliminating system, and a constant amount of drug is excreted per unit time. Phenytoin is a well known example of a drug that exhibits nonlinear elimination at therapeutic concentrations. In theory, all drugs are cleared in nonlinear fashion. In practice, the capacity to eliminate most drugs is so great that this is usually not evident, even with toxic concentrations.

PHARMACODYNAMIC PRINCIPLES

In its broadest sense, pharmacodynamics is the study of the effects of drugs on the body. Classically, pharmacologic effects have been quantified by dose–response studies. Advances in drug assay techniques and data analysis now allow definition of the relationship between the drug concentration and the associated pharmacologic effect *in vivo*. As a result, the term *pharmacodynamics* has acquired a more specific definition: the quantitative analysis of the relationship between the drug concentration in the blood, or at the site of action, and the resultant effects of the drug on physiologic processes.¹¹³

Dose–Response Curves

Dose–response studies determine the relationship between increasing doses of a drug and the ensuing changes in pharmacologic effects. Schematic dose–response curves are shown in [Figure 11-9](#), with the dose plotted on both linear and logarithmic scales. There is a curvilinear relationship between dose and the intensity of response. Low doses produce little pharmacologic effect. Once effects become evident, a small increase in dose produces a relatively large change in effect. At near maximal response, large increases in dose produce little change in effect. Usually the dose is plotted on a logarithmic scale (see [Fig. 11-9](#), right panel), which demonstrates the linear relationship between the logarithm of the dose and the intensity of the response between 20% and 80% of the maximum effect.

Figure 11-9. Left panel: A schematic curve of the effect of a drug plotted against dose. Right panel: The same curve, replotted with dose on a logarithmic scale. This

yields the familiar sigmoid dose–response curve, which is linear between 20% and 80% of the maximal effect.

Dose–response curves provide information regarding four aspects of the relationship of dose and pharmacologic effect. The *potency* of the drug—the dose required to produce a given effect—is determined. Potency is usually expressed as the dose required to produce a given effect in 50% of subjects, the *ED50*. The *slope* of the curve between 20% and 80% of the maximal effect indicates the rate of increase in effect as the dose is increased. The maximum effect is referred to as the *efficacy* of the drug. Finally, if curves from multiple subjects are generated, the *variability* in potency, efficacy, and the slope of the dose–response curve can be estimated.

The dose needed to produce a given pharmacologic effect varies considerably, even in “normal” patients. The patient most resistant to the drug usually requires a dose two- to threefold greater than the patient with the lowest dose requirements. This variability is caused by differences between individuals in the relationship between drug concentration and pharmacologic effect, superimposed on differences in pharmacokinetics. Dose–response studies have the disadvantage of not being able to determine whether variations in pharmacologic response are caused by differences in pharmacokinetics, pharmacodynamics, or both.

Concentration–Response Relationships

Ideally, the concentration of drug at its site of action should be used to define the concentration–response relationship. Unfortunately, these data are rarely available, so the relationship between the concentration of drug in the blood and pharmacologic effect is studied instead. This relationship is easiest to understand if the changes in pharmacologic effect that occur during and after an iv infusion of a hypothetical drug are considered. If a drug is infused at a constant rate, the plasma concentration initially increases rapidly, and asymptotically approaches a steady-state level after approximately five elimination half-times have elapsed (Fig. 11-10). The effect of the drug initially increases very slowly, then more rapidly, and eventually also reaches a steady state. When the infusion is discontinued, indicated by point C in Figure 11-10, the plasma concentration immediately decreases because of drug distribution and elimination. However, the effect stays the same for a short period, and then also begins to decrease—there is always a time lag between changes in plasma concentration and changes in pharmacologic response. Figure 11-10 also demonstrates that the same plasma concentration is associated with different responses if the concentration is changing. At points A and B in Figure 11-10, the plasma concentrations are the same, but the effects at each time differ. When the concentration is increasing, there is a concentration gradient from blood to the site of action. When the infusion is discontinued, the concentration gradient is reversed. Therefore, at the same plasma concentration, the concentration at the site of action is higher after, compared to during, the infusion. This is associated with a correspondingly greater effect.

Figure 11-10. The changes in plasma drug concentration and pharmacologic effect during and after an intravenous infusion. See text for explanation. (Reprinted with permission from Stanski DR, Sheiner LB: Pharmacokinetics and pharmacodynamics of muscle relaxants. *Anesthesiology* 51:103, 1979.)

In theory, there must be some degree of temporal disequilibrium between plasma concentration and drug effect for all drugs with extravascular sites of action. However, for some drugs, the time lag may be so short that it cannot be demonstrated. The magnitude of this temporal disequilibrium depends on several factors:

1. perfusion of the organ on which the drug acts
2. the tissue:blood partition coefficient of the drug
3. the rate of diffusion or transport of the drug from the blood to the cellular site of action
4. the rate and affinity of drug–receptor binding
5. the time required for processes initiated by the drug–receptor interaction to produce changes in cellular function

The consequence of this time lag between changes in concentration and changes in effects is that the plasma concentration will have an unvarying relationship with pharmacologic effect only under steady-state conditions. At steady state, the plasma concentration is in equilibrium with the concentrations throughout the body, and is thus directly proportional to the steady-state concentration at the site of action. Plotting the logarithm of the steady-state plasma concentration *versus* response generates a curve identical in appearance to the dose–response curve shown in the right panel of Figure 11-9. The $C_{p,ss,50}$, the steady-state plasma concentration producing 50% of the maximal response, is determined from the concentration–response curve. Like the *ED50*, the $C_{p,ss,50}$ is a measure of sensitivity to a drug, but the $C_{p,ss,50}$ has the advantage of being unaffected by pharmacokinetic variability. Because it takes five elimination half-times to approach steady-state conditions, it is not practical to determine the $C_{p,ss,50}$ directly. For drugs with long elimination half-times, the pseudoequilibrium during the elimination phase can be used to approximate steady-state conditions, because the concentrations in plasma and at the site of action are changing very slowly.

The onset and duration of pharmacologic effects depend not only on pharmacokinetic factors but also on the pharmacodynamic factors governing the degree of temporal disequilibrium between changes in concentration and changes in effect. The magnitude of the pharmacologic effect is a function of the amount of drug present at the site of action, so increasing the dose increases the peak effect. Larger doses have a more rapid onset of action because pharmacologically active concentrations at the site of action occur sooner. Increasing the dose also increases the duration of action because pharmacologically effective concentrations are maintained for a longer time.

Integrated pharmacokinetic–pharmacodynamic models fully characterize the relationships between time, dose, plasma concentration, and pharmacologic effect.¹¹³ This is accomplished by adding an “*effect compartment*” to a standard compartmental pharmacokinetic model. The effect compartment is also called the *biophase*. Transfer of drug between central compartment and the effect compartment, or biophase, is assumed to be a first-order process, and the pharmacologic effect is assumed to be directly related to the concentration in the biophase. By quantifying the time lag between changes in plasma concentration and changes in pharmacologic effect, these models can also define the $C_{p,ss,50}$, even without steady-state conditions. These models have contributed greatly to our understanding of factors influencing the response to intravenous anesthetics,^{114,115} opioids,^{116,117} and nondepolarizing muscle relaxants^{118,119} in humans.

Dose–response and concentration–response relationships can be altered by many factors, such as drug interactions or pathologic conditions. They are also affected by the development of tolerance, which increases the *ED50* and $C_{p,ss,50}$. When tolerance develops rapidly, it is referred to as *tachyphylaxis*, or *acute tolerance*.

Drug–Receptor Interactions

The biochemical and physiologic effects of drugs, neurotransmitters, and hormones result from the binding of these compounds to receptors, which initiates changes in cellular function. In addition to the well known muscarinic and nicotinic cholinergic receptors, and α and β -adrenoceptors, there are specific receptors for histamine, serotonin, dopamine, eicosanoids, peptide hormones, steroid hormones, endorphins and exogenous opiates, benzodiazepines, and calcium channel blockers, to name a few. Subtypes of many of these receptors have been characterized. In mammals, there are dozens of distinct receptors for various endogenous and exogenous compounds.^{120,121} Most receptors are protein molecules situated on the cell membrane, although some are located within the cell.

Binding of drugs to receptors, like the binding of drugs to plasma proteins, is usually reversible, and follows the law of mass action:

The higher the concentration of free drug or unoccupied receptor, the greater the tendency to form the drug–receptor complex. Plotting the percentage of receptors occupied by a drug against the logarithm of the concentration of the drug yields a sigmoid curve, as shown in [Figure 11-11](#).

Figure 11-11. Schematic dose–response curves representing various conditions. Either dose or concentration is plotted on the x-axis, and either effect or the number of receptors occupied on the y-axis. Curve A is a typical dose–response curve. Curve B is a parallel rightward shift of the curve, and represents a drug that is less potent than the drug depicted by curve A, but is a full agonist and thus capable of producing the same maximal effect. Curve B would also result if the drug used to generate curve A was studied in the presence of a competitive antagonist. Curve C is shifted to the right, with a reduction in slope and the maximal effect. This is the curve observed with partial agonists, and also when a full agonist (curve A) is studied in the presence of a noncompetitive antagonist.

It is often assumed that the percentage of the maximal effect observed at any given drug concentration is equal to the percentage of receptors occupied by the drug. However, this is not always the case. At the neuromuscular junction, only 20–25% of the postjunctional nicotinic cholinergic receptors need to bind acetylcholine to produce contraction of all the fibers in the muscle.¹²² Thus, 75–80% of the receptors can be considered “spare receptors.” The presence of spare receptors has two important consequences. [Equation 11-16](#) indicates that the higher the concentration of unoccupied receptors, the greater the tendency to form the drug–receptor complex. Therefore, spare receptors permit near-maximal effects at very low concentrations of drugs or neurotransmitters.¹²³ The other corollary of the existence of spare receptors is that most of the receptors must be occupied by an antagonist before transmission is affected. This accounts for the “margin of safety” of neuromuscular transmission.¹²²

The binding of drugs to receptors and the resulting changes in cellular function are the last two steps in the complex series of events between administration of the drug and production of its pharmacologic effects. There are two primary mechanisms by which the binding of an agonist to a receptor changes cellular function: receptor-linked membrane ion channels called *ionophores*, and guanine nucleotide binding proteins, referred to as *G-proteins*. The nicotinic cholinergic receptor in the neuromuscular postsynaptic membrane is one example of a receptor-ionophore complex. Binding of acetylcholine opens the cation ionophore, leading to an influx of Na⁺ ions, propagation of an action potential, and, ultimately, muscle contraction.¹²⁴ The γ -amino butyric acid (GABA) receptor–chloride ionophore complex is another example of this type of effector mechanism. Binding of either endogenous neurotransmitters (GABA) or exogenous agonists (benzodiazepines and iv anesthetics) increases Cl⁻ conductance, which hyperpolarizes the neuron and decreases its excitability.¹²⁵ β -Adrenoceptors are the prototypical receptors that alter cellular function via G-proteins. G-proteins change the intracellular concentrations of various so-called *second messengers*, such as Ca²⁺ and cyclic AMP.¹²⁶

Receptors are not static entities. Rather, they are dynamic cellular components that adapt to their environment. For example, administration of β -adrenergic agonists leads to desensitization of β -adrenoceptors.¹²⁷ This occurs by several mechanisms: reduced ability to combine with G-proteins; *sequestration*, which is the removal of receptors from the cell membrane so they are no longer accessible to agonists, and by *downregulation*, a decrease in the total number of receptors. Administration of adrenoceptor antagonists increases the number of receptors.¹²⁷

Agonists, Partial Agonists, and Antagonists

Drugs that bind to receptors and produce an effect are called *agonists*. Drugs may be capable of producing the same maximal effect, although they may differ in potency. Agonists that differ in potency but bind to the same receptors will have parallel concentration–response curves (curves A and B in [Fig. 11-11](#)). Differences in potency of agonists reflect differences in affinity for the receptor. *Partial agonists* are drugs that are not capable of producing the maximal effect, even at very high concentrations (curve C in [Fig. 11-11](#)).

Compounds that bind to receptors without producing any changes in cellular function are referred to as *antagonists*. Binding of agonists to receptors is inhibited by antagonists. Competitive antagonists bind reversibly to receptors, and their blocking effect can be overcome by high concentrations of an agonist. Therefore, *competitive antagonists* produce a parallel shift in the dose–response curve, but the maximum effect is not altered (see [Fig. 11-11](#), curves A and B). *Noncompetitive antagonists* bind irreversibly to receptors. This has the same effect as reducing the number of receptors and shifts the dose–response curve downward and to the right, decreasing both the slope and the maximum effect (curves A and C in [Fig. 11-11](#)). The effect of noncompetitive antagonists is reversed only by synthesis of new receptor molecules.

Agonists produce a structural change in the receptor molecule that initiates changes in cellular function. Partial agonists may produce a qualitatively different change in the receptor, whereas antagonists bind without producing a change in the receptor that results in altered cellular function. The underlying mechanisms by which different compounds that bind to the same receptor act as agonists, partial agonists, or antagonists are not fully understood.

CLINICAL APPLICATION OF PHARMACOKINETICS AND PHARMACODYNAMICS

In anesthesia, the usual therapeutic objectives are rapidly to produce pharmacologic effects, such as unconsciousness or muscle relaxation, to maintain the optimal intensity of these effects during the anesthetic, and to have the patient recover rapidly on conclusion of surgery. Knowledge of pharmacokinetic principles and of the pharmacokinetic and pharmacodynamic properties of the drugs used in anesthesiology makes it easier to attain these objectives. If the pharmacokinetics and the therapeutic concentration of a drug are known, then the average doses required to achieve and maintain the desired pharmacologic effect can be calculated. The steady-state plasma concentration ($C_{p,ss}$) is a function of the rate of infusion of the drug and drug clearance:

$$C_{p,ss} = \frac{\text{Infusion rate}}{Cl}; \text{ thus: Infusion rate} = C_{p,ss} \cdot Cl \quad (11-17)$$

Infusion of the drug for five elimination half-times is required to reach steady-state conditions. Therefore, for many of the iv agents used in anesthesia, it would take 24 hours or more to reach a stable plasma concentration by merely infusing the drug at a constant rate. This is obviously impractical, and does not meet the first of our therapeutic objectives.

The volume of distribution must be rapidly “filled up” with a loading dose to achieve a more rapid onset of action. The loading dose can be calculated by multiplying the volume of distribution (V_d) by the desired concentration:

$$\text{Loading dose} = C_{p,ss} \cdot V_d \quad (11-18)$$

Almost all drugs, including those used in anesthesia, have multicompartment pharmacokinetic properties. Therefore, their initial volume of distribution, which is equal to the volume of the central compartment (V_1), gets progressively larger until the ultimate volume of distribution, the volume of distribution at steady state (V_{ss}), is reached. Consequently, the loading dose can vary according to specific therapeutic objectives. A minimal loading dose is the amount of drug required to “fill up” the central compartment:

$$\text{Minimal loading dose} = C_{p,ss} \cdot V_1 \quad (11-19)$$

This rapidly achieves the desired concentration and effect, satisfying the first of the three therapeutic objectives. However, the concentration will decrease very quickly because of drug distribution and elimination, even if the loading dose is followed by an infusion (Figure 11-12). Consequently, the desired effect will be maintained for a very short period.

Figure 11-12. Plasma concentration versus time curves after administration of full, partial, and minimal loading doses, followed by a maintenance infusion at a constant rate. (See Equation 11-17, Equation 11-18, Equation 11-19 and Equation 11-20 and accompanying text for explanation.)

A full loading dose can be defined as the amount of drug needed to provide the desired concentration once distribution has been completed. It is calculated as follows:

$$\text{Full loading dose} = C_{p_{ss}} \cdot V_s \quad (11-20)$$

Figure 11-12 demonstrates the plasma concentration–time profile if a full loading dose is followed by a maintenance infusion. The concentration is initially much higher than desired, and it eventually falls to the desired concentration. The disadvantage of this combination is evident. The high initial concentration may produce adverse effects, and there may still be a high drug concentration at the conclusion of surgery, preventing rapid recovery.

As a compromise, a partial (more than the minimal, but less than the full) loading dose can be given. If this is followed by a maintenance infusion, the concentration will initially be higher than desired, and will then fall until the infusion increases the concentration, ultimately achieving the target steady-state value. Figure 11-12 demonstrates that the discrepancy between the desired and actual concentrations is less after the partial loading dose–infusion combination than with either the “full loading dose + infusion” or the “minimal loading dose + infusion” combination. The partial loading dose produces a lower initial concentration than the full loading dose, which is less likely to cause adverse effects, and there is also less likelihood of having an excessive concentration at the conclusion of the operation. The partial loading dose is less likely than the minimal loading dose to result in subtherapeutic concentrations. Therefore, the partial loading dose–maintenance infusion combination comes closest to fulfilling the three therapeutic objectives. If the nadir of the concentration results in an inadequate effect, then a supplementary bolus dose can be given. This principle can be extended by giving a minimal loading dose, followed by many progressively smaller supplementary doses, so that the concentration is close to the desired level virtually all the time.

Although the elimination half-time is often thought of as the most important pharmacokinetic parameter, it does not appear in Equation 11-17, Equation 11-18, Equation 11-19 and Equation 11-20. The elimination half-time is not a true fundamental pharmacokinetic parameter; it is a hybrid parameter that depends on the fundamental parameters: the compartmental volumes, intercompartmental clearance (which determines the rate of equilibration between compartments), and elimination clearance. During most anesthetics, termination of pharmacologic effects depends more on redistribution of drugs from their sites of action to other tissues than on elimination of drugs from the body, especially for lipophilic agents. The ultimate elimination half-time of propofol may be 10 hours or more.¹²⁸ However, even after infusion of propofol for 18 hours, a rapid decrease in the blood concentration occurs on termination of the infusion.¹²⁹ This is due to uptake of propofol by peripheral tissues, which permits redistribution of propofol from the brain to those tissues. Sufentanil is more lipophilic than alfentanil, and simulations suggest that the concentration of sufentanil at its sites of action actually may decrease faster than the concentration of alfentanil under conditions typical of the vast majority of anesthetics.¹³⁰ Therefore, when drugs are administered for just a few hours, the elimination half-time does not usefully predict the rapidity of recovery from lipophilic drugs because redistribution lowers the plasma, and hence brain, concentration below pharmacologically active levels. Less lipophilic agents, such as neuromuscular blockers, are less extensively taken up by tissues, and the rate of recovery from these drugs more closely parallels their elimination half-times.

The concept of the *context-sensitive half-time* has been proposed to predict the rapidity of recovery after infusions of intravenous anesthetics.^{131,132} Briefly, the context-sensitive half-time is derived by plotting the time required for a 50% decrease in plasma concentration after an infusion against the duration of the infusion. The longer the infusion, the longer the context-sensitive half-time. However, for lipophilic agents with multicompartmental kinetics, the context-sensitive half-time is always shorter than the elimination half-time, even for infinitely long infusions. For example after a 3-hour infusion of fentanyl (using a pharmacokinetic model having an elimination half-time of 475 min¹³¹), the context-sensitive half-time is 185 min. The times for greater or lesser decreases in concentrations after infusions can also be simulated.^{130,132} These simulations have provided new insights into the factors responsible for recovery from intravenous anesthetics.

Systems for Administration of Intravenous Agents

Several studies comparing the traditional intermittent bolus injection of iv anesthetics and adjuvants with continuous infusions suggest that the infusions have several advantages.¹³³ The pharmacologic effect is more stable, and often lower total doses are given when continuous infusions, titrated according to individual patients' requirements, are used. Administering iv infusions of iv drugs is facilitated by use of infusion pumps. In terms of operating cost, syringe pumps have a clear advantage over volumetric pumps with cassettes. The major disadvantages of syringe pumps are the relatively low volume that can be infused without interrupting the infusion to refill the syringe, and, for most pumps, a relatively low maximum infusion rate. The desirable features for iv infusion pumps are outlined in Table 11-6. Devices with the some of the programmable features listed in Table 11-6 are currently commercially available. Allowing the user to specify which drug is being delivered by the pump, and including algorithms that warn of potential overdoses is a logical extension of programmability that has yet to be fully exploited. One currently available syringe pump partly achieves this by using magnetically encoded faceplates to identify the drug to the pump, and having a microprocessor determine and control bolus and infusion doses corrected for body weight.* The pump has ranges both for bolus doses ($\text{mg} \cdot \text{kg}^{-1}$) and for maintenance infusions ($\text{mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) that are specific for the drug being infused. However, the number of drugs for which faceplates are available is limited. Another commercially available syringe pump allows entry of doses in either volume per time (*i.e.*, $\text{mL} \cdot \text{h}^{-1}$), mass per time (*i.e.*, $\text{mg} \cdot \text{h}^{-1}$), or mass per time corrected for weight (*i.e.*, $\text{mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$).*

Table 11-6. DESIRABLE FEATURES FOR INTRAVENOUS INFUSION DEVICES

Pharmacokinetic and pharmacodynamic principles have been used to develop computer-controlled drug infusion systems consisting of a computer linked to a volumetric pump via a serial interface.^{134,135} Algorithms based on compartmental pharmacokinetic models determine the infusion rates necessary to achieve and

maintain a target concentration in plasma or in the effect compartment. In essence, these systems give a minimal loading dose (Eq. 11-19), followed by a continuous infusion that replaces drug removed from the central compartment by both redistribution and elimination. The program continuously updates the concentration predicted by the pharmacokinetic model, then continuously adjusts the infusion rate to minimize the discrepancy between the predicted concentration and the desired target concentration. The anesthesiologist can increase or decrease the target concentration as dictated by clinical circumstances, allowing titration to the desired drug effect. This method of delivering intravenous anesthetic drugs and adjuvants is called *target-controlled infusion* (TCI).¹³⁶ In a given patient, the measured plasma concentration and the predicted concentration during TCI will differ because of individual pharmacokinetic variability. However, this bias is usually constant, at least for the duration of an anesthetic.^{135,137} Compared to manually controlled devices, these systems permit more rapid, precise, proportional changes of the plasma concentration of iv agents. Preliminary investigations suggest that TCI achieved more precise control of intravenous anesthetic concentrations during cardiac surgery, compared to manually controlled continuous infusions.¹³⁸ TCI systems should facilitate attainment of the therapeutic objectives in anesthesiology—rapid onset and maintenance of the optimal effect, followed by rapid recovery at the end of surgery. A TCI system for administering propofol has recently become commercially available. †

The major disadvantage of all infusion devices is their cost. At the present time, there is no conclusive evidence that using these devices either improves patient care or reduces health care costs. Intuitively, continuous infusion of iv anesthetics seems logical—after all, we do not administer volatile agents using intermittent boluses! In the current fiscal climate, demonstration of better care or lower costs is needed to justify acquisition of sophisticated infusion systems.

DRUG INTERACTIONS

Taking into account premedication, perioperative antibiotics, iv agents used for induction or maintenance, inhalational anesthetics, opioids, muscle relaxants, the drugs used to restore neuromuscular transmission, and postoperative analgesics, 10 or more drugs may be given for a relatively “routine” anesthetic. Consequently, thorough understanding of the mechanisms of drug interactions and knowledge of specific interactions with drugs used in anesthesia are essential to the safe practice of anesthesiology. Indeed, anesthesiologists often deliberately take advantage of drug interactions. For example, when cholinesterase inhibitors are given to reverse the effects of neuromuscular blockers on nicotinic cholinergic receptors, atropine or glycopyrrolate is administered concomitantly to avoid such undesirable side effects as bradycardia and bronchospasm, which would result from increased acetylcholine binding to muscarinic cholinergic receptors. (See Chapter 50 for a more complete discussion.)

Drug interactions due to physicochemical properties can occur *in vitro*. Mixing acidic drugs, such as thiopental, and basic drugs, such as opioids or muscle relaxants, results in the formation of insoluble salts that precipitate.¹³⁹ Another type of *in vitro* reaction is absorption of drugs by plastics. Examples include the uptake of nitroglycerin by polyvinyl chloride infusion sets¹⁴⁰ and the absorption of fentanyl by the apparatus used for cardiopulmonary bypass.¹⁴¹

Drugs can alter each other's absorption, distribution, and elimination. Absorption from the GI tract is altered by drugs like ranitidine, which alters gastric pH,⁵¹ and metoclopramide, which speeds gastric emptying.¹⁴² Vasoconstrictors are added to local anesthetic solutions to prolong their duration of action at the site of injection and to decrease the risk of systemic toxicity from rapid absorption.

Drugs that compete for binding sites on plasma proteins have complex interactions.⁷² Displacement of a drug from plasma proteins affects its distribution. The increase in the free drug concentration increases tissue uptake of the drug, increasing the volume of distribution. The extent of the effect on drug distribution depends on the fraction of the total drug in the body that is bound to plasma proteins. The change in distribution will be greatest when drugs with relatively large bound fractions and small volumes of distribution are displaced. Displacement of one drug by another may produce toxic free drug concentrations. When a steady state is re-established, the effect of decreased binding on total and free drug concentrations depends on the rate of clearance of the drug. For drugs with low extraction ratios, clearance varies with the degree of binding, and clearance increases proportionately to the increase in free fraction. Therefore, when a steady state is re-established, the total drug concentration will be lower, but the free drug level will be the same as the level before displacement. Clearance of drugs with high extraction ratios is not restricted to the free fraction and is not affected by changes in binding. Consequently, when a new steady state is reached, the total drug concentration is unchanged, and the higher free drug level will persist. Adverse interactions are thus most likely to occur if the displaced drug has high (nonrestrictive) clearance, a small volume of distribution, and relatively high binding to plasma proteins.

Drugs that inhibit or induce the enzymes that catalyze biotransformation reactions can affect clearance of other concomitantly administered drugs. Clearance can also be affected by drug-induced changes in hepatic blood flow. Drugs that are cleared by the kidneys and have similar physicochemical characteristics compete for the transport mechanisms involved in renal tubular secretion.

Pharmacodynamic interactions fall into two broad classifications. Drugs can interact, either directly or indirectly, at the same receptors. Opioid antagonists directly displace opioids from opiate receptors. Cholinesterase inhibitors indirectly antagonize the effects of neuromuscular blockers by increasing the amount of acetylcholine, which displaces the blocking drug from nicotinic receptors. Pharmacodynamic interactions can also occur if two drugs affect a physiologic system at different sites. Benzodiazepines and opioids, each acting on their own specific receptors, appear to interact synergistically.^{143,144} Although receptors and mechanisms are not as well defined as for the benzodiazepine–opioid interaction, this is presumably how volatile anesthetics increase sensitivity to neuromuscular blocking drugs,¹¹⁸ and also how premedication increases sensitivity to inhalational anesthetics.¹⁴⁵

*Tolerance is defined as decreasing pharmacologic effect with sustained exposure to a drug. It results in higher doses (or concentrations) being required to maintain a given effect. The mechanisms responsible for tolerance are diverse. They include adaptive or reflex responses to drug effects that alter the observed effects, and alterations in the number or sensitivity of receptors.

AUTONOMIC PHARMACOLOGY

Anesthesiology is the practice of autonomic medicine. Drugs that produce anesthesia also produce potent autonomic side-effects. The greater part of our training and practice is spent acquiring skills in averting or utilizing the ANS (autonomic nervous system) side-effects of anesthetic drugs under a variety of pathophysiologic conditions. The success of any anesthetic depends upon how well homeostasis is maintained. The numbers that we faithfully record during the course of anesthesia reflect ANS function and not necessarily the presence of surgical anesthesia.^{1,2} A knowledge of the ANS is a prerequisite to an understanding of anesthesia pharmacology.

AUTONOMIC NERVOUS SYSTEM PURPOSE

The ANS includes that part of the central and peripheral nervous system concerned with involuntary regulation of cardiac muscle, smooth muscle, glandular, and visceral functions. ANS activity refers to visceral reflexes that function essentially below the conscious level. The term *autonomic* remains the best description of this ubiquitous system, as opposed to *automatic*. Autonomic implies self-controlling, whereas automatic implies nonreflexic or intrinsic responses; however, the use of “autonomy” to describe this nervous system is also illusory. The ANS is also responsive to changes in somatic motor and sensory activities of the body. The physiologic evidence of visceral reflexes as a result of somatic events is abundantly clear. Psychosomatic disease is an expression of this connection. The ANS is therefore not as distinct an entity as the term suggests. Neither somatic nor ANS activity occurs in isolation.¹ The ANS organizes visceral support for somatic behavior and adjusts body states in anticipation of emotional behavior or responses to the stress of disease, *i.e.*, fight or flight.

Traditionally, the ANS has been viewed as strictly a peripheral, efferent (motor) system. This concept is no longer tenable. Afferent fibers from visceral structures are the first link in the reflex arcs of the ANS whether relaying visceral pain or changes in vessel stretch. Most ANS efferent fibers are accompanied by sensory fibers that are now commonly recognized as components of the ANS. The afferent components of the ANS cannot be as distinctively divided as can the efferent nerves.

Historically, many investigators have refused to classify any afferent fibers within the ANS because visceral sensory nerves are anatomically indistinguishable from somatic sensory nerves.² Visceral afferent pathways are like afferent somatic nerves in that they are unipolar. ANS efferents are bipolar ([Fig. 12-1](#)). Furthermore, afferent fibers that are anatomically aligned with ANS efferents do not differ by design, function, or drug response from somatic afferents. In addition, both somatic and visceral sensory nerves are able to initiate ANS reflexes. However, the argument is functional rather than anatomic because visceral pain can be attenuated by sympathectomy. The clinical importance of visceral afferent fibers is more closely associated with chronic pain management.

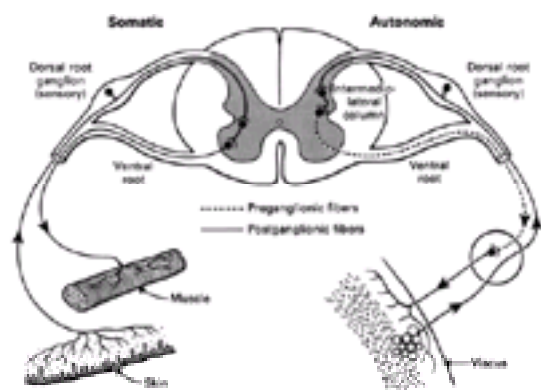

Figure 12-1. Comparison of somatic and autonomic reflex arcs. Somatic arcs are unipolar and autonomic arcs are bipolar.

FUNCTIONAL ANATOMY

The ANS naturally falls into two divisions by anatomy, physiology, and pharmacology. Langley divided this nervous system into two parts in 1921. He retained the term *sympathetic* (sympathetic nervous system, SNS), which was introduced by Willis in 1665, for the first part and introduced the term *parasympathetic* (parasympathetic nervous system, PNS) for the second. The term *autonomic nervous system* was adopted as a comprehensive name for both. Ordinarily, activation of the SNS produces expenditure of body energy, whereas the PNS produces conservation or accumulation of energy resources. [Table 12-1](#) lists the complementary effects of SNS (adrenergic) and PNS (cholinergic) activity of organ systems.

| Organ System | Response | |
|-----------------------------|---------------------------------------|---------------------------------------|
| | Adrenergic | Cholinergic |
| HEART | | |
| Atrial node | Stimulate | Stimulate |
| Sinoatrial node | Increase rate and conduction velocity | Increase rate and conduction velocity |
| Atrioventricular node | Increase rate and conduction velocity | Increase rate and conduction velocity |
| Myocardium | Increase rate and conduction velocity | Increase rate and conduction velocity |
| BLADDER | | |
| Detrusor muscle | Relaxation | Contraction |
| Internal urethral sphincter | Contraction | Relaxation |
| GI TRACT | | |
| Salivary gland | Stimulate | Stimulate |
| Stomach | Stimulate | Stimulate |
| Small intestine | Stimulate | Stimulate |
| Large intestine | Stimulate | Stimulate |
| Rectum | Stimulate | Stimulate |
| ADRENAL GLAND | | |
| Medulla | Stimulate | Stimulate |
| Cortex | Stimulate | Stimulate |
| PIE | | |
| Eye | Stimulate | Stimulate |
| Salivary gland | Stimulate | Stimulate |
| Heart | Stimulate | Stimulate |
| Small intestine | Stimulate | Stimulate |
| Large intestine | Stimulate | Stimulate |
| Rectum | Stimulate | Stimulate |
| Bladder | Stimulate | Stimulate |

| Uterus | Stimulate | Stimulate |
| Vagina | Stimulate | Stimulate |

Table 12-1. HOMEOSTATIC BALANCE BETWEEN ADRENERGIC AND CHOLINERGIC EFFECTS

Central Autonomic Organization

Pure central ANS or somatic centers are not known. Extensive overlap of function occurs. And integration of ANS activity occurs at all levels of the cerebrospinal axis. Efferent ANS activity can be initiated locally and by centers located in the spinal cord, brain stem, and hypothalamus. The cerebral cortex is the highest level of ANS integration. Fainting at the sight of blood is an example of this higher level of somatic and ANS integration. ANS function has also been successfully modulated through conscious, intentional efforts, demonstrating that somatic responses are always accompanied by visceral responses and *vice versa*.

The principal site of ANS organization is the hypothalamus. SNS functions are controlled by nuclei in the posterolateral hypothalamus. Stimulation of these nuclei results in a massive discharge of the sympathoadrenal system ([Table 12-2](#)). PNS functions are governed by nuclei in the midline and some anterior nuclei of the hypothalamus. The anterior hypothalamus is involved with regulation of temperature. The supraoptic hypothalamic nuclei regulate water metabolism and are anatomically and functionally associated with the posterior lobe of the pituitary (see [Interaction of Autonomic Nervous System Receptors](#)). This hypothalamic-neurohypophyseal connection represents a central ANS mechanism that affects the kidney by means of antidiuretic hormone. Long-term blood pressure control, reactions to physical and emotional stress, sleep, and sexual reflexes are regulated through the hypothalamus.

| Anterior | Posterior |
|--|----------------------------------|
| PARAVENTRICULAR NUCLEUS | POSTERIOR HYPOTHALAMUS |
| Oxytocin release | Increased blood pressure |
| Water conservation | Pupillary dilation |
| | Shivering |
| | Corticotropin |
| MEDIAL PREOPTIC AREA | DORSOMEDIAL NUCLEUS |
| Bladder contraction | Gastrointestinal stimulation |
| Decreased heart rate | |
| Decreased blood pressure | PERIFORNICAL NUCLEUS |
| SUPRAOPTIC NUCLEUS | Hunger |
| Water conservation | Increased blood pressure |
| | Rage |
| POSTERIOR PREOPTIC AND ANTERIOR HYPOTHALAMIC AREA | VENTROMEDIAL NUCLEUS |
| Body temperature regulation | Satiety |
| Panting | |
| Sweating | MAMMILLARY BODY |
| Thyrotropin inhibition | Feeding reflexes |
| | LATERAL HYPOTHALAMIC AREA |
| | Thirst and hunger |

Table 12-2. HYPOTHALAMIC NUCLEI

The medulla oblongata and pons are the vital centers of acute ANS organization. Together, they integrate momentary hemodynamic adjustments and maintain the sequence and automaticity of ventilation. Integration of afferent and efferent ANS impulses at this central nervous system (CNS) level is responsible for the tonic activity exhibited by the ANS. Control of peripheral vascular resistance and blood pressure is an example of this tonic activity. Tonicity holds visceral organs in a state of intermediate activity that can either be diminished or augmented by altering the rate of nerve firing. The nucleus tractus solitarius, located within the medulla, is the primary area for relay of afferent chemoreceptor and baroreceptor information from the glossopharyngeal and vagus nerves. Increased afferent impulses from these two nerves inhibits peripheral SNS vascular tone, producing vasodilation, and increase vagal tone, producing bradycardia. High spinal cord transection eliminates the medulla and results in hypotension. Studies of patients with high spinal cord lesions show that a number of reflex changes are mediated at the spinal or segmental level. ANS hyper-reflexia is an example of spinal cord mediation of ANS reflexes without integration of function from higher inhibitory centers.^{4,3}

Peripheral Autonomic Nervous System Organization

The peripheral ANS is the efferent (motor) component of the ANS and consists of two complementary parts: the SNS and the PNS. Most organs receive fibers from both divisions ([Fig. 12-2](#)). In general, activities of the two systems produce opposite but complementary effects (see [Table 12-1](#)). Actions of the two subdivisions are supplementary in some tissues, such as the salivary glands. A few tissues, such as sweat glands and spleen, are innervated by only SNS fibers. Although the anatomy of the somatic and ANS sensory pathways is identical, the motor pathways are characteristically different. The efferent somatic motor system, like somatic afferents, is composed of a single (unipolar) neuron with its cell body in the ventral gray matter of the spinal cord. Its myelinated axon extends directly to the voluntary striated muscle unit. In contrast, the efferent (motor) ANS is a two-neuron (bipolar) chain from the CNS to the effector organ (see [Fig. 12-1](#)). The first neuron of both the SNS and PNS originates within the CNS but does not make direct contact with the effector organ. Instead, it relays the impulse to a second station known as an ANS ganglion, which contains the cell body of the second ANS (postganglionic) neuron. Its axon contacts the effector organ. Schematically, then, the motor pathways of both divisions of the ANS are a serial, two-neuron chain consisting of a preganglionic neuron and a postganglionic effector neuron ([Fig. 12-3](#)).

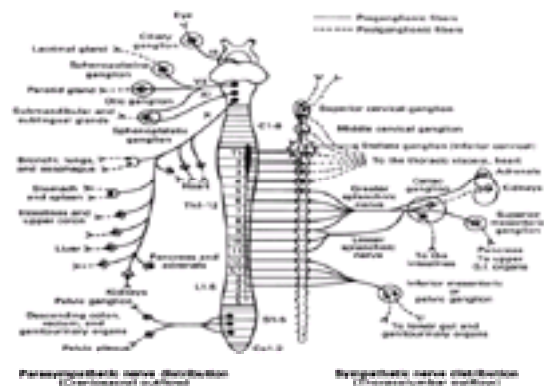

Figure 12-2. Schematic distribution of the craniosacral (parasympathetic) and thoracolumbar (sympathetic) nervous systems. Parasympathetic preganglionic fibers pass directly to the organ that is innervated. Their postganglionic cell bodies are situated near or within the innervated viscera. This limited distribution of parasympathetic postganglionic fibers is consistent with the discrete and limited effect of parasympathetic function. The postganglionic sympathetic neurons originate in either the paired sympathetic ganglia or one of the unpaired collateral plexuses. One preganglionic fiber influences many postganglionic neurons. Activation of the SNS produces a more diffuse physiologic response rather than discrete effects.

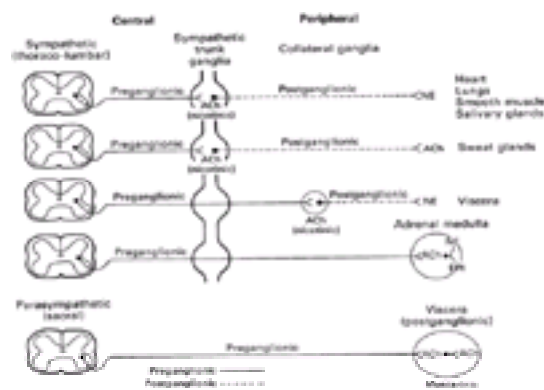

Figure 12-3. Schematic diagram of the efferent ANS. Afferent impulses are integrated centrally and sent reflexly to the adrenergic and cholinergic receptors. Sympathetic fibers ending in the adrenal medulla are preganglionic, and acetylcholine (ACh) is the neurotransmitter. Stimulation of the chromaffin cells, acting as postganglionic neurons, releases epinephrine (EPI) and norepinephrine (NE).

Preganglionic fibers of both subdivisions are myelinated, with diameters of less than $3 \mu\text{m}$.¹ Impulses are conducted at a speed of $3\text{--}15 \text{ m} \cdot \text{s}^{-1}$. The postganglionic fibers are unmyelinated and conduct impulses at slower speeds of less than $2 \text{ m} \cdot \text{s}^{-1}$. They are similar to unmyelinated visceral and somatic afferent C fibers (Table 12-3). Compared with the myelinated somatic nerves, the ANS conducts impulses at speeds that preclude its participation in the immediate phase of a somatic response.

| Description of Nerve Fibers | Group | Diameter (μm) | Conduction Velocity ($\text{m} \cdot \text{s}^{-1}$) |
|---|-------|----------------------------|--|
| Myelinated somatic | A | Alpha α | 20 |
| | | Beta β | 10 |
| | | Gamma γ | 5-40 (pain fibers) |
| | | Delta δ | 5-40 (pain fibers) |
| Myelinated visceral (preganglionic autonomic) | B | Epsilon ϵ | 2 |
| | | | <3 |
| Unmyelinated somatic | C | <2 | 0.5-2 (pain fibers) |

Table 12-3. CLASSIFICATION OF NERVE FIBERS

Sympathetic Nervous System or Thoracolumbar Division

The efferent SNS is referred to as the thoracolumbar nervous system. The origin of its preganglionic fibers provides the anatomic basis for this designation. Figure 12-2 demonstrates the distribution of the SNS and its innervation of visceral organs.

The preganglionic fibers of the SNS (thoracolumbar division) originate in the intermediolateral gray column of the 12 thoracic (T1–T12) and the first 3 lumbar segments (L1–L3) of the spinal cord. The myelinated axons of these nerve cells leave the spinal cord with the motor fibers to form the white (myelinated) communicating rami (Fig. 12-4). The rami enter one of the paired 22 sympathetic ganglia at their respective segmental levels. Upon entering the paravertebral ganglia of the lateral sympathetic chain, the preganglionic fiber may follow one of three courses: (1) synapse with postganglionic fibers in ganglia at the level of exit; (2) course upward or downward in the trunk of the SNS chain to synapse in ganglia at other levels; or (3) track for variable distances through the sympathetic chain and exit without synapsing to terminate in an outlying, unpaired, SNS collateral ganglion (Fig. 12-4). The adrenal gland is an exception to the rule. Preganglionic fibers pass directly into the adrenal medulla without synapsing in a ganglion (see Fig. 12-3). The cells of the medulla are derived from neuronal tissue and are analogous to postganglionic neurons.⁴

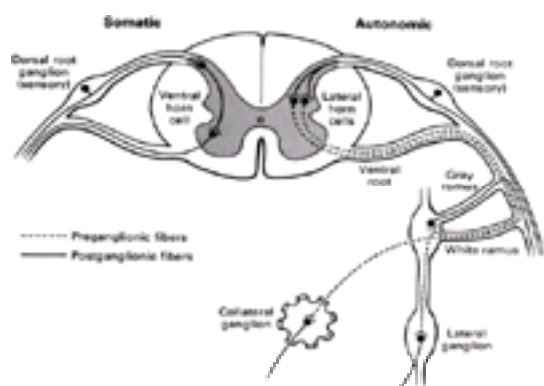

Figure 12-4. The spinal reflex arc of the somatic nerves is shown on the left. The different arrangements of neurons in the sympathetic system are shown on the right. Preganglionic fibers coming out through white rami may make synaptic connections following one of three courses: (1) synapse in ganglia at the level of exit, (2) course up or down the sympathetic chain to synapse at another level, or (3) exit the chain without synapsing to an outlying collateral ganglion.

The sympathetic postganglionic neuronal cell bodies are located in ganglia of the paired lateral SNS chain or unpaired collateral ganglia in more peripheral plexuses. Collateral ganglia, such as the celiac and inferior mesenteric ganglia (plexus), are formed by the convergence of preganglionic fibers with many postganglionic neuronal bodies. SNS ganglia are almost always located closer to the spinal cord than to the organs they innervate. The sympathetic postganglionic neuron can therefore originate in either the paired lateral paravertebral SNS ganglia or one of the unpaired collateral plexus. The unmyelinated postganglionic fibers then proceed from the ganglia to terminate within the organs they innervate.

Many of the postganglionic fibers pass from the lateral SNS chain back into the spinal nerves, forming the gray (unmyelinated) communicating rami at all levels of the spinal cord (Fig. 12-4). They are distributed distally to sweat glands, pilomotor muscle, and blood vessels of the skin and muscle. These nerves are unmyelinated C type fibers (Table 12-3) and are carried within the somatic nerves. Approximately 8% of the fibers in the average somatic nerve are sympathetic.¹

The first four or five thoracic spinal segments generate preganglionic fibers that ascend in the neck to form three special paired ganglia. These are the superior cervical, middle cervical, and cervicothoracic ganglia. The last is known as the stellate ganglion and is actually formed by the fusion of the inferior cervical and first thoracic SNS ganglia. These ganglia provide sympathetic innervation of the head, neck, upper extremities, heart, and lungs. Afferent pain fibers also travel with these nerves, accounting for chest, neck, or upper extremity pain with myocardial ischemia.

Activation of the SNS produces a diffused physiologic response (mass reflex) rather than discrete effects. Function follows design. SNS postganglionic neurons outnumber the preganglionic neurons in an average ratio of 20:1 to 30:1.⁵ One preganglionic fiber influences a larger number of postganglionic neurons, which are dispersed to many organs. In addition, the SNS response is augmented by the hormonal release of epinephrine (EPI) from the adrenal medulla.

Parasympathetic Nervous System or Craniosacral Division

The PNS, like the SNS, has both preganglionic and postganglionic neurons. This division is sometimes called the craniosacral outflow because the preganglionic cell bodies originate in the brain stem and sacral segments of the spinal cord. PNS preganglionic fibers are found in cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus). The sacral outflow originates in the intermediolateral gray horns of the second, third, and fourth sacral nerves. Figure 12-2 shows the distribution of the PNS division and its innervation of visceral organs.

The vagus (cranial nerve X) nerve has the most extensive distribution of all the PNS, accounting for more than 75% of PNS activity. The paired vagus nerves supply PNS innervation to the heart, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, and upper portions of the ureters. The sacral fibers form the pelvic visceral nerves, or nervi erigentes. These nerves supply the remainder of the viscera that are not innervated by the vagus. They supply the descending colon, rectum, uterus, bladder, and lower portions of the ureters and are primarily concerned with emptying. Various sexual reactions are also governed by the sacral PNS. The PNS is responsible for penile erection, but SNS stimulation governs ejaculation.

In contrast to the SNS division, PNS preganglionic fibers pass directly to the organ that is innervated. The postganglionic cell bodies are situated near or within the innervated viscera and generally are not visible. The proximity of PNS ganglia to or within the viscera provides a limited distribution of postganglionic fibers. The ratio of postganglionic to preganglionic fibers in many organs appears to be 1:1 to 3:1 compared with the 20:1 found in the SNS system. Auerbach's plexus in the distal colon is the exception, with a ratio of 8000:1. The fact that PNS preganglionic fibers synapse with only a few postganglionic neurons is consistent with the discrete and limited effect of PNS function. For example, vagal bradycardia can occur without a concomitant change in intestinal motility or salivation. Mass reflex action is not a characteristic of the PNS. The effects of organ response to PNS stimulation are outlined in Table 12-1.

Autonomic Innervation

Heart

The heart is well supplied by the SNS and PNS. These nerves affect cardiac pumping in three ways: (1) by changing the rate (chronotropism), (2) by changing the strength of contraction (inotropism), and (3) by modulating coronary blood flow. The PNS cardiac vagal fibers approach the stellate ganglia and then join the efferent cardiac SNS fibers; therefore, the vagus nerve to the heart and lungs is a mixed nerve containing both PNS and SNS efferent fibers. The PNS fibers are distributed mainly to the sinoatrial and atrioventricular (AV) nodes and to a lesser extent to the atria. There is little or no distribution to the ventricles. Therefore, the main effect of vagal cardiac stimulation to the heart is chronotropic. Vagal stimulation decreases the rate of sinoatrial node discharge and decreases excitability of the AV junctional fibers, slowing impulse conduction to the ventricles. A strong vagal discharge can completely arrest sinoatrial node firing and block impulse conduction to the ventricles. Vagal stimulation or vagotonic drugs such as methacholine reduce the vulnerability of the heart to ventricular fibrillation, decrease the frequency of premature ventricular beats, and can abolish ventricular tachycardia (see [Interaction of Autonomic Nervous System Receptors](#)).⁶

The physiologic importance of the PNS on myocardial contractility is not as well understood as that of the SNS. Cholinergic blockade can double the heart rate (HR) without altering contractility of the left ventricle. Vagal stimulation of the heart can reduce left ventricular maximum rate of tension development (dP/dT) and decrease contractile force by as much as 10–20%. However, PNS stimulation is relatively unimportant in this regard compared with its predominant effect on HR.

The SNS has the same supraventricular distribution as the PNS, but with stronger representation to the ventricles. SNS efferents to the myocardium funnel through the paired stellate ganglia. The right stellate ganglion distributes primarily to the anterior epicardial surface and the interventricular septum.⁷ Right stellate stimulation decreases systolic duration and increases HR. The left stellate ganglion supplies the posterior and lateral surfaces of both ventricles. Left stellate stimulation increases mean arterial pressure and left ventricular contractility without causing a substantial change in HR. Normal SNS tone maintains contractility ~20% above that in the absence of any SNS stimulation.⁸ Therefore, the dominant effect of the ANS on myocardial contractility is mediated primarily through the SNS. Intrinsic mechanisms of the myocardium, however, can maintain circulation quite well without the ANS, as evidenced by the success of cardiac transplants (see [Denervated Heart](#)).^{9,10}

Early investigations, performed in anesthetized, open-chest animals, demonstrated that cardiac ANS nerves exert only slight effects on the coronary vascular bed; however, later studies on chronically instrumented, intact, conscious animals show considerable evidence for a strong SNS regulation of the small coronary resistance and larger conductance vessels (see [Adrenergic Receptors](#)).^{11,12}

Different segments of the coronary arterial tree react differently to various stimuli and drugs. Large conductance vessels, the primary location for atheromatous plaques, are found on the epicardial surface, whereas the small, precapillary resistance vessels are found within the myocardium. Normally, the large conductance vessels contribute little to overall coronary vascular resistance. Fluctuations in resistance reflect changes in lumen size of the small, precapillary vessels. Blood flow through the resistance vessels is regulated primarily by the local metabolic requirements of the myocardium. The larger conductance vessels, however, can constrict markedly with neurogenic stimulation (see [Adrenergic Receptor Distribution and Function](#)). Neurogenic influence also assumes a greater role in the resistance vessels when they become hypoxic and lose autoregulation. There is a strong interaction between SNS and PNS nerves in organs with dual, antagonistic innervation. The tone of the coronary arteries is under this interacting control in a manner that is only now becoming understood (see [Interaction of Autonomic Nervous System Receptors](#)).¹³

Peripheral Circulation

The SNS nerves are by far the most important regulators of the peripheral circulation. The PNS nerves play only a minor role in this regard. The PNS dilates vessels, but only in limited areas such as the genitals. SNS stimulation produces both vasodilation and vasoconstriction, with vasoconstrictor effects predominating. The effect is determined by the type of receptors on which the SNS fiber terminates (see [Receptors](#)). SNS constrictor receptors are distributed to all segments of the circulation. This distribution is greater in some tissues than in others. Blood vessels in the skin, kidneys, spleen, and mesentery have an extensive SNS distribution, whereas those in the heart, brain, and muscle have less SNS innervation. SNS stimulation of the coronary arteries may produce vasoconstriction or vasodilation, depending upon the predominant receptor activity at the time of stimulation (see Table 12-1). Vagal stimulation may also produce coronary vasoconstriction (see [b-Adrenergic Receptors](#)). However, local autoregulatory factors usually have the predominant influence on coronary vascular tone.

Vascular tone is the sum of the muscular forces in the walls of blood vessels that oppose an increase in vessel diameter. Vasomotor tone denotes that portion of vasculature tone controlled by the ANS vasomotor nerves. Vascular tone is actively influenced also by local and circulating substances (such as hormones and metabolites), blood flow, and luminal hydrostatic pressure. An increase in blood flow increases shear stress at the endothelial lining of the vessel wall. This triggers release of a relaxing factor from the endothelium (see [Molecular Pharmacology and Effector Mechanisms](#)). Vasodilation ensues. Conversely, an increase in intraluminal pressure directly stimulates smooth muscle contraction independent of vasomotor effects. This component of vascular tone is referred to as myogenic tone. Blood vessels have differing sensitivities to the influence of local or neurogenic control. Arterioles and venules are under strong neurogenic control and have vasomotor tone. Local autoregulation is the predominant force at the precapillary and postcapillary sphincters.¹⁴

Basal vasomotor tone is maintained by impulses from the lateral portion of the vasomotor center in the medulla oblongata that continually transmits impulses through

the SNS, maintaining partial arteriolar and venular constriction. Circulating EPI from the adrenal medulla has additive effects. This basal ANS tone maintains arteriolar constriction at an intermediate diameter.¹⁵ The arteriole, therefore, has the potential for either further constriction or dilation. If the basal tone were not present, the SNS could effect only vasoconstriction and not vasodilation.¹ The SNS tone in the venules produces little resistance to flow compared with the arterioles and the arteries. The importance of SNS stimulation of veins is to reduce or increase their capacity. By functioning as a reservoir for ~80% of the total blood volume, small changes in venous capacitance produce large changes in venous return and, thus, cardiac preload.

Lungs

The lungs are innervated by both the SNS and PNS.¹⁵ Postganglionic SNS fibers from the upper thoracic ganglia (stellate) pass to the lungs to innervate the smooth muscles of the bronchi and pulmonary blood vessels. PNS innervation of these structures is from the vagus nerve.

SNS stimulation produces bronchodilation and pulmonary vasoconstriction.¹⁶ Little else has been conclusively proved about the vasomotor control of the pulmonary vessels, other than the fact that they adjust to accommodate the output of the right ventricle. The effect of stimulation of the pulmonary SNS nerves on pulmonary vascular resistance is not great, but may be important in maintaining hemodynamic stability during stress and exercise by balancing right and left ventricular output.^{17,18} Stimulation of the vagus nerve produces almost no vasodilation of the pulmonary circulation. The phenomenon of hypoxic pulmonary vasoconstriction appears to be an important force in regulation of pulmonary blood flow.^{19,20} Hypoxic pulmonary vasoconstriction is a local phenomenon capable of providing a faster adjustment to needs.

Both the SNS and the vagus nerve provide active bronchomotor control. SNS stimulation causes bronchodilation, whereas vagal stimulation produces constriction. PNS stimulation may also increase secretions of the bronchial glands. Vagal receptor endings in the alveolar ducts also play an important role in the reflex regulation of the ventilation cycle.²¹ The lung has important nonventilatory activity as well. It serves as a metabolic organ that removes local mediators such as norepinephrine (NE) from the circulation and converts others, such as angiotensin I, to active compounds (see [Interaction with Other Regulatory Systems](#)).^{22,23}

AUTONOMIC NERVOUS SYSTEM: NEUROTRANSMISSION

Transmission of excitation across the terminal junctional sites (synaptic clefts) of the peripheral ANS occurs through the mediation of liberated chemicals ([Fig. 12-5](#)). Transmitters interact with a receptor on the end organ to evoke a biologic response. The ANS can be pharmacologically subdivided by the neurotransmitter secreted at the effector cell. Pharmacologic parlance designates the SNS and PNS as *adrenergic* and *cholinergic*, respectively. The terminals of the PNS postganglionic fibers release acetylcholine (ACh). With the exception of sweat glands, NE is considered the principal neurotransmitter released at the terminals of the sympathetic postganglionic fibers (see [Fig. 12-3](#)). Co-transmission of ATP, neuropeptide Y (NPY), and NE has been demonstrated at vascular sympathetic nerve terminals in a number of different tissues including muscle, intestine, kidney, and skin (see [SNS Neurotransmission](#)). The preganglionic neurons of both systems secrete ACh.

Figure 12-5. The anatomy and physiology of the terminal postganglionic fibers of sympathetic and parasympathetic fibers are similar.

The terminations of the postganglionic fibers of both ANS subdivisions are anatomically and physiologically similar. The terminations are characterized by multiple branchings called terminal effector plexuses, or reticulæ. These filaments surround the elements of the effector unit "like a mesh stocking."¹⁴ Thus, one SNS postganglionic neuron, for example, can innervate ~25,000 effector cells, e.g., vascular smooth muscle.^{4,5} The terminal filaments end in presynaptic enlargements called varicosities. Each varicosity contains vesicles, ~500 µm in diameter, in which the neurotransmitters are stored ([Fig. 12-5](#)). The varicosities are also heavily populated with mitochondria, which relates to the increased energy (adenosine triphosphate, ATP) requirements of ACh and NE synthesis. The rate of synthesis depends on the level of ANS activity and is regulated by local feedback. The distance between the varicosity and the effector cell (synaptic or junctional cleft) varies from 100 µm in ganglia and arterioles to as much as 20,000 µm in large arteries. This distance determines the amount of transmitter required to stimulate and the time it takes to diffuse to the effector cell. The time for diffusion is directly proportional to the width of the synaptic gap. Depolarization releases the vesicular contents into the synaptic cleft by exocytosis.

Parasympathetic Nervous System Neurotransmission

Synthesis

Classically, ACh was considered the exclusive neurotransmitter of the PNS. Current investigation suggests a role for vasoactive intestinal peptide (VIP) as an additional PNS neurotransmitter. ACh is formed in the presynaptic terminal by acetylation of choline with acetyl coenzyme A. This step is catalyzed by choline acetyl transferase ([Fig. 12-6](#)). ACh is then stored in a concentrated form in presynaptic vesicles containing ~10,000 molecules of ACh. A continual release of small amounts of ACh, called quanta, occurs during the resting state. Each quantum results in small changes in the electrical potential of the synaptic end plate without producing depolarization. These are known as miniature end-plate potentials. Arrival of an action potential causes a synchronous release of hundreds of quanta, resulting in depolarization of the end plate. Release of ACh from the vesicles is dependent on influx of calcium (Ca^{2+}) from the interstitial space.²⁴ Drugs that alter Ca^{2+} binding or influx may decrease ACh release and affect end-organ function. ACh is not reused like NE; therefore, it must be synthesized constantly.

Figure 12-6. Synthesis and metabolism of acetylcholine.

Metabolism

The ability of a receptor to modulate function of an effector organ is dependent upon rapid recovery to its baseline state after stimulation. For this to occur, the neurotransmitter must be quickly removed from the vicinity of the receptor. ACh removal occurs by rapid hydrolysis by acetylcholinesterase ([Fig. 12-6](#)). This enzyme is found in neurons, at the neuromuscular junction, and in various other tissues of the body. A similar enzyme, pseudocholinesterase or plasma cholinesterase, is also

found throughout the body but only to a limited extent in nervous tissue. It does not appear to be physiologically important in termination of the action of ACh. Both acetylcholinesterase and pseudocholinesterase hydrolyze ACh as well as other esters (such as the ester-type local anesthetics), but they may be distinguished by specific biochemical tests.^{6,25}

Sympathetic Nervous System Neurotransmission

Traditionally, the catecholamines EPI and NE were considered the exclusive mediators of peripheral SNS activity. Evidence accumulated over the past two decades, though, suggests roles for ATP and NPY as additional sympathetic neurotransmitters. NE is released from localized presynaptic vesicles of nearly all postganglionic sympathetic nerves. Vascular SNS nerve terminals, though, also release ATP. Thus, ATP and NE are co-neurotransmitters. They are released directly into the site where they act. Their postjunctional effects appear to be synergistic in tissues studied to date. The function of NPY as a peripheral sympathetic neurotransmitter remains unknown.

The SNS fibers ending in the adrenal medulla are preganglionic, and ACh is the neurotransmitter (see Fig. 12-3). It interacts with the chromaffin cells in the medulla, causing release of EPI and NE. The chromaffin cells take the place of the postganglionic neurons.⁴ Stimulation of the sympathetic nerves to the adrenal medulla, however, causes the release of large quantities of a mixture of EPI and NE into the circulation to become neurotransmitter hormones. The greater portion of this hormonal surge is normally EPI. EPI and NE, when released into the circulation, are classified as hormones in that they are synthesized, stored, and released from the adrenal medulla to act at distant sites.²⁶

Hormonal EPI and NE have almost the same effects on effector cells as those caused by local direct sympathetic stimulation; however, the hormonal effects, although brief, last ~10 times as long as those caused by direct stimulation.^{15,27} EPI has a greater metabolic effect than NE. It can increase the metabolic rate of the body as much as 100%.¹ It also increases glycogenolysis in the liver and muscle with glucose release into the blood. These functions are all necessary to prepare the body for fight or flight.

The normal resting state of secretion by the adrenal medulla is ~0.02 µg · kg⁻¹ · min⁻¹ of EPI and ~0.02 µg · kg⁻¹ · min⁻¹ of NE.^{1,27,28} Some of the overall vascular tone results from the basal resting secretion of the adrenal medulla in addition to the tone that is maintained directly through stimulation from central vasomotor centers in the medulla.

Catecholamines: The First Messenger

The endogenous catecholamines in humans are dopamine, NE, and EPI. Dopamine is a neurotransmitter in the CNS. It is primarily involved in coordinating motor activity in the brain. It is the precursor of NE. NE is synthesized and stored in nerve endings of postganglionic SNS neurons. It is also synthesized in the adrenal medulla and is the chemical precursor of EPI. Stored EPI is located chiefly in chromaffin cells of the adrenal medulla. Eighty to eighty-five percent of the catecholamine content of the adrenal medulla is EPI and 15–20% is NE. The brain contains both noradrenergic and dopaminergic receptors, but circulating catecholamines do not cross the blood–brain barrier. The catecholamines present in the brain are synthesized there. Endogenous catecholamines are unique in that several intermediates in the synthesis function as neurotransmitters.

A catecholamine is any compound having a catechol nucleus (a benzene ring with two adjacent hydroxyl groups) and an amine-containing side chain.²⁹ The chemical configuration of five of the more common catecholamines in clinical use is demonstrated in Figure 12-7. A true catecholamine must possess this basic structure. Catecholamines are often referred to as adrenergic drugs because their effector actions are mediated through receptors specific for the SNS. Synthetic catecholamines can activate these same receptors because of their structural similarity. For example, clonidine is an α₂-receptor agonist that does not possess a catechol nucleus, and even has two ring systems that are aplanar to each other (Fig. 12-8). However, clonidine enjoys a remarkable spatial similarity to NE that allows it to activate the receptor.^{30,31} Drugs that produce sympathetic-like effects but lack the basic catecholamine structure are defined as sympathomimetics. All clinically useful catecholamines are sympathomimetics, but not all sympathomimetics are catecholamines (Table 12-4).

Figure 12-7. The chemical configurations of three endogenous catecholamines are compared with those of three synthetic catecholamines. Sympathomimetic drugs differ in their hemodynamic effects largely because of differences in substitution of the amine group on the catechol nucleus.

Figure 12-8. The spatial similarity of clonidine and NE allows it to activate presynaptic α₂ receptors inhibiting NE release.

| Drug | Trade Name |
|--------------------------|----------------|
| ADRENERGIC AMINES | |
| Catecholamines | |
| Epinephrine | Adrenalin |
| Norepinephrine | Levophed |
| Dopamine | Dostinon |
| Dobutamine | Dobutol |
| Epinephrine | Isuprel |
| Isoproterenol | |
| Noncatecholamines | |
| Metaraminol† | Aramine |
| Metoprolol† | Toprol |
| Ephedrine† | Ephedrine |
| Metaraminol | Vasomax |
| Phenylephrine | Nesylphenaline |
| Clonidine | |
| NONADRENERGICS | |
| Xanthines | Aminophylline |
| Clonidine | Clonidine |
| Digitalis | Lanolin |
| Calcium salts | |
| Salbutamol | Maxair |
| Albuterol | Brevo |

Table 12-4. SYMPATHOMIMETIC DRUGS

The effects of endogenous or synthetic catecholamines on adrenergic receptors can be direct or indirect (Table 12-4).^{32,33} Indirect-acting catecholamines have little intrinsic effect on adrenergic receptors but produce their effects by stimulating release of the stored neurotransmitter from SNS nerve terminals. Some synthetic and endogenous catecholamines stimulate adrenergic receptor sites directly, whereas others have a mixed mode of action. The actions of direct-acting catecholamines are independent of endogenous NE stores; however, the indirect-acting catecholamines are totally dependent on adequate neuronal stores of endogenous NE.

Synthesis

The main site of NE synthesis is in or near the postganglionic nerve endings. Some synthesis does occur in vesicles near the cell body that pass to the nerve endings.³⁴ Phenylalanine or tyrosine is taken up into the axoplasm of the nerve terminal and synthesized into either NE or EPI.^{4,5} Figure 12-9 demonstrates this synthesis cascade. Tyrosine hydroxylase catalyzes the conversion of tyrosine to dihydroxyphenylalanine. This is the rate-limiting step at which NE synthesis is controlled through feedback inhibition.³⁵ Dihydroxyphenylalanine and the subsequent compounds in this cascade are catecholamines.

Figure 12-9. Schematic of the synthesis of catecholamines. The conversion of tyrosine to DOPA by tyrosine hydroxylase is inhibited by increased NE synthesis. Epinephrine is shown in these steps but is primarily synthesized in the adrenal medulla.

Dopamine is formed from dihydroxyphenylalanine by dihydroxyphenylalanine decarboxylase. Synthesis to this point occurs in the cytoplasm of the neuron. Dopamine then enters the storage vesicles. In the brain, synthesis stops at this point where dopamine is the neurotransmitter. The vesicles of peripheral postganglionic neurons contain the enzyme dopamine- β -hydroxylase, which converts dopamine to NE. The adrenal medulla additionally contains phenylethanolamine-*N*-methyltransferase, which converts NE to EPI. This reaction takes place outside the medullary vesicles, and the newly formed EPI then enters the vesicle for storage (Fig. 12-10). All the endogenous catecholamines are stored in presynaptic vesicles and released on arrival of an action potential. Excitation-secretion coupling in sympathetic neurons is Ca^{2+} -dependent.

Figure 12-10. Schematic of the synthesis and disposition of NE in adrenergic neurotransmission. (1) Synthesis and storage in neuronal vesicles; (2) action potential permits calcium entry with (3) exocytosis of NE into synaptic gap. (4) Released NE reacts with receptor on effector cell. NE (5) may react with presynaptic α_2 receptor to inhibit further NE release or with presynaptic β receptor to enhance reuptake of NE (6) (uptake 1). Extraneuronal uptake (uptake 2) absorbs NE into effector cell (7) with overflow occurring systemically (8). MAO = monoamine oxidase; COMT = catechol-*O*-methyltransferase; Tyr = tyrosine; DOPA = dihydroxyphenylalanine; NE = norepinephrine.

Regulation

Increased SNS nervous activity, as in congestive heart failure or chronic stress, stimulates the synthesis of tyrosine hydroxylase and dopamine- β -hydroxylase.^{4,36} Glucocorticoids from the adrenal cortex pass through the adrenal medulla and stimulate an increase in phenylethanolamine-*N*-methyltransferase that methylates NE to EPI.

The release of NE is dependent upon depolarization of the nerve and an increase in calcium ion permeability. Calcium may trigger exocytosis of NE granules.^{25,35,36} This release is inhibited by colchicine and prostaglandin E_2 , suggesting a contractile mechanism. Blockade of prostaglandin synthesis enhances NE release. NE inhibits its own release by stimulating presynaptic (prejunctional) α_2 receptors. Phenoxybenzamine and phentolamine, α -receptor antagonists, increase the release of NE by blocking inhibitory presynaptic α_2 receptors (Fig. 12-11). Other receptors may also be important in NE regulation and are discussed later (see [Other Receptors](#)).

Figure 12-11. This schematic demonstrates just a few of the presynaptic adrenergic receptors thought to exist. Agonist and antagonist drugs are clinically available for these receptors (see Table 12-5). The α_2 receptors serve as a negative feedback mechanism whereby NE stimulation inhibits its own release. Presynaptic β stimulation increases NE uptake, augmenting its availability. Presynaptic muscarinic (MUSC) receptors respond to ACh diffusing from nearby cholinergic terminals. They inhibit NE release and can be blocked by atropine.

Inactivation

The catecholamines are removed from the synaptic cleft by three mechanisms (see Fig. 12-10).⁴ These are reuptake into the presynaptic terminals, extraneuronal uptake, and diffusion. Termination of NE at the effector site is almost entirely by reuptake of NE into the terminals of the presynaptic neuron (uptake 1). Once NE is back in the nerve terminal, it is stored in the vesicles for reuse. A small amount is deaminated in the cytoplasm of the neuron by monoamine oxidase to form dihydroxymandelic acid, which diffuses out of the nerve terminal and into the interstitial fluid. Uptake 1 is an active, energy-requiring, temperature-dependent process that can be inhibited pharmacologically.

The reuptake of NE in the presynaptic terminals is also a stereospecific process. Structurally similar compounds (guanethidine, metaraminol) may enter the vesicles and displace the neurotransmitter. Tricyclic antidepressants and cocaine inhibit the reuptake of NE, resulting in high synaptic NE concentrations and accentuated receptor response. In addition, recent evidence suggests that NE reuptake is mediated by a presynaptic b-adrenergic mechanism because b-blockade causes marked elevations of EPI and NE³⁷ (see Fig. 12-10 and Fig. 12-11), whereas a blockade does not. The clinical significance of this presynaptic b-receptor is unknown at this time.

Extraneuronal uptake (uptake 2) is a minor pathway for inactivating NE. NE is taken up by effector cells and other extraneuronal tissues. The NE that is taken up by the extraneuronal tissue is metabolized by monoamine oxidase and by catechol-O-methyltransferase to form vanillylmandelic acid (Fig. 12-12).³⁸ The minute amount of catecholamine that escapes uptake 1 and uptake 2 diffuses into the circulation (uptake 3),^{*} where it is similarly metabolized in the liver and kidney. The importance of uptake 1 and uptake 2 is diminished when sympathomimetics are given exogenously. EPI is inactivated by the same enzymes. Whereas uptake 1 is the predominant pathway for inactivation of the endogenous catecholamines, uptake 3 is the predominant pathway for catecholamines given exogenously and is clinically important. This accounts for the longer duration of action by exogenous catecholamines than that noted at the local synapse. The former is slow (liver metabolism) and the latter is fast (uptake 1).

Figure 12-12. Morton's ether inhaler (1846)

The final metabolic product of the catecholamines is vanillylmandelic acid. Vanillylmandelic acid constitutes the major metabolite (80–90%) of NE found in the urine. Less than 5% of released NE appears unchanged in the urine. The metabolic products excreted in the urine provide a gross estimate of SNS activity and can facilitate the clinical diagnosis of pheochromocytoma.

RECEPTORS

An *agonist* is a substance that interacts with a receptor to evoke a biologic response. ACh, NE, EPI, and ATP are the agonists of the ANS. An *antagonist* is a substance that interferes with the evocation of a response at a receptor site by an agonist. Receptors are therefore regarded as target sites on a cell that will, when activated by an agonist, lead to a response by the effector cell. Receptors are protein macromolecules and are located in the plasma membrane. Several thousand receptors have been demonstrated in a single cell. The enormity of this network is realized when it is considered that ~25,000 single cells can be innervated by a single neuron.^{5,39}

Cholinergic Receptors

ACh is the neurotransmitter at three distinct classes of receptors. These receptors can be differentiated by their anatomic location and their affinity to bind various agonists and antagonists.²⁵ ACh mediates the “first messenger” function of transmitting impulses in the PNS, the ganglia of the SNS, and the neuroeffector junction of striated, voluntary muscle (see Fig. 12-3). The receptors are referred to as cholinergic or cholinergic receptors. The PNS is referred to as the cholinergic system.

Cholinergic receptors are further subdivided into muscarinic and nicotinic receptors because muscarine and nicotine stimulate them selectively.⁶ However, both muscarinic and nicotinic receptors respond to ACh (see [Cholinergic Drugs](#)). Muscarine activates cholinergic receptors at the postganglionic PNS junctions of cardiac and smooth muscle throughout the body. Muscarinic stimulation is characterized by bradycardia, decreased inotropism, bronchoconstriction, miosis, salivation, gastrointestinal hypermotility, and increased gastric acid secretion (see [Table 12-1](#)). Muscarinic receptors can be blocked by atropine without effect on nicotinic receptors (see [Cholinergic Drugs](#)).

Muscarinic receptors are known to exist in sites other than PNS postganglionic junctions. They are found on the presynaptic membrane of sympathetic nerve terminals in the myocardium, coronary vessels, and peripheral vasculature (Fig. 12-11). These are referred to as adrenergic muscarinic receptors because of their location; however, they are stimulated by ACh. Stimulation of these receptors inhibits release of NE in a manner similar to α_2 -receptor stimulation.^{12,40} Muscarinic blockade removes inhibition of NE release, augmenting SNS activity. Atropine, the prototypical muscarinic blocker, may produce sympathomimetic activity in this manner as well as vagal blockade. Neuromuscular blocking drugs that cause tachycardia are thought to have a similar mechanism of action.

ACh acting on presynaptic adrenergic muscarinic receptors is a potent inhibitor of NE release.³⁷ The prejunctional muscarinic receptor may play an important physiologic role because several autonomically innervated tissues (e.g., the heart) possess ANS plexuses in which the SNS and PNS nerve terminals are closely associated.⁶ In these plexuses, ACh, released from the nearby PNS nerve terminals (vagus nerve), can inhibit NE release by activation of presynaptic adrenergic muscarinic receptors (Fig. 12-11).

Nicotinic receptors are found at the synaptic junctions of both SNS and PNS ganglia. Because both junctions are cholinergic, ACh or ACh-like substances such as nicotine will excite postganglionic fibers of both systems (see Fig. 12-3). Low doses of nicotine produce stimulation of ANS ganglia, whereas high doses produce blockade. This dualism is referred to as the nicotinic effect (see [Ganglionic Drugs](#)). Nicotinic stimulation of the SNS ganglia produces hypertension and tachycardia by causing the release of EPI and NE from the adrenal medulla. Adrenal hormone release is mediated by ACh in the chromaffin cells, which are analogous to postganglionic neurons (see Fig. 12-3). A further increase in nicotine concentration produces hypotension and neuromuscular weakness as it becomes a ganglionic blocker. The cholinergic neuroeffector junction of skeletal muscle also contains nicotinic receptors, although they are not identical to the nicotinic receptors in ANS ganglia.

Adrenergic Receptors

Von Euler differentiated the physiologic effects of EPI and NE in 1946.^{31,41} The adrenergic receptors were termed adrenergic or noradrenergic, depending on their responsiveness to EPI or NE. The dissimilarities of these two drugs led Ahlquist in 1948 to propose two types of opposing adrenergic receptors, termed alpha (a) and beta (b). This postulation further implied that selective antagonism of these receptors was possible. The receptors can be classified according to the order of potency by which they are affected by SNS agonists and antagonists. Receptors that respond with an order of potency of NE ³ EPI > isoproterenol are called a receptors. Those responding with an order of potency of isoproterenol > EPI ³ NE are called b receptors ([Table 12-5](#)). The development of new agonists and antagonists with relatively selective activity allowed Lands to subdivide the b receptors into b₁ and b₂. a Receptors were subsequently divided into a₁ and a₂. The concept of relative selective activity arises from differential potencies among tissue groups to the same drug, such that two dose–response curves are obtained (Fig. 12-13). The sympathomimetic adrenergic drugs in current use differ from one another in their effects largely because of differences in substitution on the amine group, which influences the relative a or b effect (see Fig. 12-7).²⁹

| Receptor | Subtype | Location | Effect |
|----------------|-----------------|--|--|
| α ₁ | α _{1A} | Smooth muscle, endothelium, liver, prostate, skin, uterus, intestine, splanchnic vessels | Vasoconstriction, vasodilation, relaxation, contraction |
| | α _{1B} | Smooth muscle, endothelium, liver, prostate, skin, uterus, intestine, splanchnic vessels | Vasoconstriction, vasodilation, relaxation, contraction |
| α ₂ | α _{2A} | Presynaptic, postsynaptic, extrasynaptic | Inhibits NE release, vasoconstriction, vasodilation, relaxation, contraction |
| | α _{2B} | Presynaptic, postsynaptic, extrasynaptic | Inhibits NE release, vasoconstriction, vasodilation, relaxation, contraction |
| β | β ₁ | Heart, kidney, adrenal medulla | Increases heart rate, contractility, renin release |
| | β ₂ | Smooth muscle, endothelium, liver, prostate, skin, uterus, intestine, splanchnic vessels | Vasodilation, relaxation, contraction |

Table 12-5. ADRENERGIC RECEPTORS: ORDER OF POTENCY OF AGONISTS AND ANTAGONISTS

Another major peripheral adrenergic receptor specific for dopamine is termed the dopaminergic (DA) receptor. Further studies have revealed not only subsets of the a and b receptors but also the DA receptor.^{41,42} These DA receptors have been identified in the CNS and in renal, mesenteric, and coronary vessels. The physiologic importance of these receptors is a matter of controversy because there are no identifiable peripheral DA neurons. Dopamine measured in the circulation is assumed to result from spillover from the brain.

The function of dopamine in the CNS has long been known, but the peripheral dopaminergic receptor (DA) has been elucidated only within the past three decades. The presence of the peripheral DA receptor was obscured because dopamine does not affect the DA receptor exclusively. It also stimulates a and b receptors in a dose-related manner.⁴³ However, DA receptors function independently of a or b blockade and are modified by DA antagonists such as haloperidol, droperidol, and phenothiazines. Thus, there is a necessity for the addition of the DA receptor and its subsets (DA₁ and DA₂) to the Ahlquist classification.

The determination of the anatomic location and amino acid structure of receptor binding sites has been made possible through radioligand studies.⁴⁴ The distribution of adrenoceptors in organs and tissues is not uniform, and their function differs not only by their location but also in their numbers and/or distribution.⁴⁵ Adrenoceptors are found in two loci in the sympathetic neuroeffector junction. They are found in both the presynaptic (prejunctional) and postsynaptic (postjunctional) sites as well as extrasynaptic sites (Fig. 12-14). Table 12-6 is a review of the function and synaptic location of some of the clinically important receptors that have only recently been defined.

Figure 12-14. Loci of several known adrenergic receptors. The presynaptic a₂ and DA receptors serve as a negative feedback mechanism, whereby stimulation of NE inhibits its own release. Presynaptic b₂ stimulation increases NE uptake, augmenting its availability. Postsynaptic a₂ and b₂ receptors are extrasynaptic and are considered noninnervated hormonal receptors.

| Receptor | Subtype | Location | Effect |
|----------------|-----------------|--|--|
| α ₁ | α _{1A} | Smooth muscle, endothelium, liver, prostate, skin, uterus, intestine, splanchnic vessels | Vasoconstriction, vasodilation, relaxation, contraction |
| | α _{1B} | Smooth muscle, endothelium, liver, prostate, skin, uterus, intestine, splanchnic vessels | Vasoconstriction, vasodilation, relaxation, contraction |
| α ₂ | α _{2A} | Presynaptic, postsynaptic, extrasynaptic | Inhibits NE release, vasoconstriction, vasodilation, relaxation, contraction |
| | α _{2B} | Presynaptic, postsynaptic, extrasynaptic | Inhibits NE release, vasoconstriction, vasodilation, relaxation, contraction |
| β | β ₁ | Heart, kidney, adrenal medulla | Increases heart rate, contractility, renin release |
| | β ₂ | Smooth muscle, endothelium, liver, prostate, skin, uterus, intestine, splanchnic vessels | Vasodilation, relaxation, contraction |

Table 12-6. ADRENERGIC RECEPTORS

Prejunctional receptors are considered innervated in that they are in the immediate vicinity of the neurotransmitter released by a sympathetic action potential. Postjunctional receptors are considered to be innervated or noninnervated depending upon their proximity to the synaptic cleft.⁴⁶ Receptors located directly on postjunctional membranes are considered to be innervated. However, most postsynaptic a₂ and b₂ receptors are extrasynaptic and considered noninnervated even though they are located in the vicinity of the postsynaptic membrane. These receptors are influenced more by hormonal catecholamines (EPI) than by neurotransmitter (NE). Extrasynaptic receptors also seem to be less influenced by factors causing the up- or downregulation of receptor numbers and sensitivity. This may explain the clinical observation of why EPI may work where other agonists, which work on synaptic receptors, may be ineffective. The agonist–receptor interaction of noninnervated receptors is of slower onset and longer duration as well.

a-Adrenergic Receptors

Two classes of a receptors have been demonstrated: a₁ and a₂. This classification is based on their response to the a-antagonists yohimbine and prazosin. Prazosin is a more potent antagonist of a₁ receptors, whereas a₂ receptors are more sensitive to yohimbine. The a₁-adrenergic receptors are also found in the smooth muscle cells of the peripheral vasculature of the coronary arteries, skin, uterus, intestinal mucosa, and splanchnic beds (see Table 12-5). The a₁ receptors serve as postsynaptic activators of vascular and intestinal smooth muscle as well as of endocrine glands. Their activation results in either decreased or increased tone, depending upon the effector organ. The response in resistance and capacitance vessels is constriction, whereas in the intestinal tract it is relaxation. There is now a large body of evidence documenting the presence of postjunctional a₁-adrenoceptors in the mammalian heart. a₁-Adrenoceptors have been shown to have a positive inotropic effect on cardiac tissues from most mammals studied, including humans.^{33,47} Experimental work strongly supports the concept that enhanced myocardial a₁ responsiveness plays a primary role in the genesis of malignant arrhythmias induced by catecholamines during myocardial ischemia and reperfusion. Drugs possessing potent a₁-antagonist activity, such as prazosin and phentolamine, provide significant antiarrhythmic activity. Neither the clinical mechanism nor the significance of these findings is yet clear.^{48,49} However, there is no doubt that a₁-adrenergic antagonists prevent catecholamine-induced ventricular arrhythmias.⁵⁰ In contrast, studies of the effects of b antagonists in experimental and clinical myocardial infarction have provided conflicting results.

The discovery of presynaptic a-adrenoceptors and their role in the modulation of NE transmission provided the stimulus for the subclassification of receptors into a₁ and a₂ subtypes.^{51,52} The successful cloning of genes for a₁ and a₂ receptors has provided unequivocal evidence for their separate identities and structures.

Presynaptic α_1 receptors have not been identified and appear confined to the postsynaptic membrane. α_2 Receptors are found on both presynaptic and postsynaptic membranes of the adrenergic neuroeffector junction. [Table 12-6](#) reviews these sites. Postsynaptic membranes contain a nearly equal mix of α_1 and α_2 receptors.⁵³

The α_2 -adrenoreceptors may be subdivided even further into as many as four possible subtypes. Many actions have been attributed to the postsynaptic α_2 receptor, including arterial and venous vasoconstriction, platelet aggregation, inhibition of insulin release, inhibition of bowel motility, stimulation of growth hormone release, and inhibition of antidiuretic hormone release.

α_2 Receptors can be found in cholinergic pathways as well as in adrenergic pathways. They can significantly modulate parasympathetic activity as well. Current research implies that α_2 stimulation in parasympathetic pathways plays a role in the modulation of the baroreceptor reflex (increased sensitivity), vagal mediation of heart rate (bradycardia), bronchoconstriction, and salivation (dry mouth). However, cholinergic receptors can also be found in adrenergic pathways; thus, muscarinic and nicotinic receptors have been found in presynaptic and postsynaptic locations, where they in turn modulate sympathetic activity (see [Fig. 12-11](#)). Maze speculates that although the functional role of the postsynaptic α_2 receptor in the CNS has not been well characterized, it is probable that the features that are so desirable to the anesthesiologist, such as sedation, anxiolysis, analgesia, and hypnosis, are mediated through this site.

Stimulation of presynaptic α_2 receptors mediates inhibition of NE release into the synaptic cleft, serving as a negative feedback mechanism.⁵⁴ The central effects are primarily related to a reduction in sympathetic outflow with a concomitantly enhanced parasympathetic outflow (e.g., enhanced baroreceptor activity). This results in a decreased systemic vascular resistance, decreased cardiac output (CO), decreased inotropic state in the myocardium, and decreased HR. The peripheral presynaptic α_2 effects are similar, and NE release is inhibited in postganglionic neurons. However, stimulation of postsynaptic α_2 receptors, like the α_1 postsynaptic receptor, affects vasoconstriction.

NE acts on both α_1 and α_2 receptors. Thus, NE not only activates smooth muscle vasoconstriction (postsynaptic α_1 and α_2 receptors) but also stimulates presynaptic α_2 receptors and inhibits its own release.⁵⁵ Selective stimulation of the presynaptic α_2 receptor could produce a beneficial reduction of peripheral vascular resistance. Unfortunately, most known presynaptic α_2 agonists also stimulate the postsynaptic α_2 receptors, causing vasoconstriction. Blockade of α_2 presynaptic receptors, however, ablates normal inhibition of NE, causing vasoconstriction. Vasodilation occurs with the blockade of postsynaptic α_1 and α_2 receptors.

α Receptors in the Cardiovascular System

There is a large body of evidence documenting the presence of postsynaptic α_1 and α_2 receptors in the mammalian myocardium and coronary arteries, as well as the peripheral vasculature.^{48,55}

Coronary Arteries. The presence of postsynaptic α_1 and α_2 receptors in human coronary arteries has not been established with certainty, but other mammalian models have demonstrated their presence. There is a growing consensus that sympathetic nerves cause coronary vasoconstriction, which is mediated more by postsynaptic α_2 than α_1 receptors. The larger epicardial arteries possess mainly α_1 receptors, whereas α_2 receptors and some α_1 receptors are present in the small coronary artery resistance vessels.⁵⁶ Epicardial vessels contribute only 5% to the total resistance of the coronary circulation; therefore, α_1 agonists such as phenylephrine have little influence on coronary resistance.⁵⁷

Myocardial ischemia has been shown to increase α_2 -receptor density in the coronary arteries. Ischemia has also been shown to cause a reflex increase in sympathetic activity mediated by a mechanisms. This cascade may further increase coronary constriction. Postsynaptic α_1 receptors do not rely upon extracellular Ca^{2+} to constrict the vessel, whereas the α_2 -constrictor response is highly dependent upon extracellular influx and exquisitely sensitive to calcium channel inhibitors.⁵⁸

Myocardium. The role of b receptors in mediating catecholamine-induced inotropism and arrhythmogenesis has been known for many years. Recent studies have shown the presence of postsynaptic myocardial α_1 receptors, which also exert a major, facilitatory, positive inotropic effect on the myocardium of several species of mammals including humans. Their contribution to malignant reperfusion arrhythmogenesis has also been recognized.

Phenylephrine, an α_1 agonist, can increase myocardial contractility 2–3-fold compared with a 6–7-fold increase produced by isoproterenol, a pure b agonist.⁵⁹ Myocardial postsynaptic α_1 receptors mediate perhaps as much as 30–50% of the basal inotropic tone of the normal heart.⁶⁰ This contribution is reduced to about 20–30% of total inotropism when both α_1 and b_1 activation increases, as in exercise or stress. The inotropic response of the normal myocardium is more sensitive to b agonists.

Postsynaptic myocardial α_1 receptors play a more prominent inotropic role in the failing heart by serving as reserve to the normally predominant b_1 receptors. Although the response to both α_1 and b_1 agonists is reduced in the failing myocardium, the interaction between the two receptors is more apparent. Chronic heart failure is known to produce a reduced density (downregulation) of myocardial b_1 receptors as a result of high levels of circulating catecholamines. However, there is no evidence of downregulation of either α_1 or b_2 receptors with failure.⁶¹

The increase in density of myocardial α_1 -adrenoreceptors shows a relative increase with failure and myocardial ischemia.^{59,61} Thus, enhanced myocardial α_1 -receptor numbers, and sensitivity, may contribute to the positive inotropism seen during ischemia as well as to the malignant arrhythmias that occur with reperfusion. Intracellular mobilization of cytosolic Ca^{2+} by the activated α_1 -myocardial receptors during ischemia appears to contribute to these arrhythmias.⁶¹ The α_1 receptor also increases the sensitivity of the contractile elements to Ca^{2+} . Drugs possessing potent α_1 antagonism such as prazosin and phentolamine have been shown to possess significant antiarrhythmic activity, although of limited usefulness because of hypotension.⁶² Enhanced α_1 activity with myocardial ischemia may explain why the antiarrhythmic benefits of b antagonists in patients with acute myocardial infarction are far from certain. The contribution of b receptors to positive inotropism and arrhythmogenesis during ischemia and reperfusion may be overshadowed by the α receptors during acute failure and ischemia.

Peripheral Vessels. Activation of the presynaptic α_2 -vascular receptors produces vasodilation, whereas the postsynaptic α_1 - and α_2 -vascular receptors subserve vasoconstriction. Presynaptic vascular α_2 receptors inhibit NE release. This represents a negative feedback mechanism by which NE inhibits its own release via the prejunctional receptor. Presynaptic α_2 agonists, such as clonidine, inhibit NE release at the neurosympathetic junction, producing vasodilatation. The effects of selective presynaptic α_2 -receptor agonists to ameliorate coronary vasoconstriction in humans is unclear. Excitation of the inhibitory presynaptic α_2 receptors by endogenous or synthetic catecholamines also inhibits NE release. However, most sympathomimetics are nonselective α agonists that will excite equally presynaptic α_2 vasodilators and vasoconstrictive postsynaptic α_1 and α_2 receptors.

Postsynaptic α_1 and α_2 receptors coexist in both the arterial and venous sides of the circulation, with the relative distribution of α_2 receptors being greater on the venous side.^{63,64} This may explain why pure α agonists, such as methoxamine, produce little venoconstriction, whereas many nonselective agonists produce significant venoconstriction. NE is the most potent venoconstrictor of all the catecholamines. Clinically, venoconstriction would have the effect of preloading by shifting venous capacitance centrally, whereas stimulation of arterial postsynaptic α_1 and α_2 receptors would effect afterloading by increasing arterial resistance.

α Receptors in the Central Nervous System

All subtypes of the α , b, and DA receptors have been found in various regions of the brain and spinal cord. The functional role of the cerebral α and b receptors remains under investigation, but research suggests a close association with blood pressure and HR control. Cerebral and spinal cord presynaptic α_2 receptors are also involved in inhibition of presynaptic NE release. Although the brain contains adrenergic and dopaminergic receptors, circulating catecholamines do not cross the blood–brain barrier. The catecholamines presenting in the brain are synthesized there. Many actions have been attributed to the cerebral postsynaptic α_2 receptor, including inhibition of insulin release, inhibition of bowel motility, stimulation of growth hormone release, and inhibition of antidiuretic hormone release. Postsynaptic receptors are found in specific nuclei and tracts throughout the brain and spinal cord. Central neuraxis injection of α_2 agonists, such as clonidine, act at these sites to produce analgesia, sedation, and cardiovascular depression. One might speculate that increased duration of epidural or intrathecal anesthesia by the addition of nonselective α agonists to the local anesthetic may also be producing additional analgesia through this mechanism.

a Receptors in the Kidney

The kidney has an extensive and exclusive adrenergic innervation of the afferent and efferent glomerular arterioles, proximal and distal renal tubules, ascending loop of Henle, and juxtaglomerular apparatus.⁶⁵ The greatest density of innervation is in the thick ascending loop of Henle, followed by the distal convoluted tubules and proximal tube. Both α_1 and α_2 subtypes are found in the kidney, the α_2 receptor dominating. The α_1 receptor is predominant in the renal vasculature and elicits vasoconstriction, which modulates renal blood flow. Tubular α_1 receptors enhance sodium and water reabsorption, leading to antinatriuresis, whereas tubular α_2 receptors promote sodium and water excretion.

b-Adrenergic Receptors

The b-adrenergic receptors, like the α receptor, have been divided into subtypes. They are designated as the b_1 and b_2 subtypes. The b_1 receptors predominate in the myocardium, the sinoatrial node, and the ventricular conduction system. The b_1 receptors also mediate the effects of the catecholamines on the myocardium. These receptors are equally sensitive to EPI and NE, which distinguishes them from the b_2 receptors. Effects of b_1 stimulation are outlined in [Table 12-5](#). [Table 12-6](#) outlines their effects specifically on the cardiovascular system.

The b_2 receptors are located in the smooth muscles of the blood vessels in the skin, muscle, mesentery, and in bronchial smooth muscle. Stimulation produces vasodilation and bronchial relaxation. The b_2 receptors are more sensitive to EPI than to NE. The b_1 receptors are suggested to be innervated receptors responding to neuronally released NE, whereas b_2 receptors are “normal” receptors responding primarily to circulating EPI.^{66,67}

b Receptors are found in both presynaptic and postsynaptic membranes of the adrenergic neuroeffector junction ([Table 12-6](#)). b_1 Receptors are distributed to postsynaptic sites and have not been identified on the presynaptic membrane. Presynaptic b receptors are mostly of the b_2 subtype. The effects of activation of the presynaptic b_2 receptor are diametrically opposed to those of the presynaptic α_2 receptor. The presynaptic b_2 receptor accelerates endogenous NE release, whereas blockade of this receptor will inhibit NE release. Antagonism of the presynaptic b_2 receptors produces a physiologic result similar to activation of the presynaptic α_2 receptor.

The postsynaptic b_1 receptors are located on the synaptic membrane and are innervated receptors responding primarily to neuronal NE. The postsynaptic b_2 receptors, like the postsynaptic α_2 receptor, are considered noninnervated, extrasynaptic, normal receptors responding primarily to circulating EPI.

b Receptors in the Cardiovascular System

Myocardium. Myocardial b receptors were originally classified as b_1 receptors. Those in the vascular and bronchial smooth muscle were called the b_2 subtype. However, radioligand studies have confirmed the coexistence of b_1 and b_2 receptors in the myocardium.⁶⁷ Both b_1 and b_2 receptors are functionally coupled to adenylate cyclase, suggesting a similar involvement in the regulation of inotropism and chronotropism. Postsynaptic b_1 receptors are distributed predominantly to the myocardium, the sinoatrial node, and the ventricular conduction system. The b_2 receptors have the same distribution but are presynaptic. Activation of the presynaptic b_2 receptor accelerates the release of NE into the synaptic cleft. The b_2 receptor constitutes 20–30% of the b receptors in the ventricular myocardium and up to 40% of the b receptors in the atrium.

The increased catecholamine levels associated with heart failure lead to a proportionally greater downregulation of the b_1 -receptor density with a relative sparing of the b_2 subtype and an increase in the α_1 subtype. The b_2 receptors increasingly mediate the inotropic response to catecholamines during heart failure and are facilitated by the α_1 receptor.

The effect of NE on inotropism in the normal heart is mediated entirely through the postsynaptic b_1 receptor, whereas the inotropic effects of EPI are mediated through both the b_1 - and b_2 -myocardial receptors. The b_2 receptors may also mediate the chronotropic responses to EPI because selective b_1 antagonists are less effective in suppressing induced tachycardia than the nonselective b_1 antagonist propranolol.

Peripheral Vessels. The postsynaptic vascular b receptors are virtually all of the b_2 subtype. The b_2 receptors are located in the smooth muscle of the blood vessels of the skin, muscle, mesentery, and bronchi. Stimulation of the postsynaptic b_2 receptor produces vasodilation and bronchial relaxation. Modest vasoconstriction occurs when subjected to blockade because the actions of the vascular postsynaptic b_2 receptors no longer oppose the actions of the α_1 and α_2 postsynaptic receptors.

b Receptor in the Kidney

The kidney contains both b_1 and b_2 receptors, the b_1 being predominant. Renin release from the juxtaglomerular apparatus is enhanced by b stimulation. b Blockers inhibit this response. The b subtype regulating renin release is highly species-dependent. The b_1 receptor evokes renin release in humans.⁶⁸ Renal b_2 receptors also appear to regulate renal blood flow at the vascular level. They have been identified pharmacologically and mediate an expected vasodilatory response.

Dopaminergic Receptors

Dopamine, synthesized in 1910, was recognized in 1959 not only as a vasopressor and the precursor of NE and EPI, but also as an important central and peripheral neurotransmitter. Dopamine receptors (DA) have been localized in the CNS, on blood vessels and postganglionic sympathetic nerves ([Table 12-6](#)). Two major types of DA receptors have been recognized. These are the DA_1 and DA_2 receptors. The DA_1 receptors are postsynaptic, whereas the DA_2 receptors are both presynaptic and postsynaptic. The presynaptic DA_2 receptors, like the presynaptic α_2 receptor, inhibit NE release and can produce vasodilation.^{37,54,69} There is evidence that the postsynaptic DA_2 receptor may subserve vasoconstriction similar to that of the postsynaptic α_2 receptor.⁷⁰ However, postsynaptic DA_2 receptors have not been positively identified.⁷¹ This effect is opposite to that of the postsynaptic DA_1 renal vascular receptor. Unpublished data suggest that dopamine may be the intrinsic regulator of renal function.⁷² The zona glomerulosa of the adrenal cortex also contains DA_2 receptors, which inhibit release of aldosterone.

Myocardium. Defining specific dopaminergic receptors has been difficult because dopamine also exerts effects on the α and b receptors.^{73,74} DA receptors have not been described in the myocardium. Effects of dopamine are those related to activation of b_1 receptors, which promote positive inotropism and chronotropism. b_2 Activation would produce some systemic vasodilation.

Peripheral Vessels. The greatest numbers of DA_1 -postsynaptic receptors are found on vascular smooth muscle cells of the kidney and mesentery, but are also found in the other systemic arteries including coronary, cerebral, and cutaneous arteries. The vascular receptors are, like the b_2 receptors, linked to adenylate cyclase and mediate smooth muscle relaxation. Activation of these receptors produces vasodilation, increasing blood flow to these organs. Concurrent activation of vascular presynaptic DA_2 receptors also inhibits NE release at presynaptic α_2 receptors, which may also contribute to peripheral vasodilation. Higher doses of dopamine can mediate vasoconstriction via the postsynaptic α_1 and α_2 receptors. The constrictive effect is relatively weak in the cardiovascular system where the action of dopamine on adrenergic receptors is 1/35 and 1/50 as potent as that of EPI and NE, respectively.⁷⁵

Central Nervous System. DA receptors have been identified in the hypothalamus where they are involved in prolactin release. They are also found in the basal ganglia where they coordinate motor function.^{74,73} Degeneration of dopaminergic neurons of the substantia nigra is the source of Parkinson's disease. Another central action of dopamine is to stimulate the chemoreceptor trigger zone of the medulla, producing nausea and vomiting. Dopamine antagonists such as haloperidol and droperidol are clinically effective in countering this action.

Kidney and Mesentery. Apart from their effect on the vessels of the kidney and mesentery, DA receptors on the smooth muscle of the esophagus, stomach, and small intestine enhance secretion and reduce intestinal motility.⁷⁵ Metoclopramide, a dopamine antagonist, is useful for aspiration prophylaxis by promoting gastric

emptying.

The distribution of DA receptors in the renal vasculature is well known, but DA receptors have other functions within the kidney. DA₁ receptors are located on renal tubules, which inhibit sodium reabsorption with subsequent natriuresis and diuresis. The natriuresis may be the result of a combined renal vasodilatation, improved CO, and tubular action of the DA₁ receptors. Juxtaglomerular cells also contain DA₁ receptors, which increase renin release when activated. This action modulates the diuresis produced by DA₁ activation of the tubules.

Dopamine has unique autonomic effects by activating specific peripheral dopaminergic receptors, which promote natriuresis and reduce afterload via dilatation of the renal and mesenteric arterial beds. Peripheral dopaminergic activity serves as a natural antihypertensive mechanism.⁶⁸ Its actions are overshadowed by the opposite effect of its main biologic partner, NE.⁷⁶ Plasma NE levels are known to increase with aging, likely the result of reduced clearance. Peripheral dopaminergic activity is known to diminish. Subtle changes in the DA–NE balance with aging may account for the diminished ability of the aged kidney to excrete a salt load. This may also contribute to the uniform finding of increasing systolic blood pressure in societies with high salt consumption.

Other Receptors Adenosine Receptors.

Adenosine produces inhibition of NE release.^{37,54} The effect of adenosine is blocked by caffeine and other methylxanthines. The physiologic and pharmacologic roles of adenosine-mediated inhibition of NE release are not clearly defined. The physiologic function of these receptors may be the reduction of sympathetic tone under hypoxic conditions when adenosine production is enhanced. As a consequence of reduced NE release, cardiac work would be decreased and oxygen demand reduced. Recently, adenosine has been effectively used to produce controlled hypotension.^{37,76}

Serotonin. Serotonin (5-hydroxytryptamine) depresses the response of isolated blood vessels to sympathetic nervous system (SNS) stimulation and decreases release of labeled NE in these preparations. This inhibitory action of serotonin is antagonized by raising the external calcium ion concentration. Thus, serotonin may inhibit neuronal NE release by a mechanism that limits the availability of calcium ions at the nerve terminal.

Prostaglandin E₂, Histamine, and Several Opioids. Prostaglandin E₂, histamine, and several opioids have been reported to act on prejunctional receptor sites to inhibit NE release in certain sympathetically innervated tissue. However, these inhibitory receptors are unlikely to play a physiologic role in limiting NE release because inhibitors of cyclo-oxygenase, histamine antagonists, and naloxone produce no increase in NE release.

Histamine acts in a manner similar to the neurotransmitters of the SNS.⁷⁷ It has membrane receptors specific for histamine, with the individual response being determined by the type of cell being stimulated. Two receptors for histamine have been determined. These have been designated H₁ and H₂, for which it has been possible to develop specific agonists and antagonists. Stimulation of the H₁ receptors produces bronchoconstriction and intestinal contraction. The major role of the H₂ receptors is related to acid production by the parietal cells of the stomach; however, histamine is present in relatively high concentrations in the myocardium and cardiac conducting tissue, where it exerts positive inotropic and chronotropic effects while depressing dromotropism. The positive inotropic and chronotropic effects of histamine are H₂-receptor effects that are not blocked by b antagonism. These effects are blocked by H₂ antagonists, such as cimetidine, which accounts for the occasional report of cardiovascular collapse following the use of cimetidine.⁷⁸ The negative dromotropic effect and that of coronary spasm caused by histamine are H₁ receptor effects.

Adrenergic Receptor Numbers or Sensitivity

Receptors, once thought to be static entities, are now thought to be dynamically regulated by a variety of conditions and in a constant state of flux. Receptors are synthesized in the sarcoplasmic reticulum (SR) of the parent cell, where they may remain extrasynaptic or externalize to the synaptic membranes, where they may cluster. Membrane receptors may be removed or internalized to intracellular sites for either dehydration or recycling.⁷⁹ The numbers and sensitivity of adrenergic receptors can be influenced by normal, genetic, and developmental factors.⁸⁰ Changes in the number of receptors alter the response to catecholamines. Alteration in the number, or density, of receptors is referred to as either upregulation or downregulation.⁸¹ As a rule, the number of receptors is inversely proportional to the ambient concentration of the catecholamines.⁸² Extended exposure of receptors to their agonists markedly reduces, but does not ablate, the biologic response to catecholamines.⁸³ For example, increased adrenergic activity occurs in response to reduced perfusion as a result of acute or chronic myocardial dysfunction. Plasma catecholamines are increased. As a result, myocardial postsynaptic b₁ receptors “downregulate.” This is thought to explain the diminished inotropic and chronotropic response to b₁ agonists and exercise in patients with chronic heart failure. However, calcium-induced inotropism is not impaired because b₂-receptor (extrasynaptic) numbers remain relatively intact.⁸⁴ The b₂ receptors may account for up to 40% of the inotropism of the failing heart compared with 20% in the normal heart.⁸⁵ Tachyphylaxis to infused catecholamines is also thought to be the result of acute downregulation of receptor numbers. There appears to be a reduction in numbers or sensitivity of b receptors in hypertensive patients who also have elevated plasma catecholamines. Downregulation is the presumptive explanation for the lack of correlation between plasma catecholamine levels and the blood pressure elevation in patients with pheochromocytoma. Chronic use of b agonists such as terbutaline, isoproterenol, or EPI for the treatment of asthma can result in tachyphylaxis because of downregulation. Even short-term use (1–6 hours) of b agonists may cause downregulation of receptor numbers.

Downregulation is reversible on termination of the agonist. Chronic treatment of animals with nonselective b blockade causes a 100% increase in the number of b receptors.^{80,86} This accounts for the propranolol withdrawal syndrome in which the acute discontinuation of the b antagonist leaves the a receptors unopposed plus an increased number of b receptors. Clonidine withdrawal can be explained by the same mechanism.⁸⁷ Acute discontinuation of the a₂-inhibitory agonist would permit a resumption of stimulation of adrenoreceptors that upregulated during the time NE release was inhibited.

Up- or downregulation of receptor numbers may not alter sensitivity of the receptor. Likewise, sensitivity may be increased or decreased in the presence of normal numbers of receptors. The pharmacologic factors affecting up- or downregulation of the a and b receptors are similar.

MOLECULAR PHARMACOLOGY AND EFFECTOR RESPONSE

Autonomic agonists trigger a cascade of intracellular chemical reactions culminating in the cell's biologic response. The receptor is only the first link in a communication series. Understanding such ligand-triggered signaling cascades promises to be of vital importance to the anesthesiologist in management of autonomic responses to surgery and anesthesia.

A remarkable homology exists in the molecular composition of receptors and intracellular signaling cascades of the ANS. A superfamily of integral membrane proteins has been identified, which includes the adrenergic and cholinergic receptors, as well as receptors to dopamine, purines (such as adenosine and ATP), serotonin, angiotensin, vasopressin, vasoactive intestinal peptide, glucagon, histamine, leukotrienes, thrombin, g-aminobutyric acid (GABA), opioids, and a host of others.^{88,89} and ⁹⁰ These receptors have two important characteristics in common: (1) each has seven hydrophobic amino acid domains, which are believed to constitute transmembrane spanning regions critical in defining ligand specificity; (2) agonist binding to the receptor is linked to the activation of one or more distinct guanine nucleotide-binding regulatory proteins (G proteins). These G proteins are a family of cytoplasmic membrane-associated proteins that act as intermediaries between the diverse array of membrane receptors and activation of a relatively smaller group of cellular effector mechanisms.^{88,89,90} and ⁹¹ G proteins are linked to receptor binding in cells of nearly every organ system of the body.

With respect to autonomic agonists, G protein-activated mechanisms may be grouped into five principal categories: (1) activation of adenylate cyclase (AC), (2) inhibition of AC, (3) direct potassium channel activation, (4) direct calcium channel inhibition, and (5) activation of phospholipase C.

For years, the b-adrenergic receptor was considered the prototypical adrenergic receptor. This largely reflected the pioneering work of Sutherland, who revealed that the biologic activity of the b receptor is dependent upon intracellular production of cyclic adenosine monophosphate (cAMP).⁹² The current understanding is that ligand binding to b₁ and b₂ receptors, as well as dopaminergic types D₁ and D₅, activates s-type (stimulatory) G protein (Gs) (Fig. 12-15). Gs, in turn, stimulates AC (also membrane-bound) to produce cAMP. cAMP acts as the cytoplasmic mediator, or second messenger, of the catecholamine-triggered cellular response. The biologic activity of cAMP is effected largely through cAMP-dependent protein kinase A (PKA). Proteins phosphorylated by PKA include ion flux channels, such as Ca²⁺, K⁺, and Cl⁻ channels, as well as myosin light chain kinase, troponin, and other kinases and synthases linked to cellular contraction and stimulus-secretion coupling.^{88,89} and ^{90,93}

Figure 12-15. Cellular effector mechanisms of adrenergic receptors. Receptor (R) binding of the extracellular agonist activates one of five principal G protein-triggered mechanisms: (1) Activated Gs stimulates adenylate cyclase (AC) to produce free cytoplasmic cyclic AMP (cAMP), which, in turn, activates protein kinase A (PKA). PKA has a number of cellular activities including increasing K⁺ and Ca²⁺ channel conductances, increasing Ca²⁺ ATPase activity, and phosphorylation of cytoplasmic proteins such as troponin and myosin light chain kinase (MLCK), which mediate cellular contractile activity. (2) Activated Gi inhibits AC. (3) Activated Gi or Go directly increases K⁺ channel conductance. (4) Activated Gi or Go directly inhibits cell membrane Ca²⁺ channel conductance. (5) Activated Gq stimulates phospholipase C (PLC), which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂) to yield membrane-bound 1,2-diacylglycerol (DAG) and cytoplasmic inositol 1,4,5-trisphosphate (IP₃). IP₃ interacts with its receptor on the membranes of internal Ca²⁺ stores. The IP₃ receptor is itself a Ca²⁺ channel, which, when bound to IP₃, increases its conductance, releasing Ca²⁺ into the cytoplasm. DAG increases cytoplasmic membrane Ca²⁺ conductance and activates protein kinase C (PKC).

In the myocardium, PKA-induced protein phosphorylation results in an increase in chronotropy, inotropy, lusitropy (rate of relaxation), and dromotropy.^{89,93} Phosphorylation increases depolarization-triggered Ca²⁺ influx across L-type (voltage-sensitive) channels, thereby increasing intracellular Ca²⁺ and, hence, inotropy. Ca²⁺ affinity of troponin I is decreased by PKA, and phospholamban phosphorylation by PKA increases SR Ca²⁺-ATPase activity, allowing the more rapid Ca²⁺ cycling necessary to increase lusitropy and sustain the increase in chronotropy. Further, PKA increases sarcolemmal Cl⁻ and K⁺ channel currents, counteracting the tendency of the increased Ca²⁺ influx to prolong depolarization. Increased pacemaker currents are also cAMP-dependent, although the precise mechanism is unclear.

In contrast to cardiac muscle, cAMP and PKA mediate relaxation of smooth muscle. The mechanism for this may involve one or more of the following: (1) decreased cytoplasmic Ca²⁺ secondary to enhanced uptake by SR Ca²⁺-ATPase, (2) hyperpolarization due to increased sarcolemmal K⁺ conductance, and (3) phosphorylation of myosin light chain kinase, reducing its affinity for myosin light chain.^{89,94,95}

In addition to b-adrenergic and D₁ and D₅ receptor systems, receptor subtypes for adenosine, serotonin, vasopressin, histamine (H₂ receptors), and glucagon, to name a few, have been identified as Gs-linked activators of AC (Table 12-7).

| Receptor | Principal Effector Mechanisms | | | | |
|--------------------------------|-------------------------------|-------------|------------------------------|--|------------------------------------|
| | Gs ↑cAMP | Gi ↓cAMP | Gq ↑IP ₃ , DAG | Ca ²⁺ ↑Ca ²⁺ influx | Other ↑Ca ²⁺ release |
| Adrenergic (α ₁) | + | - | + | + | - |
| Adrenergic (α ₂) | - | + | - | - | + |
| Dopaminergic (D ₁) | + | - | - | + | - |
| Dopaminergic (D ₂) | - | + | - | - | + |
| Adenosine (A ₁) | - | + | - | - | + |
| Adenosine (A _{2A}) | + | - | - | + | - |
| Adenosine (A _{2B}) | + | - | - | + | - |
| Glucagon | + | - | - | + | - |
| Histamine (H ₂) | + | - | - | + | - |
| Serotonin (5-HT ₂) | + | - | - | + | - |
| Vasopressin (V ₁) | + | - | - | + | - |

Table 12-7. RECEPTOR-MEDIATED EFFECTOR MECHANISMS

In contrast to Gs, i-type (inhibitory) G protein (Gi) inhibits AC, thereby reducing cytoplasmic cAMP and its subsequent effects (Fig. 12-15). Gi is linked to numerous receptor types including α₂-adrenergic, dopaminergic types D₂-D₄, and muscarinic and serotonergic subtypes (Table 12-7). Thus, opposing cellular responses to different agonists may reflect opposing activities on AC-dependent effector mechanisms.

In the case of the α₂ receptor, inhibition of AC is responsible for many but not all of its biologic effects. Coupling of the α₂ adrenoceptor with Gi or Go (other type G protein) is directly linked to membrane Ca²⁺ channel inhibition and K⁺ channel activation. The subsequent hyperpolarization and decreased intracellular Ca²⁺ are believed to be responsible for α₂-mediated suppression of CNS function as well as presynaptic inhibition of NE release at sympathetic nerve terminals.^{90,94} Ca²⁺ and K⁺ channel conductances are similarly affected by other Gi-linked receptors. Unlike Gi, Go does not alter AC activity.

A fourth G protein, Gq, is responsible for mediating the activity of a host of other receptors including α₁-adrenoceptors, and certain muscarinic and serotonergic receptor subtypes (Table 12-7). Gq activates phospholipase C (PLC), a protein that hydrolyzes the constituent membrane phospholipid phosphatidylinositol 4,5-bisphosphate (PIP₂) to yield membrane-bound 1,2-diacylglycerol (DAG) and cytoplasmic inositol 1,4,5-trisphosphate (IP₃) (Fig. 12-15). IP₃ triggers a surge in cytoplasmic free Ca²⁺ by binding to its receptor on the membranes of internal calcium stores such as the SR and the endoplasmic reticulum. The IP₃ receptor is itself an ion channel which, when bound to IP₃, increases its conductance to Ca²⁺. This receptor therefore acts as a gate for triggered release of Ca²⁺ into the cytoplasm of vascular smooth muscle cells, endothelial cells, and neurologic, immunologic, and endocrine tissues. The rapid rise of cytoplasmic Ca²⁺ is ultimately responsible for many of the Gq-triggered biologic responses, including cellular contraction, secretion, increased metabolism, and proliferation. Of note, the IP₃ receptor channel is not found in myocardium or skeletal muscle. Instead, a closely related receptor is found: the ryanodine-sensitive calcium channel, which is believed to play a principal role in the pathophysiology of malignant hyperthermia.⁹⁶

The remainder of the effects of the Gq-PLC pathway are mediated by DAG-induced activation of protein kinase C (PKC). Activated PKC affects cellular activity by phosphorylating serine and threonine residues on numerous intracellular proteins. In vascular smooth muscle, activated PKC plays a potentiating role in agonist-induced contraction, increasing Ca²⁺ influx and sensitivity of the contractile process to Ca²⁺.^{89,90,93,95}

Gq activation has been shown to activate phospholipase A₂ (PLA₂) in addition to PKC. The physiologic role of this activation, though, remains to be determined. Hydrolysis of membrane phospholipids by PLA₂ produces arachidonic acid (AA). AA, in turn, inhibits myosin light chain phosphorylase. The subsequent elevation in phosphorylated (activated) myosin may increase the contractile activity of the cell.⁹⁴ On the other hand, AA is also metabolized by endothelial cells to produce prostacyclin (PGI₂), which is a potent vasodilator.

A new concept of endothelial control of vascular smooth muscle function has gained recognition over the past decade. An increase in endothelial cell intracellular Ca²⁺, as triggered by compounds such as ACh, NE, histamine, bradykinin, ATP, and thrombin, has been shown to stimulate production and release of an endothelium-dependent vasodilatory factor (EDRF).^{97,98} Compounds capable of stimulating EDRF formation are termed endothelium-dependent vasodilators. With regard to adrenergic agonists, the precise physiologic and pathophysiologic roles of endothelium-dependent effects and direct smooth muscle binding effects are complex and remain to be defined.

EDRF is generally believed to be nitric oxide (NO), the synthesis of which is stimulated by Ca²⁺ bound to calmodulin in the cytoplasm (Fig. 12-16).^{97,98} NO is synthesized from L-arginine by NO synthetases (NOS), which are found in neurons, vascular endothelial cells, macrophages, and several other cell types, notably excluding muscle cells. NO is a short-lived free radical that freely diffuses out of the endothelial cell to affect adjacent cells such as the smooth muscle cell. Its primary

biologic effect is to stimulate production of cyclic guanosine monophosphate (cGMP) by activating cytosolic guanylate cyclase (GC).⁹⁹ cGMP stimulates cGMP-dependent protein kinase G (PKG), which reduces cytoplasmic Ca^{2+} levels and, in the case of vascular smooth muscle, inhibits contraction.¹⁰⁰ It is interesting to note that elevated cAMP levels are associated with activation of PKG in addition to PKA, providing, for example, an additional pathway for β adrenoceptor- and dopaminergic-induced vasorelaxation.^{94,101}

Figure 12-16. Receptor-mediated activation of nitric oxide synthase (NOS). Receptor (R) activation triggers an increase in cytoplasmic Ca^{2+} as depicted in Figure 12-15. Ca^{2+} then binds to calmodulin, and the complex of the two stimulates cytoplasmic nitric oxide synthase (NOS). NOS catalyzes the reaction of L-arginine and oxygen to form nitric oxide (NO) and citrulline. The membrane-permeable free radical NO has multiple sites of activity within the cell of origin and in nearby cells. One site is cytosolic guanylate cyclase (GC), which it stimulates, converting GTP into cyclic GMP (cGMP). cGMP, in turn, activates protein kinase G (PKG), which ultimately decreases cytoplasmic Ca^{2+} levels.

In the CNS, NO is believed to function as a principal neurotransmitter. In the immune system, it is an intermediate in macrophage-induced oxidation. In addition to its role as a vasodilator, NO release by endothelium inhibits platelet aggregation and adhesion. Indeed, the ability of adrenergic agonists to affect EDRF/NO has added a new level of complexity to the scope of adrenergic activity.

Each signal must be transient in nature for these systems to be effective modulators of cell activity. This is assured by the rapid inactivation of G proteins and G protein-stimulated enzymes upon dissociation of the agonist from the receptor. cAMP and cGMP are hydrolyzed to inactive metabolites by phosphodiesterase (PDE) enzymes. A variety of cyclic nucleotide PDEs have been identified, with variable substrate specificities for cAMP and cGMP.¹⁰² At any moment in time, the cytoplasmic concentrations of cAMP and cGMP, and hence their activities, reflect not only their rates of production but also their rates of hydrolysis. The activities of the PDEs, like those of AC and GC, are hormonally regulated, providing an alternative mechanism for hormonal control of cyclic nucleotide second-messenger function. For instance, insulin receptor binding is linked to activation of a PDE. Furthermore, agents that increase cytoplasmic Ca^{2+} have been shown to activate a Ca^{2+} -calmodulin-dependent form of PDE. Cardiac myocyte α_1 -adrenoceptors activate a cAMP-specific PDE.⁴⁸ In each case cytoplasmic levels of cAMP and/or cGMP are reduced. Lastly, cyclic nucleotides themselves are able to influence PDE function: cGMP stimulates a nonselective form of PDE and inhibits a cAMP-specific form.¹⁰⁰

Therefore, the response of a receptor to a catecholamine can be regulated by (1) the concentration of the catecholamine agonists, (2) receptor numbers and binding affinity, (3) factors affecting receptor coupling to kinase or ion channel activation, (4) PDE activities, and (5) availability of ions such as calcium. All these factors can be medically manipulated, with the possible exception of receptor numbers.

AUTONOMIC NERVOUS SYSTEM REFLEXES

The ANS reflex has been compared to the computer circuit.¹⁰³ This control system, as in all reflex systems, has (1) sensors, (2) afferent pathways, (3) CNS integration, and (4) efferent pathways to the receptors and efferent organs. Fine adjustments are made at the local level according to positive and negative feedback mechanisms. The baroreceptor is an example. The variable to be controlled (blood pressure) is sensed (carotid sinus), integrated (medullary vasomotor center), and adjusted through specific effector-receptor sites. Drugs or disease can interrupt this circuit at any point. β Blockers may attenuate the effector response, whereas an agonist such as clonidine may alter both the effector and the integrator functions of blood pressure control (see [Antihypertensives](#)).⁸⁷

Baroreceptors

Several reflexes in the cardiovascular system help control arterial blood pressure, CO, and HR. Cardiovascular ANS reflexes are an anachronism. The business of circulation is to provide blood flow. Yet, the most important controlled variable to which the sensors are attuned is blood pressure, a product of flow and resistance.¹⁰⁴

In 1859, Etienne Marey noted that the pulse rate is inversely proportional to the blood pressure—an observation now known as Marey's law.⁸ Subsequently, Hering, Koch, and others demonstrated that the alterations in HR evoked by changes in blood pressure are dependent on baroreceptors located in the aortic arch and the carotid sinuses. These pressure sensors react to alterations in stretch caused by blood pressure. Impulses from the carotid sinus and aortic arch reach the medullary vasomotor center by the glossopharyngeal and vagus nerves, respectively. Increased sensory traffic from the baroreceptors, caused by increased blood pressure, inhibits SNS effector traffic. The relative increase in vagal tone produces vasodilation, slowing of the HR, and a lowering of blood pressure.¹⁰⁵ Real increases in vagal tone occur when blood pressure exceeds normal limits.^{103,106}

The arterial baroreceptor reflex can best be demonstrated by the Valsalva maneuver (Fig. 12-17). The Valsalva maneuver raises the intrathoracic pressure by forced expiration against a closed glottis. The arterial blood pressure rises momentarily as the intrathoracic blood is forced into the heart (preload).⁵ Sustained intrathoracic pressure diminishes venous return, reduces the CO, and drops the blood pressure. Reflex vasoconstriction and tachycardia ensue. Blood pressure returns to normal with release of the forced expiration, but then briefly "overshoots" because of the vasoconstriction and increased venous return. A slowing of the HR accompanies the overshoot in pressure, according to Marey's law.

Figure 12-17. (A) The normal blood pressure response to the Valsalva maneuver is demonstrated. Pulse rate moves in a reciprocal direction according to Marey's law of the heart. (B) An abnormal Valsalva response is shown in a patient with C5 quadriplegia.

The cardiovascular responses to the Valsalva maneuver require an intact ANS circuit from peripheral sensor to peripheral adrenergic receptors. The Valsalva maneuver has been used to identify patients at risk for anesthesia due to ANS instability (Fig. 12-17). This was once a major concern in patients receiving catecholamine-depleting drugs such as reserpine. Dysfunction of the SNS is implicated if exaggerated and prolonged hypotension develops during the forced expiration phase (50% from resting mean arterial pressure).^{8,103} In addition, the overshoot at the end of the Valsalva maneuver is absent. Dysfunction of the PNS can be assumed if the HR does not respond appropriately to the blood pressure changes. The Valsalva maneuver may still be a valid clinical preoperative test for detecting

the autonomic dysautonomia that accompanies diabetes.

Venous baroreceptors may be more dominant in the moment-to-moment regulation of CO. Baroreceptors in the right atrium and great veins produce an increase in HR when stretched by increased right atrial pressure.¹⁰⁷ Reduced venous pressure decreases HR. Unlike the arterial baroreceptors, venous sensors are not thought to alter vascular tone; however, venoconstriction is postulated to occur when atrial pressures decline.¹⁰⁸ Stretch of the venous receptors produces changes in HR opposite to those produced when the arterial pressure sensors are stimulated. The arterial and venous pressure receptors are separately monitoring two of the four major determinants of CO: afterload and preload, respectively. Venous baroreceptors sample preload by stretch of the atrium. Arterial baroreceptors survey resistance, or afterload, as reflected in the mean arterial pressure. Afterload and preload produce opposite effects on CO; thus, one should not be surprised that the venous and arterial baroreceptors produce effects opposite those of a similar stretch stimulus, pressure.

Bainbridge described the venous baroreceptor reflex and demonstrated that it can be abolished by vagal resection. Numerous investigators have confirmed the acceleration of the HR in response to volume.⁸ However, the magnitude and direction of the HR response are dependent on the prevailing HR at the time of stimulation. The exact mechanism of the Bainbridge reflex remains in doubt. The denervated, transplanted mammalian heart also accelerates in response to volume loading.¹⁰⁹ HR, like CO, can apparently be adjusted to the quantity of blood entering the heart.^{110,111}

The Bainbridge reflex relates to the characteristic but paradoxical slowing of the heart seen with spinal anesthesia.¹¹² Blockade of the SNS levels of T1–T4 ablates the efferent limb of the cardiac accelerator nerves. This source of cardiac deceleration is obvious, as the vagus nerve is unopposed. However, bradycardia during spinal anesthesia is more closely related to the development of arterial hypotension than to the height of the block. The primary defect in the development of spinal hypotension is a decrease in venous return. Theoretically, the arterial hypotension should reflexly produce a tachycardia through the arterial baroreceptors. Instead, bradycardia is more common. Greene suggests that in the unmedicated person, the venous baroreceptors are dominant over the arterial. A reduced venous pressure, therefore, slows HR.¹¹³ In contrast, humorally mediated tachycardia is the usual response to hypotension or acidosis from other causes.

Denervated Heart

Reflex modulation of the adrenergic agonists is best seen in the denervated transplant heart, which retains the recipient's innervated sinoatrial node and the donor's denervated sinoatrial node.¹¹⁴ Table 12-8 is a summary of drug effects on the transplanted heart.^{9,109,115} NE simultaneously activates α and β receptors of the intact heart and vessels. NE infusion in the transplanted heart produces a slowing of the recipient's atrial rate through vagal feedback as the blood pressure rises. In the unmodulated donor heart, atrial rate increases. Methoxamine-induced hypertension and nitrite-induced hypotension fail to induce deceleration and acceleration of the donor atrial rate. The baroreceptors are therefore not operant in the transplanted heart. Isoproterenol, a pure β agonist, increases the discharge rate of both the recipient and donor node by direct action, with the donor rate near doubling that of the recipient node. Atropine accelerates the recipient's atrial rate, whereas no effect is seen on the donor rate, which now controls HR.

| Drug | Sinoatrial Node | | Atrioventricular Conduction Velocity | Intraventricular Conduction Velocity | Blood Pressure | Cardiac Output | Systemic Vascular Resistance |
|---------------|-----------------|--------|--------------------------------------|--------------------------------------|----------------|----------------|------------------------------|
| | Response | Change | | | | | |
| Isoproterenol | ↑ | ↑ | Normal | Normal | ↓ | Normal | Normal |
| Atropine | ↑ | ↑ | Normal | Normal | Normal | Normal | Normal |

Table 12-8. DRUG EFFECTS ON THE DENERVATED HEART

Hypersensitivity to β cardiac stimulation in denervated dog hearts has been demonstrated. Whether or not this occurs in the human heart remains unclear. Patients who have undergone chemical sympathectomy with bretylium or guanethidine are known to be hyper-reactive to the usual doses of catecholamines.

β Blockade produces comparable slowing of the sinoatrial node of both recipient and donor. The exercise capability of the denervated heart is conspicuously reduced by β blockade, presumably because of its reliance on circulating catecholamines. Propranolol has also been demonstrated to reduce the β response to chronotropic effects of NE and isoproterenol in the transplanted heart. The CO of the transplanted heart varies appropriately with changes in preload and afterload.

INTERACTION OF AUTONOMIC NERVOUS SYSTEM RECEPTORS

Strong interactions have been noted between SNS and PNS nerves in organs that receive dual, antagonistic innervation. Release of NE at the presynaptic terminal is modified by the PNS. For example, vagal inhibition of left ventricular contractility is accentuated as the level of SNS activity is raised.⁶ This interaction, termed *accentuated antagonism*, is mediated by a combination of presynaptic and postsynaptic mechanisms. The coronary arteries present an example of this phenomenon and deserve special attention.

The myocardium and coronary vessels are abundantly supplied with adrenergic and cholinergic fibers.^{8,116,117} Strong activity of both α and β receptors has been demonstrated in the coronary vascular bed. Selective stimulation of both the α_1 and postsynaptic α_2 receptors increases coronary vascular resistance, whereas selective α blockade eliminates this effect. Therefore, both β_1 and α_1 adrenoceptors are present on coronary arteries and accessible to NE from sympathetic nerves.^{11,116}

The close anatomic proximity of the postganglionic vagal and SNS nerve endings in coronary arteries provides the morphologic basis for strong interaction.^{6,14} SNS and PNS nerve terminals are found in such close proximity that transmitters from one can easily reach the other and affect transmitter release. In addition, the presynaptic adrenergic terminals of the myocardium and coronary vessels, like all blood vessels examined, contain muscarinic receptors.^{37,118} Recent observations confirm that muscarinic agents and vagal stimulation, acting on the presynaptic, SNS muscarinic receptor, inhibit the release of NE in a manner similar to that of the presynaptic α_2 and DA₂ receptors (Fig. 12-11). Conversely, blockade of the muscarinic receptors with atropine markedly augments the positive inotropic responses to catecholamines.⁶ Suppression of NE release explains, in part, vagal-induced attenuation of the inotropic response to strong SNS stimulation (accentuated antagonism) and a weak negative inotropic effect of vagal stimulation when there is low background SNS activity. This may also explain why vagal activity reduces the vulnerability of the myocardium to fibrillation during infusions of NE.

ACh may cause coronary spasm during periods of high SNS tone.^{12,119} Inhibition of NE release by presynaptic adrenergic muscarinic receptors of the smooth muscle of coronary vessels would diminish the coronary relaxation normally produced by NE on the β_1 receptor (Fig. 12-11). In anesthetized dogs, the rate of NE outflow into the coronary sinus blood, evoked by cardiac SNS stimulation, is markedly diminished by simultaneous vagal efferent stimulation.^{120,121} This action is known to be prevented by atropine, which also causes coronary vasodilation. Methacholine, a muscarinic parasympathomimetic agent, has been reported to cause coronary vasoconstriction.¹²² However, it simultaneously reduces ventricular irritability by reducing NE release in myocardial fibers.⁶

The concept of accentuated antagonism has yet to be clearly defined because it is unusual for high SNS and PNS activity to coexist, except during anesthesia. The importance of accentuated antagonism in the intact, conscious human has yet to be demonstrated; however, it may explain the clinical observation that angina and myocardial infarction owing to coronary spasm in humans are not often related to cardiac work, as is angina caused by sclerotic coronary disease. Attacks of angina usually occur at rest, often waking the patient from sleep. This diurnal variation also corresponds to the greatest activity of the PNS system. The mechanism by which coronary arterial spasm occurs remains unknown, but this continues to be an exciting area of investigation.

INTERACTION WITH OTHER REGULATORY SYSTEMS

The ANS is integrally related to several endocrine systems that ultimately sum to control blood pressure and regulate homeostasis. These include the

renin–angiotensin system, antidiuretic hormone, glucocorticoids, and insulin.

Antidiuretic hormone, or vasopressin, is formed in the hypothalamus and released from nerve endings in the posterior pituitary gland. It causes vasoconstriction and increased reabsorption of water in the distal collecting ducts of the kidney. It therefore affects not only central blood volume but also plasma osmolality. The primary regulator of antidiuretic hormone release is plasma osmolality; however, several other stimuli may outweigh this control in stressful situations.¹²³ Release is also triggered by decreased central blood volume *via* low-pressure atrial receptors and hypotension *via* the carotid baroreceptors. Stress, pain, hypoxia, anesthesia, and surgery also stimulate release of antidiuretic hormone. Infusion of catecholamines may alter its release, but these effects appear to be mediated by the carotid baroreceptors. ANS drugs that induce hypotension or decreased cardiac filling may induce release of antidiuretic hormone and thus affect plasma osmolality.

Both α and β receptors have been found in the endocrine pancreas and modulate insulin release (see [Table 12-5](#)). β stimulation increases insulin release, whereas α stimulation decreases it. The overall importance of this interaction is not entirely clear, but decreased tolerance to glucose and potassium has been noted in subjects taking β -blocking drugs.^{124,125}

The renin–angiotensin system is a complex endocrine system that modulates both blood pressure and water–electrolyte homeostasis ([Fig. 12-18](#)). Renin is a proteolytic enzyme contained within the cells of the juxtaglomerular apparatus of the renal cortex. When released, it acts on plasma angiotensinogen to form angiotensin I. Angiotensin I is then converted to angiotensin II by converting enzyme in the lung. Angiotensin II is a powerful direct arterial vasoconstrictor. It also acts on the adrenal cortex to release aldosterone and on the adrenal medulla to release EPI. In addition to its direct effects on vascular smooth muscle, angiotensin II augments NE release *via* presynaptic receptors, thus enhancing peripheral SNS tone. A group of drugs called angiotensin-converting enzyme inhibitors act by interfering with the formation or function of angiotensin II. These drugs have been found useful in the treatment of essential and renovascular hypertension and of congestive heart failure. Captopril, enalapril, and lisinopril inhibit the action of converting enzyme, thus preventing the conversion of angiotensin I to angiotensin II.^{124,125,126,127,128,129,130} and ¹³¹ They have supplanted diuretics and β blockers as first-line agents in the treatment of hypertension. Saralasin is a direct angiotensin II receptor antagonist that is useful as an antihypertensive drug but is not in common use.

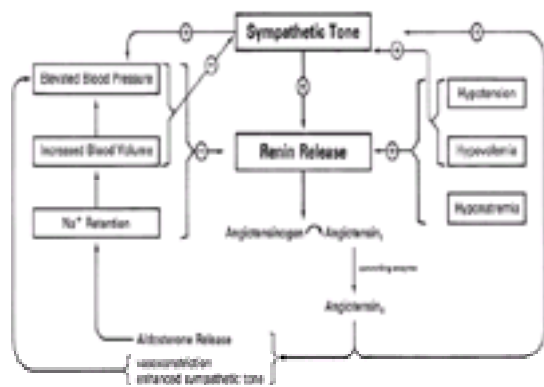

Figure 12-18. The interactions of the renin–angiotensin and SNS in regulating homeostasis are shown schematically along with the physiologic variables that modulate their function. Arrows with a plus sign (+) represent stimulation, and those with a minus sign (–) represent inhibition.

Renin is released in response to hyponatremia, decreased renal perfusion pressure, and ANS stimulation *via* β receptors on juxtaglomerular cells. Changes in sympathetic tone may thus alter renin release and affect homeostasis in a variety of ways. The mechanism of action of some antihypertensive agents is thought to involve alterations in activity of the renin–angiotensin system in parallel with the ANS.

The ANS is also intimately related to adrenocortical function. As outlined earlier, glucocorticoid release modulates phenylethanolamine-*N*-methyltransferase formation, and hence synthesis of EPI. Glucocorticoids are also important in regulating the response of peripheral tissues to changes in SNS tone. Thus, the ANS is intimately related to other homeostatic mechanisms.

CLINICAL AUTONOMIC NERVOUS SYSTEM PHARMACOLOGY

The clinical application of ANS pharmacology is based on knowledge of ANS anatomy, physiology, and molecular pharmacology. Drugs that modify ANS activity can be classified by their site of action, by their mechanism of action, or by the pathology for which they are most commonly used. Antihypertensive drugs are an example of the third category.

Site of Action

ANS drugs may be broadly categorized as working on the CNS or at peripheral nerve sites. This classification is a matter of degree because considerable functional overlap occurs. An example of classification by site relates to the ganglionic agonists or blocking agents. ANS drugs can be further categorized as those that act at the prejunctional membrane and those acting postjunctionally. They can then be more specifically classified by the predominant receptor or receptors on which they act.

Mode of Action

ANS drugs may be broadly classified by mode of action according to their mimetic or lytic actions. This may also be termed *agonist* or *antagonist*. Sympathomimetics, such as ephedrine, mimic SNS sympathetic activity by stimulation of adrenergic receptor sites both directly and indirectly. Sympatholytic drugs cause dissolution of SNS activity at these same receptor sites. β -Receptor blockers are examples of sympatholytic drugs. The terms *parasympathomimetic* and *parasympatholytic* are self-explanatory and may be further divided by their site of action on the muscarinic or nicotinic receptors.

Several modes of ANS drug action become evident when one follows the cascade of neurotransmission. The mode is related to site. Drugs that act on prejunctional membranes may therefore (1) interfere with transmitter synthesis (*α*-methyl paratyrosine), (2) interfere with transmitter storage (reserpine), (3) interfere with transmitter release (clonidine), (4) stimulate transmitter release (ephedrine), or (5) interfere with reuptake of transmitter (cocaine). Drugs may also (6) modify metabolism of the neurotransmitter in the synaptic cleft (anticholinesterase). Drugs acting at postjunctional sites may (7) directly stimulate postjunctional receptors and (8) interfere with transmitter agonist at the postjunctional receptor.

The ultimate response of an effector organ to an agonist or antagonist depends on (1) the drug, (2) its plasma concentration, (3) the number of receptors in the effector organ, (4) binding by the receptor, (5) the concurrent activities of other drugs and hormones, (6) the cellular metabolic status, and (7) reflex adjustments by the organism. This is the source of conflicting results for drugs used in differing clinical circumstances.

Ganglionic Drugs

SNS and PNS ganglia are pharmacologically similar in that transmission through these ANS ganglia is effected by ACh (see [Fig. 12-3](#)). Most ganglionic agonists and antagonists are not selective and affect SNS and PNS ganglia equally.¹³² This nonselective property creates many undesirable and unpredictable side-effects, thereby limiting the clinical usefulness of this category of drug.

Agonists

There are essentially no clinically useful ganglionic agonists. Nicotine is the prototypical ganglionic agonist. In low doses, it stimulates ANS ganglia and the neuromuscular junction of striated muscle. High doses produce ganglionic and neuromuscular blockade. Low-dose stimulation and high-dose blockade are referred to as nicotinic effects in describing any drug with similar effects. Most ganglionic agonists and antagonists produce their effects through their nicotinic effects. The protean side-effects of nicotinic stimulation render it useful only as an investigative tool.

Despite its lack of clinical usefulness, nicotine is widely used in the form of tobacco. The novice tobacco user can often describe the overlap of SNS and PNS side-effects of nicotinic stimulation, which appear as nausea and vomiting, tachycardia, bradycardia, diarrhea, and sometimes fainting as a result of high-dose

ganglionic blockade.⁶

Antagonists

Drugs that interfere with neurotransmission at ANS ganglia are known as ganglionic blocking agents. Nicotine, in high doses, is the prototypical ganglionic blocking agent also; however, early stimulatory nicotinic activity can be blocked at the ganglia and muscle end plates with other ganglionic blockers and muscle relaxants, respectively, without blocking muscarinic effects.¹³³ Ganglionic blockers produce their nicotinic effects by competing, mimicking, or interfering with ACh metabolism. Hexamethonium, trimethaphan, and pentolinium produce a selective nondepolarizing blockade of neurotransmission at ANS ganglia without producing nicotinic neuromuscular blockade. They compete with ACh in the ganglia without stimulating the receptors. Decamethonium, a depolarizing muscle relaxant, selectively produces neuromuscular blockade in a manner similar to that of nicotine, but possesses no ganglionic effect.⁶ The depolarization produced is initially associated with increased excitability, but depolarization persists. The neuron, therefore, cannot be excited, and block exists. *d*-Tubocurarine (dTC), however, produces a competitive nondepolarizing block of both motor end plates and ANS ganglia. The action of motor paralysis predominates, but the concomitant ganglionic blockade at higher doses explains part of the hypotensive effect often seen with the use of dTC for muscle relaxation. Histamine release is the major hypotensive factor that is common to dTC and other ganglionic blockers. Anticholinesterase drugs may produce nicotinic-type ganglionic blockade by competition with ACh as well as by persistent depolarization via accumulated ACh.

The overall effects of ganglionic blockers on particular organ systems depend on whether the ANS activity of the system is predominantly sympathetic or parasympathetic (see [Table 12-1](#)). The overall effect on peripheral vessels is vasodilation due to release from SNS ganglionic constrictor control. The effect on the gastrointestinal tract may produce ileus. Although these drugs have a parasympathetic effect, blockade of the SNS ganglia and vascular dilation are the properties for which they were first used. They were initially used to treat chronic hypertension, but their lack of selectivity and global side-effects curtailed their popularity. The introduction of drugs that produce vasodilation directly or by action on the SNS vasomotor center has made the ganglionic blockers obsolete.

Trimethaphan is the only ganglionic blocker available in the United States. Trimethaphan produces blockade by competition with ACh for receptors, thus stabilizing the postsynaptic membrane. However, side-effects and rapid onset tachyphylaxis have markedly reduced its use in anesthesia.¹³⁴ The patient's pupils become fixed and dilated during administration, which obscures eye signs, an important consideration for neurosurgery. In this regard, it is distinctly inferior to nitroprusside. The major advantage of trimethaphan is its short duration of action, which is the result of pseudocholinesterase hydrolysis.

Pentolinium is a ganglionic blocking drug available in the United Kingdom.¹³⁵ Its mechanisms of action are similar to those of trimethaphan, but it is devoid of muscle-relaxant properties. The main disadvantage of pentolinium is its relative lack of controllability compared with trimethaphan or nitroprusside. Pupillary dilation, as with trimethaphan, occurs. Hypotension and vasomotor instability may outlast the procedure.

Cholinergic Drugs

Cholinergic drugs may be classified by the following outline, which follows physiologic response and site of action.

I. Cholinergic drugs: agonists⁶

- A. Nicotinic
 - 1. ANS ganglionic transmission
 - 2. Neuromuscular transmission
- B. Muscarinic
 - 1. Direct-acting
 - 2. Indirect-acting

II. Cholinolytic agents: antagonists

- A. Nicotinic
 - 1. ANS ganglionic transmission
 - 2. Neuromuscular transmission
- B. Muscarinic

Muscarinic Agonists

The cholinomimetic muscarinic drugs act at sites in the body where ACh is the neurotransmitter of the nerve impulse. These drugs may be divided into three groups, the first two of which are direct muscarinic agonists.^{136,137} The third group acts indirectly. These groups are choline esters (ACh, methacholine, carbamylcholine, bethanechol), alkaloids (pilocarpine, muscarine, arecoline), and anticholinesterases (physostigmine, neostigmine, pyridostigmine, edrophonium, echothiophate).

Direct Cholinomimetics

ACh has virtually no therapeutic applications because of its diffuse action and rapid hydrolysis by cholinesterase (see [Fig. 12-6](#)).¹³⁶ One may encounter the use of topical ACh (1%) drops during cataract extraction when a rapid miosis is desired. Systemic effects are not usually seen because of the rapidity of ACh hydrolysis.

Other choline esters have been synthesized, mostly derivatives of ACh, which possess more selective muscarinic activity than ACh. They differ from ACh in being more resistant to inactivation by cholinesterase and thus having a more prolonged and useful action. They also differ from ACh in their relative muscarinic and nicotinic activities.¹³⁸ The best studied of these drugs are methacholine, bethanechol, and carbamylcholine.⁶ The chemical structures of ACh and these choline esters are shown in [Figure 12-19](#). Their pharmacologic actions are compared with those of ACh in [Table 12-9](#). These are not important drugs in anesthesiology, but they deserve discussion because anesthesiologists may encounter patients who are receiving them, and they may be useful in the postoperative period to alleviate cardiac tachyarrhythmias, urinary retention, and ileus.¹³⁹

Figure 12-19. Chemical structures of direct-acting cholinomimetic esters and alkaloids.

breakdown.^{144,145} National experience has favored the latter opinion.

The interactions between ACh and the anticholinesterases are complex.¹⁴⁶ Anticholinesterase drugs inhibit hydrolysis of ACh by binding to either or both the anionic or esteratic sites of acetylcholinesterase, forming inhibitor–enzyme complexes that are more stable than ACh–enzyme complexes. These complexes prevent proper stereotactic access of ACh to the active enzyme sites; thus, hydrolysis is delayed, and ACh accumulates.

Clinically, anticholinesterase drugs may be divided into two types: the reversible and nonreversible cholinesterase inhibitors.^{25,137} Reversible cholinesterase inhibitors delay the hydrolysis of ACh from 1 to 8 hours. Nonreversible drugs are so named because their inhibitory effects may last from days to weeks. The differences in duration of various anticholinesterases apparently depend on whether they inhibit the anionic or esteratic site of acetylcholinesterase.¹⁴¹ Therefore, the anticholinesterase drugs have also been pharmacologically subdivided. Drugs that inhibit the anionic site are called prosthetic, competitive inhibitors. Their action is due to competition between the anticholinesterase and ACh for the anionic site. These drugs tend to be short-acting. Edrophonium is an example of this type. Drugs that inhibit the esteratic site are called acid-transferring inhibitors. These drugs include the longer-acting neostigmine, pyridostigmine, and physostigmine. Thus, the differences in the mechanism of inhibition produced by prosthetic inhibitors (edrophonium) and acid-transferring inhibitors (neostigmine) account for the longer duration of action associated with the latter agents.

Most of the reversible cholinesterase inhibitors are quaternary ammonium compounds and do not cross the blood–brain barrier. Physostigmine is a tertiary amine that readily passes into the CNS (Fig. 12-20). It produces central muscarinic stimulation, and thus is not used to reverse neuromuscular blockade but can be used to treat atropine poisoning. Conversely, atropine is used to treat physostigmine poisoning. Physostigmine has also been found to be a specific antidote in the treatment of postoperative delirium (see [Central Anticholinergic Syndrome](#)).^{6,26}

Figure 12-20. Structural formulas of clinically useful reversible anticholinesterase drugs. Physostigmine is a tertiary amine and crosses the blood–brain barrier. It is useful in treating the central anticholinergic syndrome.

The irreversible cholinesterase inhibitors are mostly organophosphate compounds. These are also considered acid-transferring inhibitors, which form a phosphorylated enzyme resistant to attack by water. The phosphorylated enzyme cannot hydrolyze ACh to any measurable degree. In addition, the organophosphate compounds are highly lipid-soluble; they readily pass into the CNS and are rapidly absorbed through the skin. They are used as the active ingredient in potent insecticides and the chemical warfare agents known as nerve gases. [Table 12-10](#) lists some of these agents. The only therapeutic drug of this group is echothiophate, which is available in the form of topical drops for the treatment of glaucoma. Its primary advantage is its prolonged duration of action. Topical absorption is variable but considerable. Echothiophate can remain effective for 2 or 3 weeks following cessation of therapy.¹⁴⁷ A history of use of echothiophate is important in avoiding prolonged action of succinylcholine, which requires pseudocholinesterase for its hydrolysis.

Organophosphate poisoning manifests all the signs and symptoms of excess ACh.¹⁴⁸ The antidote cartridges dispensed to troops to counter the effects of anticholinesterase nerve gases contain only atropine, which would effectively counter the muscarinic effects of the gas; however, atropine does little to counter the high-dose nicotinic muscle paralysis or the central ventilation depression that contributes to death from nerve gases. Treatment requires high doses of atropine, 35–70 mg · kg⁻¹ iv every 3–10 minutes until muscarinic symptoms abate. Lower doses at less frequent intervals may be required for several days. Central ventilatory depression and nicotinic paralysis or weakness require respiratory support and specific therapy of the cholinesterase lesion. Pralidoxime has been reported to reactivate cholinesterase activity by hydrolysis of the phosphate enzyme complex. It is particularly effective with parathion poisoning and is the only cholinesterase reactivator available in the United States.¹³⁷

Muscarinic Antagonists

Muscarinic antagonist refers to a specific drug action for which the term anticholinergic is widely used. Any drug that interferes with the action of ACh as a transmitter can be considered an anticholinergic agent. The term anticholinergic refers to a broader classification that would include the nicotinic antagonists.

Atropinic Drugs

Atropine, scopolamine, and glycopyrrolate are the most commonly used muscarinic antagonists used in anesthesia ([Fig. 12-21](#)). The use of antimuscarinic drugs for premedication is outlined in [Chapter 21](#).

Figure 12-21. Structural formulas of the clinically useful antimuscarinic drugs.

The actions of these drugs include inhibition of salivary, bronchial, pancreatic, and gastrointestinal secretions to antagonize the muscarinic side-effects of anticholinesterases during reversal of muscle relaxants. Atropine is useful in increasing CO with sinus bradycardia due to vagal stimulation if hypoxia is ruled out. It has many uses outside of anesthesia for the treatment of renal colic, gastrointestinal spasm, gastric secretion, and asthma. Historically, atropine was introduced to anesthesia practice to prevent excessive secretions during ether anesthesia and to prevent vagal bradycardia during the administration of chloroform.¹⁴⁹ Atropine and scopolamine also possess antiemetic action. Atropine, however, reduces the opening pressure of the lower esophageal sphincter, which theoretically increases the risk of passive regurgitation.¹⁵⁰ Atropinic drugs also produce dilation of the pupil (mydriasis) and paralysis of accommodation (cycloplegia).

Antimuscarinic agents do not inhibit transmission equally, and there are marked variations in sensitivity at different muscarinic sites owing to differences in penetration and affinities of the various receptors.¹⁵¹ Differences in relative potency between the different antimuscarinics are outlined in [Table 12-11](#). For example, glycopyrrolate produces less tachycardia than atropine and is a more potent antisialogogue.

| | Duration | | CNS | GIT [†] | Gastric Acid | Airway Secretions* | Heart Rate |
|----------------|-----------|--------|-----|------------------|--------------|--------------------|------------|
| | in | in | | | | | |
| Atropine | 15-30 min | 2-4 hr | ++ | -- | - | - | +++‡ |
| Scopolamine | 30-60 min | 4-6 hr | +++ | - | - | ---- | -‡ |
| Glycopyrrolate | 2-4 hr | 6-8 hr | 0 | --- | --- | --- | -‡ |

*Secretions may be reduced by inspiration.

†CNS effect often manifest as sedation before stimulation.

‡May decrease initially.

Table 12-11. COMPARISON OF ANTIMUSCARINIC DRUGS

The antimuscarinic effects of the atropinic drugs are the result of competitive inhibition of ACh at the receptors of organs innervated by cholinergic postganglionic nerves. The antagonism can be overcome by sufficient concentrations of cholinomimetic drugs or anticholinesterases that increase ACh levels at the receptor site. This explains most of the therapeutic actions of atropinic drugs; however, they are neither purely antimuscarinic nor purely antagonist.⁶

The belladonna alkaloids (atropine and scopolamine) also block ACh transmission to sweat glands, which, although they are cholinergic, are innervated by the SNS. Antimuscarinic agents produce antinicotinic actions at higher doses and result in important actions on CNS transmission that are pharmacologically similar to the postganglionic cholinergic function.¹⁵²

Atropine and scopolamine are tertiary amines (Fig. 12-21) and easily penetrate the blood–brain barrier and placenta. Glycopyrrolate is a quaternary amine which, like the reversible anticholinesterase drugs, does not easily penetrate these barriers. Glycopyrrolate, a synthetic antimuscarinic, has gained popularity because it avoids the central effects of the other two drugs. Atropine and scopolamine have notable CNS effects that are dissimilar. Scopolamine differs from atropine mainly in its central depressant effects, which produce sedation, amnesia, and euphoria. Such properties are widely used for premedication for cardiac patients in combination with morphine and a major tranquilizer. Atropine, as a premedicant, has slight effects on the CNS, including mild stimulation. Higher doses such as those given for reversal of muscle relaxants (1–2 mg) may produce restlessness, disorientation, hallucinations, and delirium (see [Central Anticholinergic Syndrome](#)). Excessive stimulation may be followed by depression and paralysis of respiration. Occasionally, scopolamine in low doses may cause restlessness and delirium. This syndrome is more frequently seen in the elderly and patients experiencing pain, e.g., in obstetric patients.

Atropine and scopolamine are noted to produce a paradoxical bradycardia when given in low doses. Scopolamine (0.1–0.2 mg) usually causes more slowing than atropine but also produces less cardiac acceleration at higher doses. The usual intramuscular premedicant doses of scopolamine cause either a decrease or no change in HR. The paradoxical bradycardia was once thought to be caused by an early central inhibition of the medullary cardioinhibitory center. However, this phenomenon occurs in animals that have had total vagotomy. Atropine may also produce sympathomimetic effects by blocking presynaptic muscarinic receptors found on adrenergic nerve terminals.^{12,37} ACh stimulation of these receptors inhibits NE release, and blockade by atropine releases this inhibition (see [Cholinergic Receptors: Muscarinic](#)).

Atropinic drugs are widely used in ophthalmology as mydriatics and cycloplegics. Atropine is contraindicated in patients with narrow-angle glaucoma. Pupillary dilation thickens the peripheral part of the iris, which narrows the iridocorneal angle. Drainage of aqueous humor is impaired, and intraocular pressure increases. Doses of atropine used for premedication have little effect in this regard, whereas equal doses of scopolamine cause mydriasis. Prudence would dictate avoidance of either agent in patients with narrow-angle glaucoma. The need for antimuscarinic premedication is questionable in this situation.¹³⁵

Atropine is best avoided where tachycardia would be harmful, as may occur in thyrotoxicosis, pheochromocytoma, or obstructive coronary artery disease. Theoretically, antimuscarinic drugs should benefit coronary spasm, but the benefit may be offset by the oxygen cost of the ensuing tachycardia. Atropine should be avoided in hyperpyrexial patients because it inhibits sweating.

Central Anticholinergic Syndrome

The belladonna alkaloids have long been known to produce undesirable side-effects ranging from stupor (scopolamine) to delirium (atropine). This syndrome has otherwise been called postoperative delirium and atropine toxicity. The central anticholinergic syndrome appears to involve the muscarinic receptor.⁶ Biochemical studies have demonstrated abundant muscarinic ACh receptors in the brain that can be affected by any drug possessing antimuscarinic activity and capable of crossing the blood–brain barrier. Hundreds of drugs meet the criteria with which this syndrome has been associated. [Table 12-12](#) lists some of those drugs.^{6,152}

| | |
|---|------------------------------------|
| Belladonna Alkaloids | Over-the-Counter |
| Atropine sulfate | Atropine (Eye) - atropine 1% |
| Scopolamine hydrobromide | Compazine - scopolamine solution |

Table 12-12. ANTIMUSCARINIC COMPOUNDS ASSOCIATED WITH CENTRAL ANTICHOLINERGIC SYNDROME

High doses of atropinic alkaloids rapidly produces dryness of the mouth, blurred vision with photophobia (mydriasis), hot and dry skin (flushed), and fever.¹⁵² Mental symptoms range from sedation, stupor, and coma to anxiety, restlessness, disorientation, hallucinations, and delirium. Convulsions and ventilatory arrest may occur if lethal poisoning has occurred. Although an alarming reaction may occur, fatalities are rare. Intoxication is usually short-lived and followed by amnesia. These reactions can be controlled by the iv injection of physostigmine.¹³⁸ Physostigmine is an anticholinesterase that, by virtue of being a tertiary amine, readily passes into the CNS to counter antimuscarinic activity. It should be given slowly in 1-mg doses, not exceeding 3 mg, to avoid producing peripheral cholinergic activity. Neostigmine, pyridostigmine, and edrophonium are not effective because they cannot pass into the CNS. Likewise, atropine is an effective antidote for physostigmine overdose.¹⁹ The duration of physostigmine action may be shorter than that of the offending antimuscarinic agent and require repeated injection if symptoms recur. Physostigmine appears safe when used within dose recommendations and when indications are established. Central disorientation alone does not establish a diagnosis.¹⁵¹ Peripheral signs of antimuscarinic activity should be present in addition to a central anticholinergic syndrome.

Physostigmine has been reported to reverse the CNS effects of many of the drugs listed in [Table 12-12](#), including antihistamines, tricyclic antidepressants, and tranquilizers. Reversal of the sedative effects of opioids and benzodiazepines has also been reported.^{153,154} However, anticholinesterase agents potentiate cholinergic synaptic transmission and increase neuronal activity, even if no receptor antagonist is present. Thus, arousal may not be a function independent of its cholinesterase activity, and claims that physostigmine is a nonspecific CNS stimulant may be unwarranted and could, in fact, be dangerous.⁶ These phenomena require more study.

Adrenergic Drugs

Adrenergic Agonists

Until recently, sympathomimetics were the most common means of treating the hypotension associated with shock.³⁶ A vasopressor is a drug that is used to elevate

arterial blood pressure above the existing level because the pressure is too low. However, elevation of arterial blood pressure alone has repeatedly been demonstrated to be an insufficient goal in the treatment of shock.^{155,156} The goal, instead, is to re-establish blood flow to vital organs. Although blood pressure has been the historical gold standard for estimating perfusion, there is no correlation between blood pressure and flow (Fig. 12-22).¹⁵⁷ In physiologic as well as constructed systems, flow tends to be least when pressure is highest. Flow used in this context refers to cardiac output (CO).

Figure 12-22. Correlation between mean arterial pressure (MAP) and O₂ delivery (DO₂) during the perioperative period in patients undergoing aorta bifemoral bypass grafting. (Reprinted with permission from Reinhart K: Principles and Practice of Svo₂ Monitoring, pp 121–124. London, Intensive Care World, King and Worth, Publishers, vol 5, no 4, Dec 1988.)

Oxygen transport (DO₂) is the product of the arterial oxygen content (CA₂) and CO:

$$DO_2 = CA_2 \times CO$$

Therefore, there is a close correlation between oxygen transport and CO. Unfortunately, oxygen transport is not identical to cellular oxygen supply, which can be inadequate despite normal or elevated oxygen transport. Cellular oxygen supply can be inadequate because of maldistribution of blood flow to vital organs or from the inability of the cell to use oxygen.^{157,158} Improving cellular oxygen utilization remains enigmatic, but the catecholamines can be of some assistance in the redistribution of flow.

The physiologic equation that expresses how flow (CO) is generated states that CO is the product of the HR and stroke volume (SV):

$$CO = HR \times SV$$

However, SV is determined by three factors: (1) the contractile or inotropic state of the myocardium; (2) preload, or end-diastolic myocardial fiber length; and (3) afterload, or resistance to ejection. The physiologic determinants of CO can therefore be expressed as

$$CO = HR \times (\text{inotropism} : \text{preload} : \text{afterload})$$

Synchrony of AV contraction is an additional determinant when dysrhythmias develop. This equation is illustrated in Figure 12-23 to emphasize that the biologic mechanisms that produce and regulate flow are interdependent. Terms such as inotropism, preload, and afterload cannot be defined independently or isolated in the clinical setting. We can now measure, calculate, and manipulate each of the links in the chain of events that determine flow. Note that blood pressure is not among the determinants of flow. It is the product, not the cause. Most catecholamines affect one or more of these factors *via* the receptors and may cause changes in blood pressure by altering flow, vascular tone, or both. A measured blood pressure does not distinguish changes in flow, resistance, inotropism, or HR; therefore, blood pressure and oxygen transport do not correlate.

HEART RATE

Heart rate (HR) becomes an important support of CO when SV is decreased. A change in either HR or SV invariably causes an alteration of the other by reflex activity. Tachycardias can reduce SV by not allowing sufficient diastolic ventricular filling time. Coronary blood flow to the ventricles and especially the subendocardium, occurs primarily during diastole. The subepicardial muscle is perfused during systole as well as diastole. However, subendocardial blood flow is totally dependent upon diastolic perfusion time, diastolic pressure, and microcirculatory tone.¹⁵⁹

Diastolic perfusion time becomes even more critical with ventricular hypertrophy. Increases in HR will not only shorten the percent diastolic perfusion time for the endocardium but also increase oxygen demand.¹⁶⁰ Increased HR, alone, has been shown to increase the severity of ischemia and the incidence of reperfusion arrhythmias. Animal studies have shown that myocardial blood flow and contractile function decrease with increased inotropic activity and tachycardia. This does not occur when increased inotropism is not accompanied by tachycardia.

Diastolic perfusion time has a curvilinear relationship with HR, increasing rapidly as rates fall below 75 beats/min (Fig. 12-24). Once HR goes above 90 beats/min in the adult, there is little further decrease in percent diastole. There is an exponential increase in percent diastole below rates of 70 beats/min.¹⁵⁹ Wide swings in percent diastolic time are of little consequence in the patient with normal coronary function, but can be critical in those with obstructive coronary artery disease.

Figure 12-24. Small changes in HR produce large changes in percent diastole especially at low HRs due to the curvilinear relationship between rate and diastolic time. Shortening of electromechanical systole (QS₂) produces an upward shift of the curve. Shortening of QS₂ or a decrease in HR, or both, will increase percent diastolic perfusion time. Cardioactive drugs may affect diastolic perfusion time through either or both mechanisms.¹⁶⁸

Two factors actually determine the duration of systole: HR and electromechanical systole (QS₂). HR and QS₂ have an inverse relationship (Fig. 12-25).¹⁵⁹ Percent diastolic perfusion time is calculated as the cardiac cycle (R-R) minus QS₂. A decrease in HR and/or shortening in QS₂ will result in prolongation of the total diastolic period and *vice versa*. HR is the more important factor because small changes in the HR can produce significant changes in percent diastole as a result of the curvilinear relationship between HR and diastolic perfusion time. Changes in HR alone produce movement along that curve, whereas changes in QS₂ result in shifts of the curve. Dopamine and dobutamine (DBT) affect diastolic perfusion time by altering HR and QS₂. DBT has been shown to increase percent diastole without significantly altering HR. The increase in diastolic perfusion time is due to a shortening of QS₂. Isoproterenol reduces percent diastole because it reduced QS₂.

proportional to the increase in HR. Beta blockers, particularly atenolol, will significantly decrease HR and increase percent diastole because it has little effect on QS_2 in the usual clinical dose range. The beneficial effects of beta blockers on myocardial oxygen delivery and consumption can be related to a reduced HR alone, although higher doses may reduce inotropism as well. Diastolic perfusion pressure may also increase with β blockade because of an unopposed relative increase in vascular tone. Lidocaine has no effect on either HR or QS_2 .

Figure 12-25. Nomogram for the relationship between electromechanical systole (QS_2), heart rate (HR), and percent diastole. The percent diastole can be obtained from QS_2 and HR.¹⁶⁸ (Reprinted from Boudoulas H, Rittgers SE, Lewis RP *et al*: Changes in diastolic time with various pharmacologic agents. *Circulation* 60:164, 1979.)

PRELOAD

Preload is clinically synonymous with the volume of venous return to the heart, which establishes CO by the purported Frank–Starling mechanism. Preload has repeatedly been demonstrated to be of paramount importance in supporting cardiovascular function in the normal heart. It can be increased by adding volume to the circulation or by acute venous constriction. The catecholamines can be selected for their effect on preload by either increasing (α_1 , α_2) or decreasing (β_2 , DA_1 , DA_2) venous tone.⁶⁴ Positive or negative preloading can be a major unrecognized benefit of some sympathomimetic agents. Although venoconstriction produces little increase in total vascular resistance (afterload), minimal venoconstriction is capable of producing large shifts of blood volume into the central circulation because the capacitance vessels contain 60–80% of the total blood volume, an effect that has largely been ignored. The central distributive effect of a catecholamine may be as important as its inotropic action in increasing the CO in the hypovolemic patient. Likewise, a central distribution of capacitance blood may be undesirable if the heart is failing, even though that agent may possess inotropic properties.

AFTERLOAD

Afterload is a measure of impedance to ventricular ejection and is the dominant factor in determining CO when inotropism is impaired. In the absence of outlet obstruction, the clinical correlate of afterload to the left ventricle is the systemic vascular resistance reflected by the mean arterial pressure. Afterload is the only factor of the four major determinants of CO that, if increased, will reduce flow. Ohm's law states that blood flow through any organ is directly related to the blood pressure gradient across that organ but is inversely proportional to the resistance (afterload).

INOTROPISM

Inotropism is defined as the force and velocity of ventricular contraction when preload and afterload are held constant. Vasoactive drugs can be described as having either a positive or negative inotropic effect. Inotropic agents, such as dopamine and DBT, represent therapeutic agents that altogether increase myocardial contractility. As yet, there are no clinically feasible means to directly measure inotropism at the bedside. We can define failure of inotropism better than we can define what it is. The myocardium permits CO to be regulated at any level below its inotropic limit.

Several direct indicators of cardiac inotropism appear useful in lieu of direct force velocity measurements. Pump function can be estimated clinically by work-pressure curves using the Frank–Starling mechanism. When inotropism is normal, CO is more dependent on extracardiac factors such as preload and afterload (Fig. 12-23).

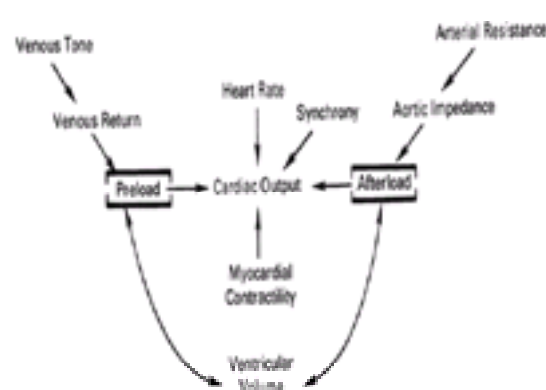

Figure 12-23. The four principal factors determining CO are demonstrated. Synchrony of AV-contraction is an additional factor becoming important with the development of cardiac dysrhythmias. (Reprinted with permission from Lawson NW, Wallfisch HK: *Cardiovascular pharmacology: A new look at the "pressors."* In Stoelting RK, Barash PG, Gallagher TJ (eds): *Advances in Anesthesia*, p 195, Chicago, Year Book Publishers, 1986.)

LUSITROPISM

Lusitropism is a factor determining CO that is not depicted in Figure 12-23. Lusitropism describes abnormalities of myocardial relaxation, or diastole, as opposed to problems of inotropism. Some vasodilators such as nitroglycerin and some sympathomimetic "inodilators" are thought to improve cardiac function by promoting diastolic relaxation and hence ventricular filling (preloading) and coronary perfusion. Lusitropic dysfunction may play a larger role in chronic heart failure than hitherto appreciated: it is now known to play a large role in many myocardial disease processes and may, in fact, precede inotropic dysfunction.¹⁶¹ Decreased lusitropism is characteristic of the aging myocardium.

Figure 12-23 deliberately emphasizes preload and afterload as balancing forces in producing CO. They are antagonistic and assume differing degrees of dominance depending on whether the myocardium is healthy or ailing. Preload is the dominant regulator of CO in the normal cardiovascular system. Afterload dominates flow regulation when the myocardium is failing. Figure 12-26 compares the contrasting effects of preload and afterload on the CO of both the healthy and failing myocardium. Acute increases (in afterload) in the healthy patient are tolerated, up to a 4-fold increase. In contrast, even small increases in afterload produce large reductions in CO when the myocardium is depressed by disease or anesthesia.¹⁶² The use of vasodilators for afterload reduction in the patient with a failing myocardium is based on this concept.

The problems associated with the earlier use of vasopressors are now recognized as having been caused, in large part, by an insufficient understanding of clinical cardiovascular physiology and the inability to monitor critically ill patients. We can now selectively detect and manipulate the weak links in the chain of cardiovascular events that produce blood flow and oxygen transport rather than the mindless increase in blood pressure. The term *vasopressor*, once synonymous with vasoconstriction, has now become a generic term for several species of drugs which, by whatever means, increase CO and may or may not increase blood pressure. Their uses in anesthesia include (1) maintenance or organ perfusion, (2) treatment of allergic reactions, (3) prolongation of the action of local anesthetics, and (4) for cardiopulmonary resuscitation.

Selection of Adrenergic Effect

The selection of vasoactive drugs requires a knowledge of both the hemodynamic disturbance and pharmacology of the available drugs. The catecholamines and sympathomimetic drugs continue to be the pharmacologic mainstay of cardiovascular support for the low-flow state.³² Sustained interest in the catecholamines is related to their predictable pharmacodynamics and favorable pharmacokinetic profiles. Their effects are linearly related to plasma levels, which are directly and linearly related to the rate of infusion. There are few clinical surprises within any given dose range and the pharmacokinetics of catecholamines allow rapid titration to the effect. The half-life of most is short, ranging from 2 to 3 minutes. Undesirable side-effects dissipate within minutes of lowering or stopping the infusion. Sympathomimetics, as a group, produce a wide range of hemodynamic effects and can be used in combination to achieve a yet wider spectrum of effects. As a result, one need become familiar with but a few agents to manage most clinical situations.

The goal for managing the low-output syndrome is to establish and maintain adequate tissue perfusion. Aggressive fluid therapy will suffice in most instances. Sympathomimetics are not a substitute for volume. However, once intravascular volume is optimized, a vasoactive drug may be required to sustain CO. During the early 1990s the term *inodilator* entered our lexicon to supplant the more archaic term *vasopressor*. This neologism reflects a change in philosophy in managing low-flow states, particularly those characterized by heart failure. The new synthetic sympathomimetics have been chemically engineered to obtain inotropism and vasodilation rather than pressor effects. The potential for benefit or harm can best be understood in terms of receptor characteristics. For example, activation of the inotropic β_1 and β_2 receptors results in positive inotropism and chronotropism. Selective stimulation of the vascular β_2 receptors causes vasodilatation. Left ventricular outflow may improve as a function of increased afterload reduction and inotropism. However, chronotropism may not be a desirable feature in a patient with mitral stenosis or coronary artery disease.

CATECHOLAMINE RECEPTOR-EFFECTOR COUPLING

The net physiologic effect of a sympathomimetic is usually defined as the algebraic sum of its relative actions on the α , β , and DA receptors.³³ Most adrenergic drugs activate or block these receptors to varying degrees. Each catecholamine has a distinctive effect, qualitatively and quantitatively, on the myocardium and peripheral vasculature. Table 12-13 demonstrates the relative potency of the adrenergic amines on the various myocardial and vascular receptors. This relative potency is also dose-related, adding yet another variable. The use of pluses (+) or zeros (0) is the classical method by which the relative sensitivities of catecholamine-receptor coupling are demonstrated. The plus sign is also symbolic, suggesting the apparent summation effect of the catecholamines on the receptors. The summation effect further implies a finite number of adrenergic receptor sites to which adrenergic agonists can compete.

| Sympathetic activity | Receptor | | | | | | Dose Dependence (a, b, or DA) | Comments |
|----------------------|------------|------------|-----------|-----------|-----|-----------------|---|----------|
| | α_1 | α_2 | β_1 | β_2 | DA | DA ₂ | | |
| Isoproterenol | ++++ | + | 0 | 0 | 0 | 0 | Nonselective only | |

*The clinical significance of the effects of agonism and antagonism is not yet known.

Table 12-13. ACTIONS OF ADRENERGIC AGONISTS

For many years, the focus on catecholamines was devoted, almost entirely, to their actions on the myocardium and on arteriolar resistance vessels. Changes in venous resistance contribute little to total vascular resistance and blood pressure. However, small changes in venous capacitance result in large changes in venous return because 60–70% of the circulating blood volume is the venous circulation.^{107,163} The effect of the sympathomimetic amines on the venous circulation appears to be distributive in that acute venular constriction increases the central blood volume (preload), whereas dilatation decreases venous return by the promotion of peripheral pooling.^{164,165} The distributive effect of a catecholamine may be as important as its inotropic action and more important than its arteriolar effect.^{23,166} Further definition should elucidate some of the complex and confusing data generated when clinical observations are limited solely to adrenergic effects on the myocardium and arteriolar vasculature.

Intravenous and intra-arterial infusions of EPI in humans have been shown to cause marked constriction of the veins. Arteriolar vasoconstriction precedes venoconstriction; however, SV does not increase until the onset of venoconstriction. The initial increase in CO seen with the infusion of EPI is more an effect of increased preload than an arteriolar or direct cardiac effect.¹⁶⁷ NE produces a similar effect, but the onset of venoconstriction is slower.

A differential ability of the amines to constrict veins has been noted in animals.¹⁶⁸ The data are expressed as the average percentage contribution of venous resistance to total change in vascular resistance (Table 12-14). Methoxamine and NE are considered equipotent α_1 arteriolar vasoconstrictors; however, these effects differ dramatically from their effects on venoconstriction. The lack of venoconstrictor response to methoxamine has been demonstrated in humans.

| Agent | $\Delta VR/\Delta TR \times 100$ |
|----------------|----------------------------------|
| Norepinephrine | 13.8 |
| Tyramine | 8.0 |
| Metaraminol | 7.2 |
| Ephedrine | 3.3 |
| Mephentermine | 1.9 |
| Phenylephrine | 1.8 |
| Methoxamine | 1.4 |

Table 12-14. AVERAGE PERCENTAGES OF CONTRIBUTIONS OF INCREMENTS IN VENOUS RESISTANCE TO INCREMENTS IN TOTAL RESISTANCE (DVR/DTR \times 100)

A similar study in humans found similar results.¹⁶⁹ Table 12-15 demonstrates relative potencies of several catecholamines on resistance versus capacitance vessels. These data represent only the relative potencies of the amines within either resistance or capacitance vessels and are not a comparison of potency ratio between the two. Nevertheless, the data point out the marked differences between the agents. NE is the most potent amine with respect to arteriolar and venous constriction. Metaraminol is 1.5 times more potent than phenylephrine in constricting resistance vessels; however, phenylephrine is 1.5 times more effective in constricting capacitance vessels than metaraminol. NE proved to be 12 times more potent than metaraminol in constricting resistance vessels and 24 times more effective in constricting capacitance vessels.

| Resistance Vessels | | Capacitance Vessels | |
|--------------------|------------------|---------------------|------------------|
| Drug | Relative Potency | Drug | Relative Potency |
| Norepinephrine | 1.0000 | Norepinephrine | 1.0000 |
| Metaraminol | 0.0674 | Phenylephrine | 0.0570 |
| Phenylephrine | 0.0684 | Metaraminol | 0.0419 |
| Tyramine | 0.0148 | Methoxamine | 0.0068 |
| Mephentermine | 0.0049 | Ephedrine | 0.0025 |

Table 12-15. RELATIVE POTENCIES OF SEVERAL SYMPATHOMIMETIC AMINES IN HUMANS WITH RESPECT TO CONSTRICTOR EFFECTS ON RESISTANCE VESSELS AND CAPACITANCE VESSELS

Brown *et al.*¹⁷⁰ reported the responses of resistance and capacitance vessels to catecholamines in humans on cardiopulmonary bypass. This is a unique method of examining hemodynamic drug response because flow rate (CO) is fixed, excluding the myocardial effects of the drugs. Changes in resistance or capacitance are reflected as either changes in pressure or changes in reservoir volume, respectively. The α_1 agonist phenylephrine produced a marked decrease in venous capacitance (venoconstriction). Arteriolar resistance increased also, but to a lesser degree, confirming the study by Schmid *et al.*¹⁶⁹ Dopamine produces significant venoconstriction at doses that have no direct arteriolar or cardiac effect, confirming studies of dopamine in animals^{166,170,171} (Fig. 12-27).

Figure 12-27. The spectrum of dose-related adrenergic activity of dopamine is demonstrated. Progressive rates of infusion produce dopaminergic (DA), b_1 , then a_1 activity. Infusion rates of greater than $15 \mu\text{g} \cdot \text{kg}^{-1} \text{min}^{-1}$ produce a predominant a_1 effect, like that of NE. Early a_1 venoconstriction may be an important redistributive feature of infused dopamine.

De Mey and Vanhoutte⁶⁴ compared the effects of sympathetic agonists on rings of arterial and venous vessels from dogs. Their data were similar to the information in Table 12-15. NE was the most potent arterial and venous constrictor, and relative sensitivity of the arterioles to phenylephrine and methoxamine was also similar. Their study demonstrated that the differences in response between veins and arteries lay in the uneven distribution of postjunctional α_1 and α_2 receptors. Their results indicate the presence of both receptors on venous smooth muscle, whereas arterial smooth muscle cells contain mainly postjunctional α_1 receptors.

Table 12-16 is a summary of the available data on the relative potencies of the amines on the α receptors of the resistance and capacitance vessels. Scant data permit inaccuracies, but the table is derived from sources that demonstrate remarkable consistency. It is offered as a clinical guide to drug selection. The peripheral receptors of both resistance and capacitance vessels subserve vasoconstriction, but with divergent effects on afterload and preload; therefore, the α_1 receptors have been subdivided into α_{1a} arterial (α_{1a}) and α_{1v} venous (α_{1v}). Note that methoxamine and phenylephrine, both pure α drugs, are equipotent arterial vasoconstrictors. Phenylephrine, however, is a potent venous constrictor, and methoxamine has virtually no effect on the capacitance vessels. Dopamine has potent venoconstrictor (α_{1v}) effect at doses at which few α_{1a} or b_1 effects are noted.

| | Vasoconstriction | |
|----------------|--|--|
| | α_{1a} Arterial (α_{1a}) | α_{1v} Venous (α_{1v}) |
| Norepinephrine | +++++ | +++++ |
| Metaraminol | +++++ | +++++ |
| Phenylephrine | +++++ | +++++ |
| Methoxamine | ++++ | +++ |
| Epinephrine | +++++ | +++++ |
| Dopamine | +++++ | +++ |

Table 12-16. COMPARISON OF RELATIVE α_1 CATECHOLAMINE RESPONSES ON PERIPHERAL RESISTANCE AND CAPACITANCE VESSELS*

Drug Dosage and Adverse Effects

The major adverse effects of the sympathomimetic amines are related to excessive a or b activity. The potential for harm can be understood in terms of receptor characteristics. Excessive b_1 activity may increase contractility but increase HR and myocardial oxygen consumption beyond supply. Severe dysrhythmias frequently accompany excess b_1 activity as a result of increased conduction velocity, automaticity, and ischemia. The b_2 activity has the potential to increase CO by reducing resistance (afterload) while reducing blood pressure. An excessive decrease in diastolic pressure, however, reduces obstructive coronary perfusion and may further aggravate myocardial ischemia. The b_1 and b_2 effects of adrenergic agonists are more useful clinically than α_1 effects and can be used for longer periods of time. Unfortunately, it is difficult to separate the inotropic, dromotropic, and chronotropic effects in the clinical setting. The characteristics of the ideal positive inotropic agent are listed in Table 12-17 for comparison with each drug as it is discussed.

side-effects of any inotropic agent become critical to selection because all are multireceptor agonists.

Myocardial failure exists when the heart cannot pump enough blood to meet metabolic needs. The clinical manifestations of heart failure result from peripheral circulatory derangements that are the result of the heart's forward output lagging behind the input. Venous pressure increases and produces congestion. There are marked differences between chronic heart failure, whatever the cause, and acute failure from infarction. These differences are now fully appreciated.¹⁷⁷ Patients with chronic heart failure have retention of sodium and water and are typically hypervolemic, whereas patients with acute heart failure are either normovolemic or commonly hypovolemic. Cardiomegaly is a common compensatory feature of chronic heart failure but is absent with acute heart failure. Circulating catecholamines and myocardial catecholamine content are decreased in chronic failure but markedly elevated in the acute infarct. Thus, the response to inotropic drugs in chronic heart failure is influenced not only by the lack of myocardial catecholamine stores but also by downregulation of β receptors. The CO in chronic failure is borderline to decreased, whereas it is usually normal or elevated with acute failure as a result of the compensatory mechanism.

Acute failure is the most common complication of infarction, occurring in 40–50% of patients, which reflects a 20–25% involvement of the myocardium. In contrast to the patient with chronic heart failure, this dysfunction is usually transient, lasting from 48 to 72 hours. Drugs with a predominant inotropic action are used alone or in combination to acutely improve cardiac contractility. Therefore, it is a major concern that myocardial damage not be extended during this transient period by inappropriate inotropic or chronotropic support. This is not as major a concern in the patient with hypertrophy, in whom increased inotropism may actually reduce oxygen consumption by reducing ventricular mass.

Table 12-18 presents one approach to the management of cardiogenic shock listed in order of relative importance. The use of sympathomimetic support is placed in proper perspective. It emphasizes the essential role that invasive hemodynamic monitoring and volume management play in confirming a diagnosis of cardiogenic failure. Although volume expansion and reduction of afterload may improve CO, other pharmacologic interventions may still be necessary to optimize CO and its distribution. Invasive monitoring is a prerequisite for the rational use of the vasoactive drugs to (1) establish that a sympathomimetic is necessary, (2) select drugs for the hemodynamic condition, (3) follow resultant hemodynamic changes because many of the beneficial effects of the catecholamines are hidden to the clinical eye, and (4) avoid complications of pressor therapy that are visible to all. Drug selection for the low-output state remains the most enigmatic.

1. Assure adequate ventilation and oxygenation
2. Relieve pain and symptoms of recurrent ischemia
3. Institute hemodynamic monitoring (pulmonary artery, pulmonary capillary wedge, and arterial pressures, urine output, cardiac output)
4. Optimize left ventricular filling pressure
5. Correct metabolic abnormalities
6. Control dysrhythmias (2 priority if life-threatening)
7. Pharmacologic support
 - a. Vasodilators
 - b. Inotropic drugs
 - c. Diuretics—chronic heart failure
8. Rule out "correctable" causes of shock (septal or left ventricle rupture, mitral regurgitation, acute aneurysm)
9. Mechanical support of circulation
10. Surgical correction if possible

Note: Hemodynamic monitoring is essential in confirming a diagnosis, optimizing filling pressures and cardiac output, selecting pharmacologic support, and avoiding complications. Adjustment of left ventricular filling pressure may require additional volume or a relative volume reduction with vasodilators. The diagnostic criteria for cardiogenic shock are not met until step 4 is accomplished.

Table 12-18. MANAGEMENT OF LOW OUTPUT SYNDROME CAUSED BY MYOCARDIAL DYSFUNCTION

Table 12-19 is a summary of the hemodynamic effects of some of the currently popular and once popular sympathomimetic drugs. Many of the hemodynamic effects are dose-related. The dose ranges are listed and a standard infusion rate cited. Standard rates of infusion are simply guidelines, and the actual dose administered should be determined by patient response.

| Drug | Dose Range | Standard Infusion Rate | Primary Effect | Secondary Effect | Other Effects |
|----------------|------------------------------|------------------------------|----------------|------------------------|------------------------|
| Dopamine | 2–10 $\mu\text{g/kg/min}$ | 2–10 $\mu\text{g/kg/min}$ | Inotropic | Arteriole dilation | Renal vasodilation |
| Norepinephrine | 0.1–1 $\mu\text{g/kg/min}$ | 0.1–1 $\mu\text{g/kg/min}$ | Pressor | Arteriole constriction | Renal vasoconstriction |
| Epinephrine | 0.1–1 $\mu\text{g/kg/min}$ | 0.1–1 $\mu\text{g/kg/min}$ | Pressor | Arteriole constriction | Renal vasoconstriction |
| Methoxamine | 0.1–1 $\mu\text{g/kg/min}$ | 0.1–1 $\mu\text{g/kg/min}$ | Pressor | Arteriole constriction | Renal vasoconstriction |
| Phenylephrine | 0.1–1 $\mu\text{g/kg/min}$ | 0.1–1 $\mu\text{g/kg/min}$ | Pressor | Arteriole constriction | Renal vasoconstriction |
| Isoproterenol | 0.5–2 $\mu\text{g/kg/min}$ | 0.5–2 $\mu\text{g/kg/min}$ | Inotropic | Arteriole dilation | Renal vasodilation |
| Albuterol | 0.1–0.2 $\mu\text{g/kg/min}$ | 0.1–0.2 $\mu\text{g/kg/min}$ | Inotropic | Arteriole dilation | Renal vasodilation |
| Dobutamine | 2–10 $\mu\text{g/kg/min}$ | 2–10 $\mu\text{g/kg/min}$ | Inotropic | Arteriole dilation | Renal vasodilation |

Table 12-19. DOSE SCHEDULE AND HEMODYNAMIC EFFECTS OF THE ADRENERGIC AGONISTS

Methoxamine and Phenylephrine

Methoxamine is the prototypical pure vasoconstrictor. Phenylephrine produces similar actions, but there are important clinical differences. Methoxamine possesses only α_1 properties and produces almost no venoconstriction. Its only pharmacologic effects are to increase arterial resistance, increase afterload, and reduce flow, even though blood pressure is elevated. Few clinical uses for methoxamine remain except for cardiopulmonary resuscitation (CPR). It has been useful for treating paroxysmal atrial tachycardias. A single iv dose of methoxamine can break a paroxysmal atrial tachycardia reflexly through baroreceptor stretch, obviating the need for digitalis or countershock. Carotid massage produces similar results by a similar mechanism.

Phenylephrine, considered a pure α drug, increases venous constriction more than arterial constriction in a dose-related manner similar to dopamine.^{170,178} Venous constriction may be its most redeeming feature when compared with the purely arteriolar effect of methoxamine. One cannot discount the possibility of an inotropic effect now that α_1 receptors are known to exist in the myocardium that improve inotropism. Acutely, venoconstriction favors venous return (preload), even though arterial resistance (afterload) also increases. The net effect may result in an increase in pressure and flow. Phenylephrine, like methoxamine, does not change CO in normal individuals but can cause a decreased output in patients with ischemic heart disease.^{35,162,179} It is rarely necessary to give a pure α pressor for extended periods, but phenylephrine has continued to be favored in operating rooms to sustain pressure during cardiopulmonary bypass as well as during intracranial and peripheral vascular procedures.¹⁸⁰ It does not produce dysrhythmia as a direct effect. Phenylephrine is also useful in reversing right-to-left shunt in tetralogy of Fallot when patients are having "spells" during anesthesia.²² The arterial vasoconstrictors may reduce the size of an ischemic injury when used in conjunction with intra-aortic balloon pumping or nitroglycerin.¹⁸¹

Norepinephrine

NE and metaraminol produce similar hemodynamic effects. NE is the naturally occurring mediator of the SNS and the immediate precursor of EPI. It produces direct-acting hemodynamic effects on the α and β receptors in a dose-related manner when given by infusion. NE produces increased CO and blood pressure when given in low doses (see Table 12-19), primarily as a result of predominant action at this level.¹⁸² Higher doses reduce flow because a arteriolar constriction supersedes the β effects. Reflex bradycardias may occur, as with methoxamine and phenylephrine, despite active β stimulation.

Increased plasma levels of the endogenous catecholamines NE and EPI are the sympathetic milieu in which exogenous sympathomimetics are ordinarily given. NE is the catecholamine standard against which all other catecholamines are compared. It is the endogenous neurotransmitter of the SNS. Over the years NE administered iv has gained an unseemly reputation that is perhaps unmerited.¹⁸³ Current studies indicate that NE is being used in doses that are orders of magnitude greater than that necessary to obtain its best response. Complications such as renal failure and tissue necrosis are routine and can be expected when NE is used in this manner. Personal experience and the published experience of others also indicate that if an infusion of NE is used simply to titrate to blood pressure rather than measured flow, the amount of NE infused is 5–10 times higher than necessary to obtain the best oxygen delivery and oxygen consumption.^{6,184,185} Most published dose infusion rates are based on blood pressure titration, and hence are too liberal. Although NE is less commonly used in the critically ill patient than other catecholamines, a resurgence

of interest in this agent is noted in the literature. It has remained clinically useful because its effects are predictable, prompt, and potent.^{186,187}

Objections to the use of NE (or metaraminol) for the treatment of cardiogenic shock are based on two considerations: (1) vasoconstriction increases the pressure work of the left ventricle, with an adverse effect on the oxygen economy of the already ischemic pump; (2) these drugs cause further vasoconstriction and organ ischemia in a syndrome in which intense constriction may already have occurred.³⁵ The use of NE requires invasive monitoring; otherwise, complications are to be expected. It is not usually necessary to elevate the systolic blood pressure above 90–100 mm Hg. At this level of infusion, the CO will normally be increased as a β effect without excessive peripheral vasoconstriction. NE is a potent venoconstrictor, which should alter interpretation of venous filling pressures as a guide to adequate volume repletion.

NE may also not be effective initially in patients who are receiving catechol depleters. Other undesirable effects associated with the use of NE include renal arteriolar constriction and aggravation of oliguria. In addition, prolonged therapy may produce a reduction in plasma volume as a result of fluid transudation at the capillary level. Indeed, in some instances, cardiogenic shock requiring continuous NE infusions has been reversed by fluid infusions.³⁵ The use of the minimal effective dose NE in combination with careful invasive monitoring and attention to fluid management is the only way to avoid iatrogenic disasters. Norepinephrine should only be administered in a centrally placed iv line to avoid tissue necrosis from extravasation. It can be used for its inotropic effect at low doses and titrated to effect while monitoring cardiac output. Monitoring of blood pressure alone, or titrating to a predetermined effect, is often detrimental to cardiac output. Blood pressure increases are usually due to increases in SVR and can diminish forward flow and contribute to cardiac failure. Even moderate doses of NE may have a detrimental effect on end-organ perfusion—hence the drug's ill-gotten reputation when used to titrate to pressure rather than flow. However, in clinical conditions characterized by a low perfusion pressure, high flow (vasodilatation), and maldistribution of flow, NE has been shown to improve renal and splanchnic blood flow by increasing pressure, provided the patient has been volume-resuscitated.

Epinephrine

EPI is the prototypical endogenous catecholamine. It is synthesized, stored, and released from the adrenal medulla and is the key hormonal element in the fight-or-flight response. The most widely used catecholamine in medicine, EPI is used to treat asthma, anaphylaxis, cardiac arrest, and bleeding and to prolong regional anesthesia. The cardiovascular effects of EPI, when given systemically, result from its direct stimulation of both α and β receptors. This is dose-dependent, as outlined in [Table 12-19](#).

The effect of EPI on the peripheral vasculature is mixed.^{188,200} It has predominantly α -stimulating effects in some beds (skin, mucosa, and kidney) and β -stimulating actions in others (skeletal muscle). These effects are also dose-dependent. At therapeutic doses, β -adrenergic effects predominate in the peripheral vessels, and total resistance may be reduced. Constriction, however, is maintained in the renal and cutaneous areas owing to its dominant α effect in these areas. An increase in CO with EPI may be due to a redistribution of blood to low resistance vessels in the muscle, but with further reduction in flow to vital organs. Cardiac dysrhythmias are a prominent hazard, and the strong chronotropic effects of EPI have limited its use or systematic investigation in the treatment of cardiogenic shock.

EPI is commonly used in the perioperative period in anesthesia by surgeons and anesthesiologists. It is often used to produce a bloodless field in dentistry, otolaryngology, and skin grafting, either topically or in local and field blocks. Anesthesiologists often use it to prolong regional anesthesia. The addition of EPI to arthroscopic infusions to attain a bloodless field is another area of increased EPI usage. These infusions are usually safe in maintaining a dry operative field because the solutions are very dilute at ~1:3,000,000. However, the large volumes infused and the unpredictable absorption of the epinephrine, especially in denuded cancellous bone, may expose the patient to an excessive amount of epinephrine over a short period of time despite the dilution.¹⁸⁹ The unexpected complications are those of epinephrine overdose: acute heart failure, pulmonary edema, or cardiac arrhythmias and arrest in the otherwise young and healthy patient. Impending problems during the infusion of intra-articular fluids will be noted by an increasing blood pressure exceeding that attributable to surgical pain or hypertension that is poorly responsive to deepening of anesthesia. Absent a pulsatile flow, oximetry may become dysfunctional. The patient will appear pale and cyanotic. Unless alert, one may unintentionally treat an unexpected acute heart failure or cardiac arrest with the very agent that caused the problem. The outcome is universally poor. Vasodilators and β blockers may save the day instead.

Some volatile anesthetics sensitize the myocardium to circulating catecholamines and induce cardiac dysrhythmias. This is especially true in the presence of hypoxia and hypercarbia. Halothane has the most pronounced cardiac-sensitizing action of the volatile anesthetics in use today. The mechanism has been thought to be related to the stimulation of α - and β -adrenergic receptors because blockade of these receptors consistently abolishes these cardiac dysrhythmias.¹⁹⁰ However, calcium channel blockade is equally effective.¹⁹¹ This is not surprising if the shared final pathway of β and calcium-entry blockade proves to be correct.¹⁹² The exact mechanism is further confused by studies showing that the myocardial depression produced by the volatile anesthetics is related to blockade of the slow calcium current.¹⁹³ These findings are compatible with the observations that β blockade, calcium blockade, and general anesthetics produce myocardial depression.

Intravenous and locally infiltrated adrenergic agents should be used cautiously during inhalation anesthesia, especially with halothane. The following schedule has been found to be relatively safe during halothane anesthesia:¹⁹⁴

1. EPI concentrations no greater than 1:100,000–1:200,000 ($1:200,000 = 5 \mu\text{g} \cdot \text{ml}^{-1}$);
2. adult dose no greater than 10 ml of 1:100,000 or 20 ml of 1:200,000 within 10 min;
3. total no greater than 30 ml of 1:100,000 (60 ml of 1:200,000) within 1 hour.

The doses of submuscularly injected EPI necessary to produce ventricular cardiac dysrhythmia in 50% of patients anesthetized with a 1.25 MAC of a volatile anesthetic were 10.9, 10.9, and 6.7 $\mu\text{g} \cdot \text{kg}^{-1}$ during administration of halothane, enflurane, and isoflurane, respectively.¹⁹⁵ The incidence of cardiac dysrhythmia is eliminated when this dose is halved in patients anesthetized with halothane or isoflurane. Unlike adults, children seem to tolerate higher doses of subcutaneous EPI without developing cardiac dysrhythmia.¹⁹⁶

Ephedrine

Ephedrine is one of the most commonly used noncatecholamine sympathomimetic agents. It is used extensively for treating hypotension following spinal or epidural anesthesia. Ephedrine stimulates both α and β receptors by direct and indirect actions. It is predominantly an indirect-acting pressor, producing its effects by causing NE release.³⁵ Tachyphylaxis develops rapidly and is probably related to the depletion of NE stores with repeated injection. The cardiovascular effects of ephedrine (see [Table 12-19](#)) are nearly identical to those of EPI but less potent.^{32,33} Its effects are sustained about 10 times longer than those of EPI.

Ephedrine remains the pressor of choice in obstetrics because uterine blood flow improves linearly with blood pressure.^{112,113} This effect is probably not related to its arteriolar vasoconstriction but rather to its venoconstrictive action. Ephedrine is a weak, indirect-acting sympathomimetic agent that produces venoconstriction to a greater degree than arteriolar constriction (see [Table 12-16](#)).^{164,178} This may be its most important and unappreciated effect. It causes a redistribution of blood centrally, improves venous return (preload), increases CO, and restores uterine perfusion. The mild β action restores HR simultaneously with improved venous return. An increased blood pressure is noted as a result rather than a cause of these events. Mild α_1 -arteriolar constriction does occur, but the net effect of improving venous return and HR is increased CO ([Fig. 12-29](#)). Uterine blood flow is spared. This response, however, depends on the patient's state of hydration.

Figure 12-29. Stroke volume (SV), end-diastolic volume (EDV), and systemic vascular resistance (SVR) (1) before regional block, (2) during hypotension, and (3) after therapy with ephedrine or phenylephrine. The increase in stroke volume was related entirely to an increased venous return secondary to venoconstriction in these awake, healthy patients. The afterload effects of phenylephrine at higher doses predominate in patients with heart disease or myocardial depression and reduce CO. (Reprinted with permission from Ramanathan S, Grant G: Vasopressor therapy for hypotension due to epidural anesthesia for cesarean section. *Acta Anaesthesiol*

Dopamine is an attractive alternative vasopressor for obstetrics for similar reasons. It produces strong α_1 vasoconstriction and volume redistribution at infusion rates for which α_{1a} or β effects are minimal (Fig. 12-27). The primary disadvantage of dopamine is its lack of immediate availability as an iv push drug. It requires more careful titration than ephedrine. The prophylactic administration of ephedrine before spinal blockade in obstetrics can produce misleading clinical estimates of volume status because of its effects on venous return and arterial pressure.

Dopamine, Dopaminergic Agonists, and Prodrugs

Dopamine

Dopamine offers distinct advantages over many sympathomimetics in treating the low-output syndrome.⁷¹ It is a dose-related agonist to all three types of adrenoceptors, and the desired action can be selected by changing the infusion rate. The DA receptors are most sensitive, followed by the β , and then α receptors. However, DA possesses a unique property not found with other catecholamines: it dilates renal and mesenteric vascular beds as a direct effect of its DA receptor effect. The β receptors present in the renal vasculature are not involved with DA-induced vasodilatation.

Dopamine dosage regimens have been traditionally, and arbitrarily, divided into low, medium, and high doses according to its dose-receptor sensitivity (Table 12-19). Renal and mesenteric vascular dilatation and tubular cell natriuresis are mediated through the DA receptors at low-dose infusion rates of $0.5\text{--}2.0 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. This is often referred to as "renal dose dopamine" because of the enhanced renal blood flow and diuresis. The diuresis may also be attributed, in part, to inhibition of aldosterone secretion seen with low-dose DA administration.¹⁹⁷ A general improvement in CO from afterload reduction also contributes to improvements in renal blood flow. These effects have been well demonstrated in patients with heart failure. However, the protective effect of DA on the development of renal failure in the critically ill or injured patient, although an attractive principle, is much less certain. Prevention of renal failure by prophylactic "renal dose" DA (with or without furosemide) in the critically ill or traumatized patient has not been conclusively demonstrated, even when used early.¹⁹⁸ This may be related to the adrenergic milieu into which the DA is given. The vasoconstrictive effects of DA are expected to occur only at relatively high doses. However, even relatively low doses of DA can cause renal vasoconstriction when added into pre-existing high plasma levels of endogenous catecholamines^{197,199} commonly seen in the acutely injured patient.

The hemodynamic effects of low-dose DA are primarily related to vasodilatation by activation of the DA_1 and DA_2 receptors. Activation of presynaptic DA_2 adrenoceptors add to the vasodilating effect of the DA_1 receptors by inhibiting presynaptic NE release in the renal and mesenteric vessels. The reduction of total systemic vascular resistance would be significant, considering that 25% of the CO goes to the kidneys alone (Fig. 12-30). A reduced diastolic blood pressure is often noted with a slight reflex increase in HR. Increasing the infusion rate of DA to $2\text{--}5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ begins to activate β receptors, increasing the CO by increasing chronotropism and contractility with early vasoconstriction (preload) and systemic vasodilatation (afterload reduction). Blood pressure may not increase despite significant increases in CO. This dose range would appear optimal for managing congestive heart and lung failure because it combines inotropism and afterload reduction with diuresis. Further increases in dose activate α receptors, which will increase vascular resistance and blood pressure, but further improvements in CO may be attenuated. Infusion rates greater than $10 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ produce intense α activity, which may override any beneficial DA or β vasodilation effect on total flow. High-dose dopamine behaves much like NE and, in fact, causes NE release at this dose range.²⁰⁰

Figure 12-30. Dobutamine produces a net reduction in vascular resistance. Its weak vasoconstrictive effects are balanced by a direct β_2 vasodilation with little change in vascular tone. However, further reflex arterial vasodilation occurs with increased CO. Low-dose dopamine dilates renal and mesenteric arterial beds, which reduces afterload but increases resistance at increasing doses as a result of its predominant α effect.

Despite the apparent dose-response divisions of DA, a wide variability of individual responses has been noted. The α -adrenergic effects can be seen in some individuals in doses as low as $5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, whereas doses as high as $20 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ may be required to obtain this effect in shocked patients.²⁰⁰ This wide variation in dose-response has led to a re-examination of DA as a primary adrenergic for patients in cardiogenic shock or failure. Increased venous return may not be desirable in this situation, but dopamine's hemodynamic versatility continues to be useful in cardiogenic shock when combined with other complementary catecholamines such as dobutamine (Fig. 12-31) (see combinations). The vasoconstriction or distributive effects of dopamine are useful in surgical patients in whom third-space edema and sepsis are the most common abnormalities. Dopamine increases mean pulmonary arterial pressure and is not recommended for sole support in patients with right heart failure, adult respiratory distress syndrome, or pulmonary hypertension.

Figure 12-31. A decrease in venous capacitance has been demonstrated as an early effect of dopamine. An increase in pulmonary capillary wedge pressure may be noted. Dobutamine may decrease pulmonary capillary wedge pressure by increased inotropism as well as vasodilation with minimal effect on venous capacitance. (Redrawn with permission of Eli Lilly Co., Indianapolis, Indiana.)

Dopexamine

Dopexamine (DPX) is a "designer" catecholamine that was developed in an attempt to overcome some of the disadvantages of DA in managing cardiogenic low-flow states.²⁰¹ Afterload reduction and renal vasodilatation were desirable, but a drug was needed that did not increase myocardial oxygen consumption, or provoke arrhythmias, and whose actions could be sustained for long periods. DPX is a short-acting ($t_{1/2b} = 7 \text{ min}$) iv analog of DA with predominantly β_2 and DA_1 receptor agonist activity. Post-surgical patients and those with a low output show a slightly extended elimination half-life of 11 minutes. This light prolongation is not expected to cause clinical problems. It also inhibits the direct neuronal reuptake of NE. DPX provides mild positive inotropism with systemic and renal vasodilatation through its

predominant receptor agonism. DPX has no direct b_1 or a_1 agonist activity like that possessed by DA.²⁰² It is considered an inodilator, although its inotropic actions are weak, lacking any b_1 activity except that produced by reduced NE uptake. The predominant inotropic activity is from its b_2 effect. The summed effects of DPX are due to afterload reduction *via* renal and mesenteric vasodilatation (DA_1 and b_2 receptor activation), positive inotropism (myocardial b_2 activation and reduced NE uptake), and natriuresis (DA_1 tubular receptors).²⁰³

The relative potency of DPX on the DA_1 and DA_2 receptors is only 0.3 and 0.17, respectively, than that of DA. It is 60 times more potent on b_2 receptors than DA. Downregulation of myocardial b_1 receptors occurs with chronic heart failure, but the b_2 subpopulation is preserved. This profile has the potential to be useful as an adjunct in increasing CO in patients with chronic heart failure because the myocardial b_2 subpopulation is preserved while the b_1 receptors are downregulated. However, adjunct inotropic agents will likely be required to realize the full benefits of its vasodilating DA_1 and b_2 properties.⁶¹

Doses of $2 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ will augment inotropism while significantly increasing visceral blood flow.^{201,204,205} DPX has been reported to improve renal function to a greater extent than could be attributed to an increased CO alone.²⁰⁶ Animal studies indicate that DPX has been effective in restoring renal function to control levels following acute renal failure. However, the efficacy of DPX in preventing renal failure in humans, as in the case of dopamine, is less conclusive. DPX is a less potent direct renal vasodilator than DA. The relative contributions of dopaminergic versus b_2 receptor activation in improving renal and mesenteric blood flow has been questioned. Stephan *et al* could not demonstrate DA_1 activity of DPX in patients undergoing elective coronary artery bypass.²⁰⁷ Gray found DPX at least as effective as DA for renal protection in patients undergoing liver transplantation, and Jamison *et al* were unable to demonstrate any increase in renal blood flow in patients in chronic congestive heart failure.^{208,209}

The infusion rate for effective doses of DPX ranges from 0.5 to $5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ depending upon the pathology. In the treatment of acute heart failure in patients following cardiac surgery DPX should be infused iv at an initial dose of $0.5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.²¹⁰ It can be titrated upward in dosage increments of $1.0 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ according to hemodynamic response to a maximum of $6.0 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.²¹¹ Infusion rates exceeding $6 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ can cause an intolerable tachycardia and angina in patients with pre-existing ischemic heart disease.²¹² DPX inhibits hypoxic pulmonary vasoconstriction by activation of b_2 receptors. This profile has proved beneficial in both short- and long-term management of pulmonary hypertension.²¹³ DPX appears to be a promising catecholamine, but experience with its use in the critically ill has been limited. Its ultimate value for prolonged administration remains to be established.

Fenoldopam

Fenoldopam, a benzazepine derivative, is a selective DA_1 agonist with no a - or b -receptor activity compared to dopamine or dopexamine.^{200,214,215} Oral bioavailability is poor, but it is an effective antihypertensive when given iv. The oral medication is no longer available but the iv drug is now available. Intravenous fenoldopam promotes natriuresis, diuresis, and an increase in creatinine clearance. It may offer some advantages in the acute resolution of severe hypertension, particularly if the patient has pre-existing renal impairment. Preservation or augmentation of renal blood flow during blood pressure reduction presents a potential for use during several situations in the perioperative period. Fenoldopam has an elimination half-life of 5 minutes. This property might well lend itself to producing hypotensive anesthesia while preserving renal function.²¹⁶ Aronson *et al* reported a comparative study using SNP and fenoldopam in dogs under general anesthesia. A 30% reduction in mean arterial pressure was produced by either fenoldopam or SNP. Fenoldopam maintained renal blood flow while SNP showed a reduction.^{214,216,217}

Human studies have since demonstrated that fenoldopam is a potent direct renal vasodilator. It appears to improve renal function while lowering blood pressure in patients with pre-existing renal disease. Left ventricular function has been noted to improve with afterload reduction. Kien's study suggests that the improvement in renal function is a direct vasodilator effect of the drug.²¹⁶ Intravenous fenoldopam may prove to be ideal for treating conditions in which renal vasoconstriction is an expected complication. An example is cyclosporine-induced renal vasoconstriction.^{218,219} Brooks *et al*, using oral fenoldopam in rats, prevented acute renal vasoconstriction in the acute phase and reversed chronic nephrotoxicity.²¹⁸ These data, also using oral medication, were reproduced in human kidney transplant recipients. Few data are available regarding the use of fenoldopam in the perioperative period. However, fenoldopam would appear to be a new option in the management of perioperative renal function.^{200,220}

Bromocriptine

This compound is a selective DA_2 agonist. DA_2 agonists reduce neuronal release of NE. The magnitude of the response will be directly proportional to the background of sympathetic activity. Bromocriptine was originally found effective in humans in the treatment of Parkinson's disease and acromegaly, which can be attributed to DA_2 receptors. It also lowers blood pressure in normotensive and hypertensive individuals.

Ibopamine

This compound is an orally active prodrug that is rapidly converted into its active metabolite, epinine (*n*-methyldopamine). The pharmacologic properties of ibopamine are qualitatively similar to DA. It is a nonselective agonist of DA_1 and DA_2 receptors. Ibopamine is an effective natriuretic and diuretic in patients with congestive heart failure.

Levodopa

Levodopa has been one of the most widely used prodrugs of DA. It is the immediate precursor of DA and has been used for many years in the treatment of Parkinson's disease. It is decarboxylated (after absorption) into DA. Dose restrictions are necessary when levodopa is given alone because α -adrenergic activity can occur in higher oral doses. For this reason, it is most often combined with carbidopa, which inhibits peripheral carboxylase activity allowing therapeutic CNS levels of DA without the peripheral vascular side-effects. Oral levodopa has been used effectively in treating patients with advanced heart failure.²²¹ The effects noted are an increase in SV, decrease in vascular resistance, and little change in HR or blood pressure. The effects are similar to those noted in patients receiving low-dose DA. Decreased NE release may be a factor in producing vasodilatation.

Dobutamine

Dobutamine (DBT) is a synthetic catecholamine modified from the classic inodilator isoproterenol. Isoproterenol was, in turn, synthesized from dopamine. Variations and similarities in structure can be seen in [Figure 12-7](#). Isoproterenol, the parent drug of DBT, is a potent nonselective b_1 and b_2 agonist that increases HR and contractility while reducing vascular resistance and diastolic pressure. Deleterious side-effects include serious cardiac arrhythmias, tachycardia, and reduced coronary artery perfusion. Increased myocardial oxygen demand with only a modest improvement in CO makes isoproterenol an unattractive drug for many situations, especially ischemic heart failure. It does remain useful in the temporary management of third-degree heart block, asthma, and some forms of cor pulmonale and heart transplants.

DBT has clear advantages over isoproterenol and dopamine in many clinical situations. It acts directly on b_1 receptors but exerts much weaker b_2 stimulation than isoproterenol. It does not cause NE release or stimulate DA receptors. DBT, unlike isoproterenol or DPX, possesses weak a_1 agonism, which can be unmasked by b blockade as a prompt and dramatic increase in blood pressure.²²² Ordinarily, changes in arterial blood pressure do not occur because the mild a_1 activity is countered by the b_2 activity. DBT produces strong inotropism but with weak chronotropic or vascular effects. Increases in CO are primarily through increased inotropism and secondarily by reduced afterload.

DBT increases automaticity of the SA node and increases conduction through the AV nodes and ventricles. DBT produces less increase in HR per unit gain in CO than dopamine, but it is not devoid of chronotropic activity. Troublesome tachycardias can occur in sensitive individuals and caution should be exercised in patients with established atrial fibrillation or recurrent tachycardias. Early studies found DBT preferable to dopamine, EPI, or isoproterenol because of its lack of chronotropic effects.^{223,224} DBT increases HR more than EPI for a given increase in CO.²²⁵

DBT may decrease diastolic coronary filling pressure because of its vasodilator properties. However, many animal and human studies show improvement of ischemia and augmentation of myocardial blood flow with DBT.¹⁶⁰ It appears to produce coronary vasodilation in contrast to the constriction produced by dopamine. These studies suggest that DBT produces an overall favorable metabolic climate in the ischemic myocardium despite an increase in inotropism. Improvement is rate-limited. DBT has been used effectively to improve coronary flow to differentiate, by echocardiography, responsive or unresponsive areas of dyskinesia in patients following

myocardial infarction.²²⁶

DBT is highly controllable, with a half-life of 2 minutes. Tachyphylaxis is rare but may be noted if given over 72 hours. The net hemodynamic effects of DBT include an increase in CO, a decrease in left ventricular filling pressure, and a decrease in systemic vascular resistance without a significant increase in chronotropism at lower doses.^{227,228} It has been proved to be as effective as combined dopamine and nitroprusside in treating heart failure with infarction. It is even more effective when summed with the dopaminergic properties of DA. In contrast to dopamine, DBT seems to inhibit hypoxic pulmonary vasoconstriction. Like its parent compound isoproterenol, DBT may prove to be useful in managing right ventricular failure as well.

Isoproterenol

Isoproterenol is a potent balanced β_1 - and β_2 -receptor agonist with no vasoconstrictor effects. It increases HR and contractility while decreasing systemic vascular resistance. Although it can increase CO, it is not useful in shock because it redistributes blood to nonessential areas by its preferential effect on the cutaneous and muscular vessels.¹⁷⁴ As a result, it produces variable and unpredictable results on CO and blood pressure in patients with cardiogenic shock. Isoproterenol is a potent dysrhythmogenic drug and extends myocardial ischemic areas. Deleterious effects on an evolving ischemic process include cardiac dysrhythmias, tachycardia, and reduced diastolic coronary perfusion pressure and time. Increased myocardial oxygen demand with but modest hemodynamic improvement makes it an unattractive drug for patients in shock, especially after acute myocardial infarction.

Isoproterenol is helpful in managing cardiac failure associated with bradycardia, asthma, and cor pulmonale. It is also a useful chemical pacemaker in third-degree heart block until an artificial pacemaker can be inserted or the cause can be removed. Isoproterenol might be useful in treating both idiopathic and secondary pulmonary hypertension.^{34,35} It has also been reported as useful in improving the forward flow in patients with regurgitant aortic valvular disease, but it should not be used if there is an accompanying stenosis.^{181,182}

COMBINATION THERAPY

Dopamine and DBT are the two most popular primary inodilators in use today. A comparison of these two drugs will underscore the importance of the extracardiac side-effects in selecting a drug either for use alone or in combination.²²⁹ This comparison is particularly appropriate because dopamine and DBT are considered equipotent inotropic agents, and are effective in the same dose range of $2\text{--}15 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Their differences can be compared at low ($0.5\text{--}4 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), medium ($5\text{--}9 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), and high ($10\text{--}15 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) doses. This comparison will illustrate the divergent effects of two drugs on preload and afterload while sharing the property of inotropism. Although they share several clinical indications, these drugs are pharmacologically distinct and not interchangeable. Their divergent properties, however, make them particularly valuable when used in combination.²³⁰

DBT is a direct-acting catecholamine that produces a positive inotropic β_1 effect but with minimal changes in β_2 HR or vascular resistance (β_2 , α_1 counteraction). Thus, DBT may not alter blood pressure even though CO is markedly improved. Dopamine may do both. Low-dose dopamine can produce hemodynamic changes similar to those of DBT (inotropism and mesenteric vasodilatation) (see Fig. 12-30). Dopamine produces an increase in blood pressure at higher doses related to its direct and indirect α_1 activation. This increased afterload with dopamine may attenuate any further increase in CO comparable to that of an equal dose of DBT.

DBT does not have any clinically important vasoconstrictor activity, in contrast to dopamine in which an increase in ventricular filling pressure can be noted at low doses. This contrasting effect on preload is seen in Figure 12-31. The cardiac response to all vasodilators is dependent upon the pre-existing preload status. Patients who have acute failure with normal or only slightly elevated end-diastolic volumes may not respond to afterload reduction with an increase in CO. Balanced vasodilators such as nitroprusside or venodilators such as the nitrates may actually reduce CO in these patients. Patients with dilated left ventricles and elevated filling pressures usually exhibit impressive improvement in CO with afterload reduction. This underscores the importance of monitored volume loading before proceeding apace with vasoactive drugs (Table 12-18). It is possible, indeed likely, that a portion of the reduced effectiveness of long-term vasodilator therapy results from inadequate preload, which in some circumstances can actually be a consequence of successful drug therapy.²³¹ Clinical studies suggest that DBT is less likely to increase HR than dopamine for a given dose, which is a major concern in the patient with coronary artery disease. DBT is a coronary artery dilator, whereas dopamine is not. A dopamine-induced tachycardia, however, may be of less concern in the septic patient who commonly has a maldistribution of volume, low vascular resistance, and a pre-existing refractory tachycardia but a previously healthy heart. The empirical preference of dopamine in surgical units and DBT in coronary units has been observed and is perhaps well founded. The surgical patient is more likely to have distributive defects and fluid shifts from major trauma and surgery. The hemodynamics of the septic patient are characterized by low vascular resistance, hypotension, high CO, and some degree of myocardial depression. The renal, distributive, inotropic, and pressor effects of dopamine would seem ideal for this condition. However, a shift of blood volume to the central circulation, tachycardia, or an unpredictable increase in afterload may not be appropriate for the patient in congestive heart failure or the patient with an acute infarct (Fig. 12-28). DBT, with its dose-related inotropism, afterload reduction, and relative lack of chronotropism would seem more appropriate for these circumstances.

Dobutamine does not cause NE release or stimulate DA receptors. Dopamine does both, but the effect is dose-related. The dopaminergic effects of increased renal perfusion is seen at low doses of DA, whereas NE is stimulated only at higher doses. Dopamine offers distinctive advantages over many sympathomimetics in managing the low-output syndrome with oliguria. This effect is ablated at higher doses. DBT does not selectively increase renal blood flow but, like DPX, does improve renal blood flow secondarily with improved CO and weak β_2 vasodilation. Much of the reduced afterload observed with the use of DBT may be related more to a reduced sympathetic tone with improved flow than to active vasodilatation. DBT belongs on the opposite end of the spectrum from amrinone. DBT is a potent inotropic agent but a weak vasodilator, whereas amrinone is a potent vasodilator but a weak inotrope.

Dopamine and DBT also have contrasting effects on the pulmonary vasculature. Dopamine has been noted to increase pulmonary artery pressure and does not inhibit the pulmonary hypoxic response. It is not recommended for patients in right heart failure. DBT does vasodilate the pulmonary vasculature and is helpful in treating right heart failure and cor pulmonale.³⁶ The adrenergic effects of combined sympathomimetics, like the solo drugs, also appear to be additive and competitive for receptor sites. Many combinations of adrenergic drugs have been described as having a synergistic effect. Synergism is the joint action of agents such that their combined effect is greater than the algebraic sum of their individual effects. This synergism may be a clinical interpretation of a summed receptor effect that appears synergistic. For example, infusions of the combination of dopamine and DBT have been noted to produce a greater improvement in CO, at lower doses, than can be achieved by either drug alone. Although equipotent inotropic agents, each drug dilates different vascular beds. Therefore, the summation of afterload reduction by both drugs could produce a greater improvement in CO than could be achieved by either drug alone, even at the same level of inotropism. Summation is more consistent with current receptor pharmacology and can be used to advantage in selectively avoiding unwanted side-effects of one drug while supplementing its desired attributes with another. The summation principle obviates the necessity of knowing a large number of drugs. One need become familiar with but a few agents to manage most clinical situations.

Because of summation, many combinations of vasoactive drugs have been found useful in making fine hemodynamic adjustments in the critically ill. The available sympathomimetic agents provide a wide range of hemodynamic effects, particularly when combined with vasodilators. For example, if a larger positive inotropic action and less vasoconstriction are desired, DBT could be added to dopamine. Also, nitroprusside could be added to dopamine or combined with any other appropriate inodilator.²³² Combinations are also useful in redistributing the CO to vital organs. This is why the combination of DBT and dopamine has been helpful. Dopamine could distribute the CO to the renal and mesenteric vascular bed, while DBT could provide additional afterload reduction by opening up the vascular beds of skin and muscle.^{233,234} (Fig. 12-32). NE has been successfully used in combination with dopamine to increase vascular resistance in septic patients while distributing a greater portion of the CO to the renal and mesenteric bed.²³³

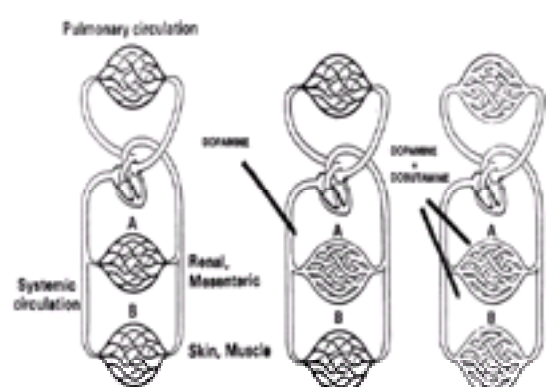

Figure 12-32. Combining low doses of dopamine and dobutamine may produce improvements in CO that are greater than can be achieved with either drug alone. This appears to be clinical synergism. However, the vasodilation of different vascular beds likely produces a summed reduction of afterload at the same level of inotropism

that only appears to be synergistic. The second law of thermodynamics remains intact.

The studied use of adrenergic combinations in patients with cardiac failure has been proposed because pathophysiology cannot be approached with the attitude that β agonism is all good and α agonism is all bad. The objective is to increase coronary perfusion and CO while decreasing afterload. This is the effect achieved by the intra-aortic balloon pump. No single vasoactive agent can achieve this, but these conditions can be approached with combination therapy. Because of receptor summation during combination therapy, standard rates of infusion (as outlined in [Table 12-19](#)) no longer apply. Invasive hemodynamic monitoring is mandatory for success; otherwise, iatrogenic disasters can be expected. Other conditions necessary for success with vasoactive drugs also require that the failing myocardium or vasculature have functional reserve, that the reserve can be stimulated, and that perfusion can be maintained.^{235,236}

Tocolytics

Tocolytic simply means to stop labor. Preterm labor is defined as labor before 37 weeks gestation. It occurs in 7–10% of all births. Eighty-five percent of early neonatal deaths unrelated to lethal abnormalities are associated with premature labor.^{237,238}

Contraindications to tocolysis are intrauterine infection, unexplained vaginal bleeding, and fetal distress. Tocolysis is often initiated in an attempt to prolong gestation to allow fetal maturation and reduce the complications of a premature birth. Bedrest and hydration, often recommended, have not proved effective in halting premature labor.

Various pharmacologic agents have been used to decrease stimulus to the myometrium (alcohol) or prevent myometrial response to stimuli. Drugs belonging to the latter category include opioids, magnesium sulfate, prostaglandin inhibitors, and calcium channel inhibitors. β Agonists have now become the focus of research in this area.²³⁹ The principal action of these drugs is to stimulate β_2 receptors of the myometrium and produce relaxation ([Table 12-5](#)).²³⁸

Ethanol was the earliest effective tocolytic and was used to reduce stimuli to the myometrium. It inhibits the release of oxytocin from the posterior pituitary. Intoxication of both the mother and fetus prohibited its extensive use.

Metaproterenol and isoxsuprine were the first β agonists to be used successfully. Unfortunately, these drugs are equipotent β_1 and β_2 agonists, and the side-effects of tachycardia and hypotension were unacceptable.^{240,241} A second generation of β -adrenergic drugs was applied in which the predominant action is β_2 . Ritodrine and terbutaline are seeing widespread use as tocolytic agents because of their predominant β_2 agonism, which minimizes the undesirable β_1 effects. Ritodrine is the only β -agonist tocolytic currently approved in the United States. It was specifically synthesized for this purpose and is structurally related to EPI.

All β -agonist tocolytic agents have both β_1 and β_2 properties but in different proportions. The circulatory effects vary from one drug to another, depending on the degree of β_1 stimulation. [Table 12-18](#) compares the β_1 cardiovascular effects of ritodrine and terbutaline while being used as tocolytics in humans. The side-effects of these drugs may result in serious consequences. Predictable complications in pregnant women include hyperglycemia with resultant hypokalemia (see [Table 12-5](#)).²⁹ All manner of cardiac dysrhythmias have been described, including ischemia and chest pain. The occurrence of pulmonary edema following the use of β -agonist tocolytics with and without corticosteroids has been described, although the mechanism is not clear.^{242,243} [Table 12-19](#) outlines contraindications for the use of β agents for inhibiting labor.²⁴⁴

[Table 12-20](#) lists the drugs that have been used as tocolytics. The majority of these prevent myometrial response to stimuli. There are no data suggesting that any of these tocolytics is effective for more than 48 hours. They may buy time for fetal lung maturation with steroids, but otherwise they are not reliable or consistent tocolytics long-term. Without a clear therapeutic advantage, the side-effects of tocolytic drugs will often determine the choice in a given patient.

Table 12-20. TOCOLYTICS

Myometrial smooth muscle is endowed with both α and β receptors. β Agonists have become the focus of research in this area. The principal action of β_2 agonists is to stimulate the β_2 receptors of the myometrium and produce relaxation. α -Adrenergic agonists increase uterine activity. However, the direct or indirect effects of the natural catecholamines on uterine activity remain unclear as both epinephrine and norepinephrine levels are markedly increased during labor. Epidural analgesia modifies this pattern, with a marked reduction in epinephrine levels but no change in norepinephrine. Epinephrine and norepinephrine are mixed α and β agonists whose effects are dose-dependent. Norepinephrine appears to stimulate uterine contraction *via* α -adrenergic receptors. The effect of epinephrine varies according to concentration.

Nonadrenergic Sympathomimetic Agents

[Table 12-4](#) classifies the drugs that mimic the SNS into two broad categories, adrenergic or nonadrenergic. Adrenergic agonists exert their action through adrenergic receptors by direct stimulation or indirectly *via* release of NE. Adrenergic agonists may be catecholamines or noncatecholamines by chemical configuration. Nonadrenergic sympathomimetic drugs also act indirectly by influencing the cAMP–calcium cascade, exclusive of the receptors (see [Fig. 12-15](#)). The functions of the second messenger (cAMP) and the third messenger (Ca^{2+}) nearly always go together.²⁴⁵ This concept reinforces the recent appreciation of the homogeneity of action of a wide variety of drugs previously thought to be unrelated. Sympathomimetics have more pharmacologic similarities than differences.

Adenosine. Adenosine, which has been around for more than 50 years, has only recently been recognized as a clinically useful drug. A by-product of ATP, it is composed of adenine and a pentose sugar. It is found in every cell in the body. Production can be increased by stimuli such as hypoxia and ischemia.^{246,247} It can combine with one, two, or three phosphates to form AMP, ADP, or ATP, respectively. This ubiquitous nucleoside has potent electrophysiologic effects in addition to having a major role in regulation of vasomotor tone. Adenosine is believed to have a cardioprotective effect by regulating oxygen supply and demand. The cardiovascular effects of adenosine depend upon which of two receptor sites is activated, α_1 or α_2 .^{246,248} The α_1 receptors in the myocardial conduction system are the most sensitive; they mediate SA node slowing and AV nodal conduction delay. The α_1 receptor inhibits production of cAMP whose formation is stimulated by β -adrenergic activity (see [Table 12-7](#)). The α_2 smooth muscle receptors require higher concentrations of adenosine; they mediate systemic and coronary vasodilatation. The α_2 receptor directly increases the rate of formation of cAMP ([Table 12-7](#)) and functions independently of β activity. Intravenous adenosine, therefore, has significant negative chronotropic effects on the SA node as well as negative dromotropism on the AV node. Thus, adenosine regulates atrial and ventricular rates independently of each other.

Adenosine hyperpolarizes atrial myocytes and decreases their action potential duration *via* an increase in outward K^+ current. These are the acetylcholine-regulated K^+ channels.²⁴⁶ Adenosine mimics the effects of acetylcholine in many ways, including an extremely short plasma half-life of mere seconds. Adenosine also antagonizes the inward Ca^{2+} current produced by catecholamines. This antidysrhythmic mechanism of Ca^{2+} channel blockade is thought to be an indirect effect and important only when β stimulation is present. This trait suggests a possible role in countering catecholamine-induced dysrhythmia. Thus, adenosine exhibits some of the traits of a

Class IV antidysrhythmic. However, the primary antidysrhythmic effect of adenosine is to interrupt re-entrant AV nodal tachycardia, which most likely relates to its K^+ current, rather than Ca^{2+} current effects. The chief indication for adenosine is paroxysmal supraventricular tachycardia (PSVT), which it may terminate in a matter of seconds. PSVT refers to a broad category of narrow complex tachycardias with acute onset and cessation. The most common forms are AV nodal re-entry tachycardia and AV reciprocating tachycardia. PSVT accounts for about one third of all cases of perioperative dysrhythmia. Clinical studies support the use of adenosine for the treatment of W-P-W syndrome and other re-entrant tachycardias involving the AV node.²⁴⁹ The same characteristics that make adenosine an effective therapeutic agent may also make it an ideal agent for diagnosing other types of dysrhythmia. The incidence of incorrect diagnosis of supraventricular dysrhythmia has been reported to be as high as 15% using conventional means.²⁵⁰ This can lead to utilization of harmful medications. For example, a broad complex tachycardia can either be a VT or an SVT with aberrant conduction. Verapamil can be fatal if the dysrhythmia is VT because the drug is long-lasting.^{251,252} However, the fleeting action (9–10 seconds) of adenosine assures that no harm will be done if the broad complex is of ventricular origin, providing a combined therapeutic and diagnostic test. Adenosine will stop SVT in 90% of cases in which the AV node forms one of the limbs of the re-entrant circuit, such as AV reciprocating tachycardia and AV nodal re-entry²⁴⁸; 60% will convert with the first dose. However, adenosine has no effect on ectopic atrial dysrhythmia such as ectopic foci, multifocal SVT, or flutter/fibrillation.²⁵⁸ Approximately 10% of SVT do not involve AV nodal re-entry. Adenosine will nevertheless slow AV nodal conduction in these cases, decrease the ventricular rate, and allow inspection of P waves. Thus, adenosine may be useful in unmasking atrial fibrillation when fast ventricular responses are noted.

A number of side-effects have been reported with the use of adenosine, including flushing, headache, dyspnea, bronchospasm, and chest pain. The majority of these are brief (seconds) and not clinically significant. Transient new dysrhythmia (65%) will be noted at the time of cardioversion, but these disappear during the half-life of the drug. Major hemodynamic changes are rare but consist of hypotension and bradycardia. Adenosine should be given by means of a rapid iv bolus with flush because of its extremely short half-life of less than 10 seconds. The initial adult dose is 6 mg ($100\text{--}150\ \mu\text{g} \cdot \text{kg}^{-1}$ pediatrics), which can be followed by 12 mg within 1–2 minutes if the initial dose is without effect.²⁵⁰ The 12-mg dose may be repeated once. The antidysrhythmic effect of adenosine occurs as soon as the drug reaches the AV node.²⁵¹

Xanthines. The clinically important xanthine is theophylline ethylenediamine (aminophylline).¹⁸¹ Caffeine is a socially important xanthine. Aminophylline has been the mainstay in the treatment of asthma and bronchospasm since 1902 because of its strong b_2 mimetic effect. EPI, isoproterenol, and ephedrine are used to treat asthma for the same reason. Levels of cAMP in the cell are governed by a magnesium-dependent phosphodiesterase (PDE). This enzyme catalyzes the second messenger 3',5'-cAMP to the less active 5'-cAMP. Three major PDE enzymes have been discovered, designated as PDE I, PDE II, and PDE III.^{102,253} The xanthines are nonspecific PDE inhibitors that interact with all three types. Inhibition of PDE results in increased levels of cAMP and b response. Increases in cAMP by this mechanism are important when reviewing the many complicated interactions of the xanthines in the clinical setting.

Catecholamines influence the accumulation of cAMP by activating adenylyl cyclase. Increased catecholamine levels, combined with the xanthines, may lead to synergistic adrenergic activity by increasing production and reducing breakdown of cAMP. Cardiac dysrhythmias are common in such circumstances and are further potentiated during general anesthesia with halothane.²⁵⁴ Serious cardiac dysrhythmia and arrest have been produced with this combination when it has not been carefully controlled.

Intravenous aminophylline produces an increase in CO as a result of its positive inotropic and chronotropic effects. It also reduces afterload by its b_2 -vasodilating effect. The cardiac-stimulating effects are still manifest in the presence of b blockade because the xanthines are not receptor-dependent for their agonism. Thus, they may be temporarily useful in those situations in which excessive b blockade has been produced.²⁹ The inotropic effects are short-lived, lasting 20–30 minutes. Care must be taken during infusion because common side-effects include hypotension and dysrhythmia. Seizures have also been reported.²⁵⁴

Phosphodiesterase Inhibitors. A new group of drugs has been developed that have pharmacologic properties approaching the characteristics of the ideal inotropic agent (see [Table 12-17](#)).^{176,255} They do not rely on stimulation of b and/or a receptors. They are the product of a search for a nonglycosidic, noncatecholamine inotropic agent. These drugs combine positive inotropism with vasodilator activity; like the xanthines, they are PDE inhibitors but differ in that they selectively inhibit PDE III.^{102,253} PDE I and II hydrolyze all cyclic nucleotides, whereas PDE III acts specifically on cAMP. The PDE III inhibitors apparently interact with PDE III at the cell membrane and impede the breakdown of cAMP.^{102,256} cAMP levels increase and protein kinases are activated to promote phosphorylation of the SR in a cascade manner similar to the effects of adrenergic drugs. In cardiac muscle, phosphorylation increases the slow inward movement of calcium current, promoting increased intracellular calcium stores. Thus, inotropism increases. In vascular smooth muscle, increased cAMP activity accounts for the vasodilation, decreased peripheral vascular resistance, and lusitropism. Amrinone, like nitroprusside and nitroglycerin, promotes diastolic relaxation, which promotes ventricular filling.^{161,257}

A variety of PDE inhibitors are undergoing clinical trials.^{257,258} The relative contribution of inotropism and vasodilation differs with each. Amrinone and milrinone are the only PDE inhibitors released for clinical use in the United States. Amrinone is the prototypical PDE III inhibitor. The degree of hemodynamic effect of these drugs depends on the dose, degree of inotropic reserve, and state of cAMP depletion.

AMRINONE. Amrinone is a bipyridine derivative that produces mild inotropic activity and strong vasodilatory effects. The characteristics of amrinone, compared with those of the ideal inotropic agent ([Table 12-17](#)), rank it near the ideal drug. It is the first oral inotrope available since the introduction of digitalis.^{256,257} However, it is not currently prescribed in its oral form. Studies of single-dose and short-term oral and iv amrinone show dose-related improvements at rest in the cardiac index and the left ventricular stroke index (40–80% increase); left ventricular end-diastolic pressure (40% decrease); pulmonary capillary wedge pressure (16–44% decrease); pulmonary artery pressure (17–33% decrease); right atrial pressure (16–44% decrease); left ventricular ejection fraction (50% increase); and systemic vascular resistance (23–50% decrease). Significantly, HR and mean arterial pressure are not affected. Hemodynamic improvement is also noted when amrinone is used in combination with hydralazine. The improvement is greater than with either drug alone. Peak response with an iv dose occurs after 5 minutes and reveals no evidence of tolerance over short-term trials (24 hours); it is compatible with other adrenergic agonists. It is an effective inotropic agent in patients receiving b blockers. Its efficacy in the patient who has been digitalized has been demonstrated.

Intravenous amrinone therapy should be initiated with a $0.75\ \text{mg} \cdot \text{kg}^{-1}$ bolus given over 2–3 minutes. It is continued with a maintenance infusion of $5\text{--}10\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, adjusted by hemodynamic monitoring. An additional bolus dose of $0.75\ \text{mg} \cdot \text{kg}^{-1}$ may be given 30 minutes after initiation of therapy. Care must be taken not to give the bolus too quickly because sudden decreases in peripheral vascular resistance may occur and result in severe hypotension. Hypotension is not a major clinical problem with appropriate monitoring of ventricular filling pressures. The infusion should not exceed a total daily dose of $10\ \text{mg} \cdot \text{kg}^{-1}$, including the bolus doses. Amrinone has the same range of infusion rates as dopamine and DBT, and dose calculation follows the “rule of six” described in [Table 12-19](#).

Amrinone has two uncommon side-effects. Dose-related thrombocytopenia occurs in some patients taking long-term oral medication. This usually responds to dose reduction. Acute iv amrinone has not produced thrombocytopenia.^{258,259,260} and ²⁶¹ Centrilobular hepatic necrosis occurs in dogs given high doses of amrinone for periods exceeding 3 months. There is no evidence of such an effect in humans, but the implications of using halothane in a patient on amrinone are obvious. If the side-effects do not prove troublesome, this will be a valuable drug. It has a therapeutic index of approximately 100:1 compared with 1.2:1 with the digitalis glycosides.

MILRINONE. Milrinone is a bipyridine inotropic agent that is a derivative of amrinone.²⁶² It has nearly 20 times the inotropic potency of the parent compound. Milrinone is active both intravenously and orally and has beneficial short-term hemodynamic effects in patients with severe refractory congestive heart failure. Improvement of CO appears to result from a combination of enhanced myocardial contractility and peripheral vasodilation. Treatment with oral milrinone for up to 11 months has been effective and well tolerated without evidence of fever, thrombocytopenia, or gastrointestinal effects.^{263,264} Milrinone recently has been approved for short-term iv therapy of congestive heart failure.²⁶⁵ It is administered with a loading dose of $50\ \mu\text{g} \cdot \text{kg}^{-1}$ over 10 minutes. The maintenance iv infusion rate ranges from a minimum of $0.375\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ to a maximum of $0.75\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (not to exceed $1.13\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$). Dosage must be adjusted in renal failure patients as milrinone is excreted in the urine primarily in unconjugated form.

ENOXIMONE. Enoximone is a newer PDE III inhibitor that has proven beneficial in patients suffering from severely impaired myocardial function.²⁶⁶ Enoximone is an imidazole derivative structurally unrelated to digitalis, catecholamines, or amrinone. It has not been implicated in platelet compromise. Its hemodynamic effects are similar to those produced by amrinone. It appears to be a more potent inotropic agent than amrinone, whose inotropic effect has been questioned. It produced pulmonary and systemic arteriolar vasodilation and can thus be classified as an inodilator. Any increase in myocardial oxygen consumption (MVO_2) by the increase in inotropism is countered by a decrease in afterload and reduced ventricular size. The drug has been administered by both the bolus technique and infusion. It has been used primarily in patients with cardiogenic shock and for weaning from cardiopulmonary bypass. Its use was instituted in patients who were proven refractory to catecholamine therapy. A definitive dosing therapy has not been established but several studies have given a $1\text{--}2\ \text{mg} \cdot \text{kg}^{-1}$ bolus followed by an infusion of $3\text{--}10\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. In all cases CI and SV increased with a decrease in ventricular filling pressure, SVR, and PVR. No increase in heart rate was noted. The bolus technique alone has been helpful in weaning patients from cardiopulmonary bypass without affecting heart rate or producing arrhythmias.

Glucagon. Glucagon is a single-chain polypeptide of 29 amino acids that is secreted by pancreas α cells in response to hypoglycemia. The liver and kidney are responsible for its degradation. Known effects of this hormone in humans include the following.^{181,267}

1. Inhibition of gastric motility
2. Enhanced urinary excretion of inorganic electrolyte
3. Increased insulin secretion
4. Hepatic glycogenolysis and gluconeogenesis
5. Anorexia
6. Inotropic and chronotropic cardiac effects

Little attention was given to glucagon until 1968, when it was demonstrated to produce positive inotropic and chronotropic effects in the canine heart. Glucagon, by activation of Gs-type G protein (Table 12-7), enhances the activation of adenylyl cyclase in a manner similar to that of NE, EPI, and isoproterenol. These cardiac actions of glucagon are not blocked by β blockade or catecholamine depletion. Glucagon, in contrast to the xanthines, rarely causes dysrhythmia, even in the face of ischemic heart disease, hypokalemia, and digitalis toxicity. Glucagon may possess antidysrhythmic activity in digitalis toxicity because it has been shown to enhance AV nodal conduction in patients with varying degrees of AV block. It should be used carefully in patients with atrial fibrillation. In humans, an iv dose of 1–5 mg of glucagon increases cardiac index, mean arterial pressure, and ventricular contractility, even in the presence of digitalis therapy. Glucagon can be mixed in 5% dextrose in water and is stable for long periods. After a bolus dose, its action dissipates in approximately 30 minutes. A continuous infusion of $5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ is augmented by an initial bolus of $50 \mu\text{g} \cdot \text{kg}^{-1}$. Onset of action occurs in 1–3 minutes and peaks at 10–15 minutes.

Nausea and vomiting are common side-effects in the awake patient, especially following a bolus dose. Hypokalemia, hypoglycemia, and hyperglycemia are also seen. Despite the obvious benefits of glucagon in cardiac patients, its use has not become popular. This may be related to its high cost and the multiple metabolic and physiologic effects that are common after its administration.

This pancreatic hormone may be of benefit when more conventional approaches have proved refractory in the following settings: (1) low CO syndrome following cardiopulmonary bypass, (2) low CO syndrome with myocardial infarction, (3) chronic congestive heart failure, and (4) excessive β -adrenergic blockade.
