Air embolization is potentially lethal. In the bloodstream, air migrates to the heart, where it creates a compressible foam that destroys the propulsive efficiency of ventricular contraction and irritates the conduction system. Air can also move into the pulmonary vasculature, where bubbles obstruct small vessels and compromise gas exchange, or it can cross through a patent foramen ovale to the left side of the heart and the systemic circulation.

Opportunities for venous air embolization through an incised vein in a surgical wound located above the heart increase with the degree of elevation of the operative site. Although the occurrence of air emboli is a relatively frequent phenomenon in head-elevated positions, most of the emboli are small in volume, clinically silent, and recognizable only by sophisticated detection techniques. Nevertheless, the potential for continuing, dangerous accumulations of entrained air requires immediate detection of the embolization, a careful search for its portal of entry, and prompt treatment of its clinical effects.

Air embolism may be diagnosed by the presence of one or several of the following, in any order: a change in heart sounds noted by a parasternal Doppler probe; a cardiac murmur; cardiac dysrhythmias; hypotension; a decrease in expired carbon dioxide; the appearance of nitrogen in the expired air; and the sudden appearance of vigorous spontaneous ventilation despite continuing mechanical ventilation. Air bubbles in the central circulation can also be recognized with transesophageal echocardiography.

Approximately 20–35% of the population¹¹⁷ has a residual foramen ovale that is functionally closed as long as pressure in the left atrium exceeds that in the right. However, in the sitting position, right atrial pressure can be higher than left. That gradient, augmented by (1) the presence of air in the right side of the heart, (2) positive-pressure ventilation, and (3) positive end-expiratory pressure, may be sufficient to reopen an existing probe-patent, but functionally closed, foramen ovale. Air in the right atrium thereby gains paradoxical access to the coronary, cerebral, and systemic circulations.¹¹⁸ In anesthetized and newly positioned patients, Perkins-Pearson *et al*¹¹⁹ suggest that, when pulmonary artery occlusion pressures are found to be lower than right atrial pressures, the head-elevated posture should be abandoned in favor of a position in which the head is level with the heart.

Cucchiara and associates¹²⁰ have injected agitated saline through a right-sided heart catheter and used transesophageal echocardiography to detect paradoxical passage of fluid across the atrial septum. Positive-airway pressure aided in determining paradoxical flow in 3 of their 20 patients.

Pneumocephalus

In the usual craniotomy, most of the brain lies subjacent to the incision. After the dura is incised, cerebrospinal fluid is removed to improve working conditions, and the surgical field is open to the air. During closure of the craniotomy, most of the intracranial air escapes from the wound and any residual pneumocephalus is of little consequence. However, when an incision is made through the dura in the posterior fossa or cervical spine of a seated patient, the bulk of the brain lies above the incision. Cerebrospinal fluid drains downward out of the wound, and tissue retraction can allow air to bubble up over the surfaces of the brain to become trapped in the upper reaches of the cranium.¹²¹ When brain mass is decreased by ventricular drainage, steroids, and diuresis, the space available to a pneumocephalus is enlarged. Diffusion of nitrous oxide into the accumulated air, or the warming of trapped gas, can produce a tension pneumocephalus with signs of increased intracranial pressure and delayed awakening from anesthesia.

Toung *et al*¹²² found postoperative pneumocephalus in all of a group of seated patients and in most of those who had been in the prone or the park bench position. Intraventricular air was present in most of the seated patients and was rare in those in the other positions. None of their group of 100 patients had neurologic changes attributable to the trapped intracranial air. Standefer *et al*¹²³ reported a 3% incidence of symptomatic (tension) pneumocephalus in seated, anesthetized patients whose duras were opened.

Ocular Compression

Pressure from a padded head rest on the eyes of a patient who has been placed in a head-elevated position can dislocate a crystalline lens or render the globe ischemic. Unilateral blindness has been reported as a result (see section on [Blindness](#), earlier).¹²⁴ Modern skull-pin head clamps that grip firmly when properly applied have made ocular compression in the sitting position a rarity. In the head-elevated lateral decubitus or prone position, the threats to the eyes are those described in the preceding discussions of those nonelevated postures.

Edema of the Face, Tongue, and Neck

McAllister¹²⁵ has encountered severe postoperative macroglossia, apparently due to venous and lymphatic obstruction caused by prolonged, marked neck flexion. The patient's chin was firmly against the chest and an oral airway was in place to protect the endotracheal tube. Ellis *et al*¹²⁶ reported a similar patient who needed a tracheostomy because of massive swelling of the tongue, lips, pharynx, and epiglottis occurring shortly after extubation at the end of administration of a lengthy anesthetic in the sitting position that involved deliberate hypotension. Extremes of neck flexion, with or without head rotation, have been widely used to gain access to structures in the posterior fossa and cervical spine, but their potential for damage should be understood and excessive flexion–rotation avoided if possible. Moore and associates¹²⁷ have described five cases of macroglossia in patients with posterior fossa disease and have suggested that the primary mechanism is neurologically determined rather than being the result of either vascular obstruction or local trauma.

Midcervical Tetraplegia

This devastating injury occurs after marked flexion of the neck, with or without rotation of the head, and is attributed to stretching of the spinal cord with resulting compromise of its vasculature in the midcervical area. An element of spondylosis or a spondylotic bar may be involved.^{128,129} The result is paralysis below the general level of the fifth cervical vertebra. Although most reports in the literature have described the condition as occurring after the use of the sitting position, midcervical tetraplegia has also occurred after prolonged, nonforced head flexion for intracranial surgery in the supine position. The role of a tethered cord in the production of the syndrome has not been established. No useful preoperative evaluation can as yet establish the potential for this complication.

Reversible changes in SSEPs elicited by stimulation of the median nerve have been found to occur after neck flexion.^{130,131} However, in studies with monkeys, Cottrell *et al*¹³² have shown that SSEPs may not be sensitive enough to detect midcervical tetraplegia, and Levy and associates¹³³ have suggested using motor evoked potentials for this purpose.

Sciatic Nerve

Stretch injuries of the sciatic nerve can occur in some seated patients if the hips are markedly flexed without bending the knees. Prolonged compression of the sciatic nerve as it emerges from the pelvis is possible in a thin, seated patient if the buttocks are not suitably padded. Foot drop may be the result of injuries to either the sciatic nerve or the common peroneal nerve and can be bilateral.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS ADVISORY ON PREVENTION OF PERIOPERATIVE PERIPHERAL NEUROPATHIES

The American Society of Anesthesiologists approved an advisory on peripheral neuropathies in 1999.¹³⁴ This advisory includes pertinent literature and a summary of the opinions of anesthesia providers on a variety of positioning and peripheral neuropathy issues. The paucity of literature related to these issues limited the advisory to recommendations based on opinions and current practices of a broadly representative group of anesthesia providers from around the United States. Additional input and opinions were obtained from consultants from around the world. A summary of the findings of the advisory is shown in [Table 24-1](#).

Preoperative assessment: When patient positioning is to be altered, it is suggested to...
 1. Assess the patient's baseline neurologic status...
 2. Assess the patient's baseline vital signs...
 3. Assess the patient's baseline hemodynamic status...
 4. Assess the patient's baseline respiratory status...
 5. Assess the patient's baseline skin temperature...
 6. Assess the patient's baseline peripheral vascular status...
 7. Assess the patient's baseline level of consciousness...
 8. Assess the patient's baseline level of pain...
 9. Assess the patient's baseline level of anxiety...
 10. Assess the patient's baseline level of hydration...
 11. Assess the patient's baseline level of nutrition...
 12. Assess the patient's baseline level of electrolyte balance...
 13. Assess the patient's baseline level of renal function...
 14. Assess the patient's baseline level of liver function...
 15. Assess the patient's baseline level of endocrine function...
 16. Assess the patient's baseline level of immune function...
 17. Assess the patient's baseline level of genetic predisposition...
 18. Assess the patient's baseline level of environmental exposure...
 19. Assess the patient's baseline level of occupational exposure...
 20. Assess the patient's baseline level of recreational exposure...
 21. Assess the patient's baseline level of travel history...
 22. Assess the patient's baseline level of family history...
 23. Assess the patient's baseline level of social history...
 24. Assess the patient's baseline level of sexual history...
 25. Assess the patient's baseline level of substance use...
 26. Assess the patient's baseline level of medication use...
 27. Assess the patient's baseline level of allergy history...
 28. Assess the patient's baseline level of surgical history...
 29. Assess the patient's baseline level of anesthesia history...
 30. Assess the patient's baseline level of transfusion history...
 31. Assess the patient's baseline level of radiation history...
 32. Assess the patient's baseline level of organ donation...
 33. Assess the patient's baseline level of organ receipt...
 34. Assess the patient's baseline level of organ transplant...
 35. Assess the patient's baseline level of organ donation...
 36. Assess the patient's baseline level of organ receipt...
 37. Assess the patient's baseline level of organ transplant...
 38. Assess the patient's baseline level of organ donation...
 39. Assess the patient's baseline level of organ receipt...
 40. Assess the patient's baseline level of organ transplant...

Table 24-1. SUMMARY OF TASK FORCE CONSENSUS

PRACTICAL CONSIDERATIONS FOR PERIOPERATIVE NEUROPATHIES

Efforts to prevent perioperative neuropathies are frequently debated, and there often is confusion over how to manage a neuropathy once it has occurred. In general, there are no data to support recommendations on any of these issues. Therefore, the following opinions have been formulated by personal experience, guided by advice from neurologists who primarily care for patients with peripheral neuropathies, and seasoned or supported by speculation derived from anecdotal case reports.

Padding Exposed Peripheral Nerves

Many types of padding materials are advocated to protect exposed peripheral nerves. They often consist of cloth (e.g., blankets and towels), foam sponges (e.g., "eggcrate" foam), and gel pads. There are no data to suggest that any of these materials is more effective than any other, or that any is better than no padding at all. A good rule of thumb would be to position and pad exposed peripheral nerves to (1) prevent their stretch beyond normally tolerated limits while awake; (2) avoid their direct compression, if possible; and (3) distribute over as large an area as possible any compressive forces that must be placed on them.

Prolonged Duration in One Position

Prolonged duration in one position appears to increase the risk of neuropathy and other integumentary damage. For example, prolonged duration in lithotomy positions greatly increases the risk of lower extremity neuropathy.^{135,136} When possible, it would appear prudent to limit as much as practical the time any patient spends in one position. However, intermittent movement of the limbs or head during the intraoperative period may increase the opportunity for a number of different problems, including but not limited to dislodging an endotracheal tube, abrading a cornea, or moving an extremity into a suboptimal position. Practitioners must judge the benefits vs. risks of any intraoperative changes in a patient's position.

Course of Action for the Patient With a Neuropathy

Although each situation is unique and requires careful assessment, the following guidelines may suggest a basic course of action that will lead to appropriate care:

- Is the neuropathy sensory or motor? Sensory lesions are more frequently transient than motor lesions. If the symptoms are numbness or tingling only, it may be appropriate to inform the patient that many of these neuropathies can be expected to resolve during the first 5 days.⁵⁰ The patient should be instructed to avoid postures that might compress or stretch the involved nerve. Arrangements should be made for frequent contact with the patient. A call to alert a neurologist is appropriate, and if the symptoms still persist on postoperative day 5, the neurologist should be consulted.
- If the neuropathy has a motor component, a neurologist should be consulted immediately. Electromyographic studies may be needed to assess the location of any acute lesion. This knowledge may direct an appropriate treatment plan. The studies may also demonstrate chronic abnormalities of the nerve or, if applicable, the contralateral nerve.

Monitoring represents the process by which anesthesiologists recognize and evaluate potential physiologic problems in a timely manner. The term is derived from *monere*, which in Latin means to warn, remind, or admonish. In perioperative care, monitoring implies the following four essential features: observation and vigilance, instrumentation, interpretation of data, and initiation of corrective therapy when indicated.

Monitoring is an essential aspect of anesthesia care. Patient safety is enhanced when appropriate monitoring is operational and clinical judgments are proper. Effective monitoring reduces the potential for poor outcomes that may follow anesthesia by identifying derangements before they result in serious or irreversible injury. Electronic monitors improve a physician's ability to respond because they are able to make repetitive measurements at higher frequencies than humans, and do not fatigue or become distracted. Monitoring devices increase the specificity and precision of clinical judgments. At no time in the history of anesthesia have practitioners had the capability routinely to monitor so many diverse physiologic variables in real time, often noninvasively, as they do today. Our understanding of the physiologic effects of anesthesia and its inherent risks is enhanced by using appropriate intraoperative physiologic monitoring.

This chapter discusses the methods by which anesthesiologists monitor organ function during anesthesia care. The descriptions of the technologic and scientific principles used in monitoring devices have been simplified for clarity.

Cost containment has been raised as a reason to discourage the use of expensive, technologically advanced monitoring systems. The value of a given monitor depends on the clinical expertise of the anesthesiologist, the clinical setting, the anesthetic technique, and the performance of the specific equipment in question. Monitoring devices should not be denied solely on the basis of expense.¹ Although it is appropriate for society to demand cost containment, anesthesiologists have a responsibility to assess how monitoring should be used. Professional societies, regulatory agencies, and the legal profession have played important roles in establishing current monitoring practices.

Standards for basic anesthetic monitoring have been established by the American Society of Anesthesiologists (ASA). Since 1986, these standards have emphasized the evolution of technology and practice. Today's standards (last amended on October 25, 1995) emphasize the importance of regular and frequent measurements, integration of clinical judgment and experience, and the potential for extenuating circumstances that can influence the applicability or accuracy of monitoring systems.²

Standard I requires qualified personnel to be present in the operating room, to monitor the patient continuously and modify anesthesia care based on clinical observations and the responses of the patient to dynamic changes resulting from surgery or drug therapy. Standard II focuses attention on continually evaluating the patient's oxygenation, ventilation, circulation, and temperature. Standard II specifically mandates the following:

1. Using an oxygen analyzer with a low concentration limit alarm during general anesthesia.
2. Quantitative assessment of blood oxygenation during any anesthesia care.
3. Continuously ensuring the adequacy of ventilation by physical diagnostic techniques during all anesthesia care. Quantitative monitoring of tidal volume and capnography are encouraged in patients undergoing general anesthesia.
4. Ensuring the adequacy of circulation by the continuous display of the electrocardiogram (ECG), and determining the arterial blood pressure at least at 5-minute intervals. During general anesthesia, circulatory function is to be continually evaluated by assessing the quality of the pulse, either electronically or by palpation or auscultation.
5. Endotracheal intubation requires qualitative identification of carbon dioxide in the expired gas. During general anesthesia, capnography and end-tidal carbon dioxide analysis are encouraged.
6. During all anesthetics, the means for continuously measuring the patient's temperature must be available. When changes in body temperature are intended or anticipated, temperature should be continuously measured and recorded on the anesthesia record.

The ASA standards emphasize the melding of physical signs with instrumentation. Electronic monitoring, no matter how sophisticated or comprehensive, does not necessarily reduce the need for clinical skills such as inspection, palpation, and auscultation. Although the authors believe that electronic monitors augment clinical judgments when properly used, there is little evidence that electronic monitors, by themselves, reduce mortality or morbidity. Moreover, there is considerable controversy regarding the need to apply specific monitors in unique clinical situations, particularly those that may add significant cost. Monitoring can be classified as invasive, minimally invasive, or noninvasive. Invasive monitors place patients at risk for complications related to their application and use. Anesthesiologists must balance the potential risk of instituting invasive monitoring with the presumed benefits derived from its application.

The variety of devices available for patient monitoring is expansive and changing as advances in biomedical engineering find their way into the marketplace. The Association for the Advancement of Medical Instrumentation has been effective in promoting design guidelines to ensure patient and operator safety and reduce stress and distractions often associated with medical monitoring.³

The proliferation of alarm tones during anesthesia care can be disturbing and may paradoxically impair clinical vigilance. Monitoring systems may be insufficiently sensitive to reject errors. During routine anesthesia care, a minimum of five alarms (inspired oxygen, airway pressure, oximetry, blood pressure, and heart rate) should be operational. Unfortunately, spurious warnings occur with high frequency during routine anesthesia monitoring. The integration of alarm signals is an important area in need of continuing evaluation. Loeb⁴ reported that anesthesia providers have difficulty in accurately recognizing the source of an alarm tone. Alarm annunciators using unique sound and visual prompts are being incorporated into anesthesia equipment. Warning signals for ventilation, oxygenation, drug administration, temperature, and cardiovascular parameters need to be designed so that problem identification is fast, simple, and relevant.

INSPIRATORY AND EXPIRED GAS MONITORING: OXYGEN

The concentration of oxygen in the anesthetic circuit must be measured. Measuring inspired oxygen does not guarantee the adequacy of arterial oxygenation.⁵ Gas machine manufacturers place oxygen sensors on the inspired limb of the anesthesia circuit to ensure that hypoxic gas mixtures are never delivered to patients. Oxygen monitors require a fast response time (2–10 seconds), accuracy ($\pm 2\%$), and stability when exposed to humidity and inhalation agents.

Paramagnetic Oxygen Analysis

Oxygen is a highly paramagnetic gas. Paramagnetic gases are attracted to magnetic energy because of unpaired electrons in their outer shell orbits. Differential paramagnetic oximetry has been incorporated into a variety of operating room monitors (Datex Medical Instruments, Inc. Tewksbury, Massachusetts). These instruments detect the change in sample line pressure resulting from the attraction of oxygen by switched magnetic fields. Signal changes during electromagnetic switching correlate with the oxygen concentration in the sample line.

Galvanic Cell Analyzers

Galvanic cell analyzers meet the performance criteria necessary for operative monitoring. These analyzers measure the current produced when oxygen diffuses across a membrane and is reduced to molecular oxygen at the anode of an electrical circuit. The electron flow (current) is proportional to the partial pressure of oxygen in the fuel cell. Galvanic cell analyzers require regular replacement of the galvanic sensor capsule. In the sensor, the electric potential for the reduction of oxygen results from a chemical reaction. Over time, the reactants require replenishment.⁶

Polarographic Oxygen Analyzers

Polarographic oxygen analyzers are commonly used in anesthesia monitoring. In this electrochemical system, oxygen diffuses through an oxygen-permeable polymeric membrane and participates in the following reaction: $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$. The current change is proportional to the number of oxygen molecules surrounding the electrode. Polarographic oxygen sensors are versatile and are important components of gas machine oxygen analyzers, blood gas analyzers, and transcutaneous and transconjunctival oxygen analyzers.

MONITORING OF EXPIRED GASES

Carbon Dioxide

Expiratory CO_2 monitoring ($PECO_2$) has evolved as an important physiologic and safety monitor. CO_2 is usually sampled near the endotracheal–gas delivery interface. Alterations in ventilation, cardiac output (CO), distribution of pulmonary blood flow, and metabolic activity influence $PECO_2$ and the capnograph display obtained during quantitative expired gas analysis.

Capnometry is the measurement and numeric representation of the CO_2 concentration during inspiration and expiration. A *capnogram* is a continuous concentration–time display of the CO_2 concentration sampled at a patient's airway during ventilation. *Capnography* is the continuous monitoring of a patient's capnogram. The capnogram is divided into four distinct phases (Fig. 25-1). The first phase (A–B) represents the initial stage of expiration. Gas sampled during this phase occupies the anatomic dead space and is normally devoid of CO_2 . At point B, CO_2 -containing gas presents itself at the sampling site, and a sharp upstroke (B–C) is seen in the capnogram. The slope of this upstroke is determined by the evenness of ventilation and alveolar emptying. Phase C–D represents the alveolar or expiratory plateau. At this phase of the capnogram, alveolar gas is being sampled. Normally, this part of the waveform is almost horizontal. Point D is the highest CO_2 value and is called the end-tidal CO_2 ($ETCO_2$). $ETCO_2$ is the best reflection of the alveolar CO_2 ($PACO_2$). As the patient begins to inspire, fresh gas is entrained and there is a steep downstroke (D–E) back to baseline. Unless rebreathing of CO_2 occurs, the baseline approaches zero.

Figure 25-1. The normal capnogram. Point D delineates the end-tidal CO_2 . $ETCO_2$ is the best reflection of the alveolar CO_2 tension.

The utility of capnography depends on an understanding of the relationship between arterial CO_2 ($PaCO_2$), alveolar CO_2 ($PACO_2$), and $ETCO_2$. This concept assumes that ventilation and perfusion are appropriately matched, that CO_2 is easily diffusible across the capillary–alveolar membrane, and that no sampling errors occur during measurement. If these conditions are met, changes in $ETCO_2$ reflect changes in $PaCO_2$ even if it is assumed that all alveoli do not empty at the same time. If one assumes an idealized mathematical model of ventilation–perfusion, $ETCO_2 \approx PACO_2 \approx PaCO_2$. If the $PACO_2$ – $PaCO_2$ gradient is constant and small, capnography provides a noninvasive, continuous, real-time reflection of ventilation. During general anesthesia, the $ETCO_2$ – $PACO_2$ gradient typically is 5–10 mm Hg. A maldistribution of ventilation and perfusion (\dot{V}/\dot{Q}) or problems in gas sampling may result in a widening of the $ETCO_2$ – $PACO_2$ gradient. \dot{V}/\dot{Q} maldistribution is a common cause of an increased $PACO_2$ – $PaCO_2$ gradient. Other patient factors that may influence the accuracy of $ETCO_2$ monitoring by widening the $PACO_2$ – $ETCO_2$ gradient include shallow tidal breaths, prolongation of the expiratory phase of ventilation, or uneven alveolar emptying.

Dead space (wasted) ventilation is the extreme example of \dot{V}/\dot{Q} mismatch where a complete absence of perfusion in the presence of adequate alveolar ventilation occurs. Because only perfused alveoli can participate in gas exchange, the nonperfused alveoli have a $PACO_2$ of zero. The ventilation-weighted average of the perfused and nonperfused alveoli determines the $ETCO_2$. Therefore, conditions resulting in an increase of dead space ventilation lower the $ETCO_2$ measurement and increase the $PACO_2$ – $ETCO_2$ gradient. The common clinical causes associated with a widened $PACO_2$ – $ETCO_2$ gradient include embolic phenomena (thrombus, fat, air, amniotic fluid), hypoperfusion states with reduced pulmonary blood flow, and chronic obstructive pulmonary disease. In contrast, conditions that increase pulmonary shunt (perfusion in the absence of ventilation) result in minimal changes in the $PACO_2$ – $ETCO_2$ gradient.

Capnography is an essential element in determining the appropriate placement of endotracheal tubes. The presence of a stable $ETCO_2$ for three successive breaths indicates that the tube is not in the esophagus. A continuous, stable CO_2 waveform ensures the presence of alveolar ventilation but does not necessarily indicate that the endotracheal tube is properly positioned in the trachea. For example, the tip of the tube could be located in a mainstem bronchus. Capnography is also a monitor of potential changes in perfusion or dead space, is a very sensitive indicator of anesthetic circuit disconnects and gas circuit leaks, and is a method to detect the quality of CO_2 absorption. Increases in $ETCO_2$ can be expected when CO_2 production exceeds ventilation, such as in hyperthermia or when an exogenous source of CO_2 is present. [Table 25-1](#) summarizes the common elements that may be reflected by changes in $ETCO_2$ during anesthesia care.

| Increases in ETco ₂ | Decreases in ETco ₂ |
|--|--------------------------------|
| ELEMENTS THAT CHANGE CO₂ PRODUCTION | |
| Increases in metabolic rate | Decreases in metabolic rate |
| Hyperthermia | Hypothermia |
| Sepsis | Hypothyroidism |
| Malignant hyperthermia | |
| Hyperthyroidism | |
| Shivering | |
| ELEMENTS THAT CHANGE CO₂ ELIMINATION | |
| Hypoventilation | Hyperventilation |
| Rebreathing | Hypoperfusion |
| | Pulmonary embolism |

Table 25-1. FACTORS THAT MAY CHANGE END-TIDAL CO₂ (ETCO₂) DURING ANESTHESIA

A sudden drop in ETCO₂ to near zero followed by the absence of a CO₂ waveform is a potentially life-threatening problem that could indicate malposition of an endotracheal tube into the pharynx or esophagus, sudden severe hypotension, pulmonary embolism, a cardiac arrest, or an artifact resulting from disruption of sampling lines. When a sudden drop of the ETCO₂ occurs, it is essential quickly to verify that there is pulmonary ventilation and to identify physiologic and mechanical factors that might account for a zero line capnogram. During life-saving cardiopulmonary resuscitation, the generation of adequate perfusion can be assessed by the restoration of the CO₂ waveform.

Whereas abrupt decreases in the ETCO₂ are often associated with an altered cardiopulmonary status (e.g., embolism or hypoperfusion), gradual reductions in ETCO₂ more often reflect decreases in PaCO₂ that occur after increases in minute ventilation where ventilation overmatches CO₂ production.

Gas sampling errors also affect the PaCO₂–ETCO₂ gradient. With sidestream analyzers, the tidal sample can be diluted with fresh gas, producing a falsely low ETCO₂. This can be particularly significant in neonates, infants, and small children with small tidal volumes. The site of sampling can affect accuracy. The best site for sampling is immediately adjacent to the endotracheal tube connector. Sampling errors resulting from loose connections or system leaks also may dilute the expiratory sample and reduce the estimate of ETCO₂.

The size and shape of the capnogram waveform can be informative.⁷ A slow rate of rise of the second phase (B–C) is suggestive of either chronic obstructive pulmonary disease or acute airway obstruction as from bronchoconstriction (asthma). A normally shaped capnogram with an increase in ETCO₂ suggests alveolar hypoventilation or an increase in CO₂ production. Transient increases in ETCO₂ are often observed during tourniquet release, aortic unclamping, or the administration of bicarbonate.

Several methods for the quantification of CO₂ have been applied to patient monitoring systems. One of the most commonly used methods is based on infrared absorption spectrophotometry (IRAS).

Infrared Absorption Spectrophotometry

Asymmetric, polyatomic molecules like CO₂ absorb infrared light at specific wavelengths. Operating room IRAS devices can detect CO₂, N₂O, and the potent inhaled anesthetic agents. Operating room instruments are designed to measure the unique energy absorbed by the gases and vapors of interest when a sample of the inspired and expired gas is placed into the optical path of an infrared beam.⁸ The mixtures complicate the analysis because of interactions between the gases and vapors and the closeness of absorption spectra for the gases of interest. All anesthetic vapors absorb infrared light at 3.6 μm. Therefore, manufacturers using this signature cannot display with certainty the concentration of a specific anesthetic agent of interest. Optical filters and unique detection systems enhance the sensitivity of IRAS monitoring and permit estimation of CO₂, N₂O, and the specific potent inhalational agent present in the measurement chamber. IRAS devices have five components: an infrared light source, a gas sampler, an optical path, a detection system, and a signal processor. The light source produces the infrared energy. The light is focused and filtered so that the quality of the photons with respect to the energy and frequency is stable over time. Narrow wavelengths are then presented to the gas stream. Most instruments in common use continuously withdraw a small sample of gas from the airway. Sample rates vary from 50 to 300 ml · min⁻¹. The sample stream can be scavenged or returned to the breathing circuit. Water vapor must be removed before the sample is placed into the measurement chamber; liquid contamination of the sample stream affects the performance of IRAS devices. Once the sample has entered the measurement chamber, a detection system calibrated to determine the concentration of a specific gas or agent over time is activated. Changes in temperature, pressure, and acoustic characteristics in the detection chamber can be used to determine the concentration of the gas or agents of interest. Signal detectors create electrical currents analyzed by the signal processor, which transforms the current change to a measurement. The capnogram or agent waveform is an oscilloscopic representation of the electrical current changes over time. The signal-processing section of an IRAS instrument has a memory section that correlates the absorbed energy with a concentration as predicted by the Lambert-Beer law.

Multiple Expired Gas Analysis

Most operating room gas analyzers incorporate methods so that they can monitor concentrations of at least O₂, CO₂, and the inhaled anesthetic agents. Intraoperative breath-by-breath analysis of respiratory and anesthetic gases requires stand-alone monitors or a single instrument that is multiplexed to a collecting system, which permits the sampling of the gas stream from multiple locations. Currently, multiroom *mass spectrometry systems* are the only systems that use multiplexing for respiratory gas monitoring. Mass spectrometers bombard the gas mixture with electrons, creating ion fragments of a predictable mass and charge. These fragments are accelerated in a vacuum. A sample of this mixture enters a measurement chamber, where the fragment stream is subjected to a high magnetic field. The magnetic field separates the fragments by their mass and charge. The fragments are deflected onto a detector plate, and each gas has a specific landing site on the detector plate. The ion impacts are proportional to the concentration of the parent gas or vapor. The processor section of the mass spectrometer system calculates the concentration of the gases of interest and sends the information to the respective location of the original sample.

Another unique approach to monitor respiratory gases is based on *Raman scattering*. Raman scattering results when photons generated by a high-intensity argon laser collide with gas molecules. After impact, the gases are momentarily excited to unstable vibrational and rotatory states. When the gases return to their normal state, photons of a characteristic frequency are emitted. The scattered photons are measured as peaks in a spectrum that determines the concentration and composition of respiratory gases and inhaled vapors. Advances in laser technology have made Raman spectroscopic monitors available for clinical use. The instrument is fast and easy to calibrate. O₂, N₂, N₂O, CO₂, and H₂O vapor are all measurable using Raman scattering technology.

The clinical indications for routine CO₂ and O₂ gas monitoring are well documented. Monitors equipped to measure anesthetic gases are also prevalent and desirable. Nitrogen monitoring provides quantification of washout during preoxygenation. A sudden rise in N₂ in the exhaled gas indicates either introduction of air from leaks in the anesthesia delivery system or venous air embolism. Critical events that can be detected by the analysis of respiratory gases and anesthetic vapors are listed in [Table 25-2](#).

| Event | Monitoring Modality |
|--|--|
| Error in gas delivery | O ₂ , N ₂ , CO ₂ , agent analysis |
| Anesthesia machine malfunction | O ₂ , N ₂ , CO ₂ , agent |
| Disconnection | CO ₂ , O ₂ , agent analysis |
| Vaporizer malfunction or contamination | Agent analysis |
| Anesthesia circuit leaks | N ₂ , CO ₂ analysis |
| Endotracheal cuff leaks | N ₂ , CO ₂ |
| Poor mask or LMA fit | N ₂ , CO ₂ |
| Hypoventilation | CO ₂ analysis |
| Malignant hyperthermia | CO ₂ |
| Airway obstruction | CO ₂ |
| Air embolism | CO ₂ , N ₂ |
| Circuit hypoxia | O ₂ analysis |
| Vaporizer overdose | Agent analysis |

LMA = laryngeal mask airway.

Table 25-2. DETECTION OF CRITICAL EVENTS BY IMPLEMENTING GAS ANALYSIS

OXYGENATION MONITORING

The assessment of oxygenation is an integral part of anesthesia practice. Early detection and prompt intervention may limit serious sequelae of hypoxemia. The clinical signs associated with hypoxemia (e.g., tachycardia, altered mental status, cyanosis) are often masked or difficult to appreciate during anesthesia. The mechanisms responsible for hypoxemia are multifactorial. Oxygen analyzers assess oxygen delivery to the patient. Other noninvasive technologies detect the presence of arterial hypoxemia. Arterial oxygen monitors do not ensure adequacy of oxygen delivery to, or utilization by, the tissues and should not be considered a replacement for arterial blood gas measurements when more definitive information regarding oxygenation is desired.

Pulse Oximetry

Pulse oximetry is the standard of care for monitoring oxygenation during anesthesia. Pulse oximeters measure pulse rate and oxygen saturation of hemoglobin (Hb) (SpO_2) on a noninvasive, continuous basis. [Figure 25-2](#) displays the oxyhemoglobin dissociation curve that defines the relationship of hemoglobin saturation and oxygen tension. On the steep part of the curve, a predictable correlation exists between SaO_2 and PO_2 . In this range, the SaO_2 is a good reflection of the extent of hypoxemia and the changing status of arterial oxygenation. Shifts in the oxyhemoglobin dissociation curve to the right or to the left define changes in the affinity of Hb for oxygen. At a PO_2 of >75 mm Hg, the SaO_2 plateaus and loses its ability to reflect changes in PaO_2 .

Figure 25-2. The oxyhemoglobin dissociation curve. The relationship between arterial saturation of hemoglobin and oxygen tension is represented by the sigmoid-shaped oxyhemoglobin dissociation curve. When the curve is left-shifted, the hemoglobin molecule binds oxygen more tightly. (Reproduced with permission from Brown M, Vender JS: Non-invasive oxygen monitoring. *Crit Care Clin* 4:493, 1988.)

Pulse oximetry is based on several premises:

1. The color of blood is a function of oxygen saturation.
2. The change in color results from the optical properties of Hb and its interaction with oxygen.
3. The ratio of O_2Hb and reduced Hb can be determined by absorption spectrophotometry.

Pulse oximetry combines the technology of plethysmography and spectrophotometry. Plethysmography produces a pulse trace that is helpful in tracking circulation. Oxygen saturation is determined by spectrophotometry, which is based on the Beer-Lambert law. At a constant light intensity and Hb concentration, the intensity of light transmitted through a tissue is a logarithmic function of the oxygen saturation of Hb. Two wavelengths of light are required to distinguish O_2Hb from reduced Hb. Light-emitting diodes in the pulse sensor emit red (660 nm) and near infrared (940 nm) light. The percentage of O_2Hb and reduced Hb is determined by measuring the ratio of infrared and red light sensed by a photodetector. Pulse oximeters perform a plethysmographic analysis to differentiate the pulsatile “arterial” Hb saturation from the nonpulsatile signal resulting from “venous” absorption and other tissues such as skin, muscle, and bone. The absence of a pulsatile waveform during extreme hypothermia or hypoperfusion limits the ability of a pulse oximeter to calculate the SpO_2 .

The SpO_2 measured by pulse oximetry is not the same as the arterial saturation (SaO_2) measured by a laboratory co-oximeter. Pulse oximetry measures the “functional” saturation, which is defined by the following equation:

$$\text{Functional } SaO_2 = \frac{O_2Hb}{(O_2Hb + \text{reduced Hb})} \times 100$$

Laboratory co-oximeters use multiple wavelengths to distinguish other types of Hb by their characteristic absorption. Co-oximeters measure the “fractional” saturation, which is defined by the following equation:

$$\text{Fractional } SaO_2 = \frac{O_2Hb}{(O_2Hb + \text{reduced Hb} + COHb + MetHb)} \times 100$$

In clinical circumstances where other Hb moieties are present, the SpO_2 measurement is higher than the SaO_2 reported by the blood gas laboratory. In most patients, MetHb and COHb are present in low concentrations so that the functional saturation approximates the fractional value.

Pulse oximetry has been used in all patient age groups to detect and prevent hypoxemia. The clinical benefits of pulse oximetry are enhanced by its simplicity. Modern pulse oximeters are noninvasive, continuous, and autocalibrating. They have quick response times and their battery backup provides monitoring during transport. The clinical accuracy is typically reported to be $\pm 2\text{--}3\%$ at 70–100% saturation and $\pm 3\%$ at 50–70% saturation. Published data from numerous investigations support accuracy and precision reported by instrument manufacturers.

The appropriate use of pulse oximetry necessitates an appreciation of both physiologic and technical limitations. Despite the numerous clinical benefits of pulse oximetry, other factors affect its accuracy and reliability. Factors that may be present during anesthesia care and that affect the accuracy and reliability of pulse oximetry include dyshemoglobins, vital dyes, nail polish, ambient light, light-emitting diode variability, motion artifact, and background noise. Electrocautery can interfere with pulse oximetry if the radiofrequency emissions are sensed by the photodetector. Reports of burns or pressure necrosis exist but are infrequent. These complications can be reduced by inspecting the digits during monitoring.

Recent developments in pulse oximetry technology permit more accurate measurements of SpO_2 during patient movement or low-perfusion conditions. These instruments use complex signal processing of the two wavelengths of light to improve the signal-to-noise ratio and reject artifact. Studies in volunteers suggest that the performance of pulse oximeters incorporating this technology is superior to conventional oximetry during motion of the hand.⁹

There is overwhelming evidence supporting the capability of pulse oximetry for detecting desaturation before it is clinically apparent. Pulse oximetry has wide applicability in many hospital and nonhospital settings. However, there are no definitive data demonstrating a reduction in morbidity or mortality associated with the advent of pulse oximetry. An older large, randomized trial did not detect a significant difference in postoperative complications when routine pulse oximetry was used.¹⁰ However, there was a sense that use of SpO_2 provided early warning of hypoxemia, and anesthesiologists using SpO_2 felt a greater level of comfort than those who did not use SpO_2 . A reduction of anesthesia mortality, as well as fewer malpractice claims for respiratory events, coincident with the introduction of pulse oximeters suggests that the routine use of these devices may have been a contributing factor. Pulse oximetry is an inexpensive, essential tool for anesthesia care.

BLOOD PRESSURE MONITORING

Perioperative measurement of arterial blood pressure is an important indicator of the adequacy of circulation. Systemic blood pressure monitoring is commonly performed indirectly using extremity-encircling cuffs or directly by inserting a catheter into an artery and transducing the arterial pressure trace. Today, anesthesiologists have a variety of techniques available for measuring changes in systolic, diastolic, and mean arterial pressure (MAP).

Arterial Pressure Wave

The size, shape, and transmission of the pressure wave throughout the arterial circulation are related to the dynamics of pulsatile flow, the acceleration and deceleration of blood, the elasticity of the large conducting arteries, and a modulated impedance that controls regional blood flow. Factors contributing to the propagation and character of the pressure pulse include the energy content imparted by ventricular systole (1–600 watts), contour transformation by the vascular tree, and reflective waves that are produced at the periphery. Arterial pressure is created by the interaction of myocardial and vascular factors that impart both potential and kinetic energy to a dynamic arterial blood volume.

Estimates of pressure recorded in the ascending aorta are different from those measured in a peripheral artery because of the aforementioned factors. [Figure 25-3](#) demonstrates that whereas MAP decreases from the aorta to distal arteries, systolic pressure increases. This is due to the tapering of peripheral arteries, which confines the pressure trace energy. Arterial blood pressure represents the lateral pressure exerted on arteries by blood flow. During the cardiac cycle, an arterial pulse wave results as the left ventricular stroke volume is ejected into the blood-filled arterial vascular tree. The elasticity of the aorta and conducting arteries, blood volume, stroke volume, CO, and peripheral vascular resistance determine the beat-to-beat arterial blood pressure.

Figure 25-3. Blood pressure and velocity measurements in normal arteries of dogs. As measurements are made farther away from the ascending aorta, estimates of systolic pressure increase while the blood velocity decreases. The apparent increases in blood pressure occur as a result of reflected waves. (Reproduced with permission from Milnor WR: Hemodynamics. Baltimore, Williams & Wilkins, 1989.)

Direct and indirect measurements of arterial blood pressure depend to a great extent on our ability to evaluate the quality and character of the arterial pulse wave. Many factors influence the accuracy of blood pressure monitoring. Monitoring techniques, no matter how simple or sophisticated, are often constrained by the natural properties of fluid motion and physiologic alterations that often influence accuracy and precision. Blood pressure measurements rely on devices (transducers) that convert pressure (force/unit area) into another form of energy. For example, the Riva-Rocci auscultatory methodology uses the character of sound energy produced when blood flow is restored in the brachial artery after its occlusion.

Discrepancies between indirect methods of estimating systemic blood pressure and intra-arterial pressure measurements occur frequently. Indirect measurements depend on changes in flow or volume and are frequently lower than simultaneously recorded intra-arterial pressure measurements. Although some of the differences are related to the constraints of hydraulically coupled transducing systems, it is probable that real differences exist because intra-arterial transducers respond to force displacement rather than transformations in flow or volume.

Indirect Measurement of Arterial Blood Pressure

The simplest method of blood pressure determination estimates systolic blood pressure by palpating the return of the arterial pulse while an occluding cuff is deflated. Modifications of this technique include the observance of the return of Doppler sounds, the transduced arterial pressure trace, or a photoplethysmographic pulse wave as produced by a pulse oximeter.

Auscultation of the Korotkoff sounds permit estimation of both systolic (SP) and diastolic (DP) blood pressures. MAP can be calculated using an estimating equation ($MAP = DP + 1/3 [SP - DP]$). Korotkoff sounds result from turbulent flow within an artery created by the mechanical deformation from the blood pressure cuff. Systolic blood pressure is signaled by the appearance of the first Korotkoff sound. Disappearance of the sound or a muffled tone signals the diastolic blood pressure.

The detection of sound changes is subjective and prone to errors based on deficiencies in sound transmission or hearing. Cuff deflation rate also influences accuracy. Quick deflations underestimate blood pressure. Palpation and auscultatory techniques require pulsatile blood flow and are unreliable during conditions of low flow. These techniques are reasonably accurate when aneroid gauges are within calibration, the encircling cuff is appropriately sized and positioned, the inflation is above the true systolic pressure, and the Korotkoff sounds or pulse is properly identified.

The American Heart Association recommends that the bladder width for indirect blood pressure monitoring should approximate 40% of the circumference of the extremity. Bladder length should be sufficient to encircle at least 60% of the extremity. Falsely high estimates result when cuffs are too small, when cuffs are applied too loosely, when the extremity is below heart level, or when uneven compression is transmitted to the underlying artery. Falsely low estimates result when cuffs are too large, when the extremity is above heart level, or after quick deflations.

Doppler sphygmomanometry is based on the detection of the Doppler shift using an ultrasonic transceiver to sense the restoration of blood flow during cuff deflation. Some instruments sense the velocity of erythrocytes, whereas others detect arterial wall motion distal to the occlusive blood pressure cuff. These instruments are more sensitive than palpatory or auscultatory techniques and are clinically useful when the peripheral pulse is faint. Compact battery-operated devices are helpful to assess the blood pressure when routine indirect methods fail.

Since 1976, microprocessor-controlled oscillometers have replaced auscultatory and palpatory techniques for routine perioperative blood pressure monitoring. Standard oscillometry measures mean blood pressure by sensing the point of maximal fluctuations in cuff pressure produced while deflating a blood pressure cuff. Most current instruments use oscillometric techniques to measure systolic, diastolic, and mean blood pressures by determining parameter identification points during cuff deflation. Substantial differences exist among the many devices designed for clinical use with respect to their method of operation.

In a generic noninvasive oscillometric monitor (*noninvasive blood pressure*, or NIBP), cuff pressure is sensed by a pressure transducer whose output is digitalized for processing. After the cuff is inflated by an air pump, cuff pressure is held constant while oscillations are sampled. If no oscillations are sensed by the pressure transducer, the microprocessor switches open a deflation valve, and the next lower pressure level is sampled for the presence of oscillations. Artifact-rejection algorithms are implemented during the stepwise deflation sequence at parameter identification points. The microprocessor controlling the operation of the NIBP compares the amplitude of oscillation pairs and numerically displays the blood pressure estimate. [Figure 25-4](#) depicts how a typical NIBP is obtained. In this example, the effect of respiratory variation, a premature ventricular complex, and cuff movement is demonstrated.

Figure 25-4. Diagram illustrating motion artifact, a premature ventricular contraction, and respiratory artifact as sensed by a Dinamap noninvasive blood pressure monitor. (Reproduced with permission from Ramsey M: Blood pressure monitoring: Automated oscillometric devices. *Journal of Clinical Monitoring* 7:56, 1991.)

Automated oscillometry has been demonstrated to correlate well with direct intra-arterial measurement of MAP and diastolic blood pressure. Automated oscillometry may underestimate systolic blood pressure, with mean errors reported from -6.9 to -8.6 mm Hg compared with direct radial artery pressure measurements.

Oscillometry requires the careful evaluation of several cardiac cycles at each increment of deflation to smooth out pronounced respiratory variations or motion artifacts. Cuff movement or erratic pulse transmission influences accuracy. In the anesthetized patient, automated oscillometry is usually accurate and versatile. A variety of cuff sizes makes it possible to use oscillometry in all age groups. Modern instruments incorporate a faster access mode, which can be useful in situations in which rapid changes in arterial blood pressure are anticipated.

Problems With Noninvasive Blood Pressure Monitoring

Cuff-based pressure monitoring continues to be the standard method used in the perioperative period. When clinical circumstances require frequent blood pressure readings for a prolonged period, it is advisable periodically to move the cuff to alternative sites. Failure to deflate the cuff increases venous pressure. Hematomas have been described both beneath and distal to the cuff. Tremors or shivering can delay cuff deflation and prolong the deflation cycle. A compartment syndrome attributed to a prolonged inflation cycle has been described. Ulnar neuropathy has been reported after the use of automated cycled blood pressure cuffs. Compression of the ulnar nerve can be avoided by applying the encircling cuff proximal to the ulnar groove. Automated sequencing may alter the timing of intravenous drug administration when the access site is located in the same extremity. Hydrostatic errors result when blood pressure cuffs are placed on extremities that are above or below the level of the right atrium. The hydrostatic offset can be mathematically corrected by adding or subtracting 0.7 mm Hg for each centimeter that the cuff is off the horizontal plane of the heart.

Indirect Continuous Noninvasive Techniques

Several methods for monitoring blood pressure continuously and noninvasively have been designed and evaluated for intraoperative blood pressure surveillance. These techniques provide clinicians with a continuous blood pressure estimate and an accurate display of the arterial blood pressure trace. *Indirect continuous noninvasive techniques* (ICNTs) continue to be evaluated because it is desirable to enhance beat-to-beat blood pressure monitoring while reducing the inherent risks and costs of direct intra-arterial monitoring. Clinical studies suggest that accuracy and precision of ICNTs are satisfactory, even under conditions of rapidly changing hemodynamics.^{11,12} and ¹³ At present, however, ICNTs are not considered substitutes for direct arterial pressure monitoring in critically ill patients in the operating room.

Invasive Measurement of Vascular (Arterial Blood) Pressure

Indwelling arterial cannulation permits the opportunity to monitor arterial blood pressure continuously and to have vascular access for arterial blood sampling. Intra-arterial blood pressure monitoring uses saline-filled tubing to transmit the force of the pressure pulse wave to a pressure transducer that converts the displacement of a silicon crystal into voltage changes. These electrical signals are amplified, filtered, and displayed as the arterial pressure trace. Intra-arterial pressure transducing systems are subject to many potential errors based on the physical properties of fluid motion and the performance of the catheter-transducer-amplification system used to sense, process, and display the pressure pulse wave.

The behavior of transducers, fluid couplings, signal amplification, and display systems can be described by a complex second-order differential equation. Solving the equation predicts the output and characterizes the fidelity of the system's ability faithfully to display and estimate the arterial pressure over time. The fidelity of fluid-coupled transducing systems is constrained by two properties: damping (z) and natural frequency (F_0). Zeta (z) describes the tendency for saline in the measuring system to extinguish motion. F_0 describes the tendency for the measuring system to resonate. The fidelity of the transduced pressure depends on optimizing z and F_0 so that the system can respond appropriately to the range of frequencies contained in the pressure pulse wave. Analysis of high-fidelity recordings of arterial blood pressure indicate that the pressure trace contains frequencies from 1 to 30 Hz.

The performance of a transducing system is often described by its bandwidth. The bandwidth contains the frequencies in which the transducing system faithfully reproduces the frequencies contained in the pulse pressure wave. Conventional disposable, saline-coupled transducers with 60 inches of pressure tubing have an acceptable bandwidth and commonly have frequency responses approaching 30 Hz. If the system begins to resonate (ringing) or becomes damp (inertia), the fidelity of the system is impaired and estimates of blood pressure become less accurate. Measuring the bandwidth of transducer systems requires complicated equipment. Estimates of z and F_0 can be obtained at the bedside.

Studies have demonstrated that system fidelity is optimized when catheters and tubing are stiff, the mass of the fluid is small, the number of stopcocks is limited, and the connecting tubing is not excessive. Damping lowers the effective bandwidth of the transducer system, which promotes the potential for resonance. [Figure 25-5](#) demonstrates the effect of damping on the character of the arterial pressure trace. In clinical practice, underdamped catheter-transducer systems tend to overestimate systolic pressure by 15–30 mm Hg and amplify artifact (catheter whip). Likewise, excessive increases in z reduce fidelity and underestimate systolic pressure. The presence of air bubbles in the coupling fluid reduces the natural frequency of the transducing system. Dynamic calibration can determine the fidelity of the pressure recording system. For clinical use, it is sufficient to place the transducer at the level of the right atrium, open the stopcock to atmosphere, and balance the electronic amplifying system to display "zero." Periodic checks of the zero reference point ensures that transducer drift is eliminated.

Figure 25-5. The relationship between the frequency of fluid-filled transducing systems and damping. The shaded area represents the appropriate range of damping for a given natural frequency (F_n). The size of the wedge also depends on the steepness of the arterial pressure trace and heart rate. (Reproduced with permission from Gardner RM: Direct blood pressure measurement: Dynamic response requirements. *Anesthesiology* 54:231, 1981.)

Gardner¹⁴ suggested using the "fast flush" test to determine the natural frequency and damping characteristics of the transducing system. This test examines the characteristics of the resonant waves recorded after the release of a flush. Damping is estimated by the amplitude ratio of the first pair of resonant waves and the

natural frequency is estimated by dividing the paper speed by the interval cycle. Kleinman *et al*¹⁵ have confirmed the utility of the fast flush test. Because many therapeutic decisions are based on changes in arterial blood pressure, it is imperative that anesthesiologists understand the physical limitation imposed by fluid-filled pressure transducer systems. Significant exaggeration of pressure measurements occur when the transducer system has a resonant frequency in the range of the pressure wave frequencies. Systolic pressure is underestimated when measured with overdamping systems and overestimated by underdamping or resonating systems. Mean pressure estimates are typically less affected even when damping and resonance are not optimal.

Arterial Cannulation

Multiple arteries can be used for direct measurement of blood pressure, including the radial, brachial, axillary, femoral, and dorsalis pedis arteries. The radial artery remains the most popular site for cannulation because of its accessibility and the presence of a collateral blood supply. In the past, assessment of the patency of the ulnar circulation by performance of an Allen's test has been recommended before cannulation. Allen's test is performed by compressing both radial and ulnar arteries while the patient tightens his or her fist. Releasing pressure on each respective artery determines the dominant vessel supplying blood to the hand. The prognostic value of the Allen's test in assessing the adequacy of the collateral circulation has not been confirmed.^{16,17}

Radial artery cannulation and blood pressure monitoring have been associated with several problems. The radial artery pulse pressure wave is subject to inaccuracies inherent to its distal location. After separation from cardiopulmonary bypass, large pressure gradients between aortic and radial arteries have been described.

Complications of Invasive Arterial Monitoring

Traumatic cannulation has been associated with median nerve dysfunction, hematoma formation, and thrombosis. Abnormal radial artery blood flow after catheter removal occurs frequently. Studies suggest that blood flow normalizes in 3–70 days. Radial artery thrombosis can be minimized by avoiding polypropylene-tapered catheters and reducing the duration of arterial cannulation. Flexible guidewires may reduce the potential trauma associated with catheters negotiating tortuous vessels. During cannula removal, the potential for thromboembolism may be diminished by compressing the proximal and distal arterial segment while aspirating the cannula during withdrawal.

Many cannulation sites have been used for direct arterial blood pressure monitoring (Table 25-3). Three techniques for cannulation are common: direct arterial puncture, guidewire-assisted cannulation (Seldinger's technique), and the transfixion–withdrawal method. A necessary condition for percutaneous placement is identification of the arterial pulse. Doppler flow probes are helpful in situations in which the location of the arterial pressure pulse is difficult to palpate.

| Arterial Cannulation Site | Clinical Points of Interest |
|---------------------------|---|
| Radial artery | Preferred site for monitoring Nontapered catheters preferred |
| Ulnar artery | Complication similar to radial |
| Brachial artery | Primary source of hand blood flow Insertion site medial to biceps tendon Median nerve damage is potential hazard |
| Axillary artery | Can accommodate 18-gauge cannula Insertion site at junction of pectoralis and deltoid muscle Specialized kits available |
| Femoral artery | Easy access in low flow states Potential for local and retroperitoneal hemorrhage |
| Dorsalis pedis artery | Longer catheters preferred Collateral circulation – posterior tibial artery Higher systolic pressure estimates |

Table 25-3. ARTERIAL CANNULATION AND DIRECT BLOOD PRESSURE MONITORING

Arterial cannulation is regarded as an invasive procedure with a documented morbidity. Ischemia after radial artery cannulation resulting from thrombosis, proximal emboli, or prolonged shock has been described.¹⁸ Contributing factors include severe atherosclerosis, diabetes, low CO, and intense peripheral vasoconstriction. Ischemia, hemorrhage, thrombosis, embolism, cerebral air embolism (retrograde flow associated with flushing), aneurysm formation, arteriovenous fistula formation, skin necrosis, and infection have occurred as the direct result of arterial cannulation, arterial blood sampling, or high-pressure flushing.

Continuous-flush devices are incorporated into disposable transducer kits and infuse at 3–6 ml · h⁻¹. In neonates, the infusion volume may contribute to fluid overload. Continuous-flush devices have little effect on the blood pressure measurement. However, pressurized flush systems may serve as a source of an air embolism. Removing air from the pressurized infusion bag, stopcocks, and tubing minimizes the potential for air embolism.

Arterial sampling is an important source of bacterial contamination of transducer systems. Shinozaki and colleagues¹⁹ found that the stopcocks are an important source of contamination. The longer the transducer system is in place, the greater the incidence of nosocomial contamination. Guidelines published by the Centers for Disease Control²⁰ (CDC) recommend that intravascular catheters should be routinely changed every 48 or 72 hours to reduce the risk of catheter-associated infection.

Direct arterial pressure monitoring requires constant vigilance. The data displayed must correlate with clinical conditions before therapeutic interventions are initiated. Sudden increases in the transduced blood pressure may represent a hydrostatic error because the position of the transducer was not adjusted after change in the operating room table's height. Sudden decreases often result from kinking of the tubing. Before initiating therapy, the transducer system should be "rezeroed" and the patency of the arterial cannula verified. This ensures the accuracy of the measurement and avoids a potentially dangerous medication error.

Central Venous and Pulmonary Artery Monitoring

Central venous cannulas are important portals for intraoperative vascular access and for the assessment of changes in vascular volume. Percutaneous insertion of central venous pressure (CVP) catheters is a skill that every anesthesiologist needs to acquire. CVP portals permit the rapid administration of fluids, insertion of pulmonary artery catheters (PACs), insertion of transvenous electrodes, monitoring of CVP, and a site for observation and treatment of venous air embolism.

The right internal jugular vein is the preferred site for cannulation because it is accessible from the head of the operating table, has a predictable anatomy, and has a high success rate in both adults and children.²¹ The left-sided internal jugular vein is also available but is less desirable because of the potential for damaging the thoracic duct or difficulty in maneuvering catheters through the jugular–subclavian junction. Accidental carotid artery puncture is a potential problem with either location.

Three techniques (posterior, central, and anterior) have been described for internal jugular cannulation. Each insertion point is referenced to the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle. Venipuncture using a 22-gauge "seeker" needle minimizes trauma to adjacent structures. When the location of the internal jugular vein is difficult to ascertain, ultrasonography can assist in identifying the proximity of internal jugular vein and the carotid artery. Alternatives to the internal jugular vein include the external jugular, subclavian, antecubital, and femoral veins.

Central Venous Pressure Monitoring

The benefit of CVP monitoring has been the subject of considerable debate. Proponents of CVP monitoring believe that CVP pressures are essentially equivalent to right atrial pressures and serve as a reflection of right ventricular preload.²² Conditions that affect right atrial pressure also influence the CVP pressure trace. The normal CVP waveform consists of three peaks (a, c, and v waves) and two descents (x, y), each resulting from the ebb and flow of blood in the right atrium (Fig. 25-6). Corresponding events occur in the left atrium and similar pressure contours are observed during monitoring of pulmonary artery pressure when the PAC is placed in the occluded position.

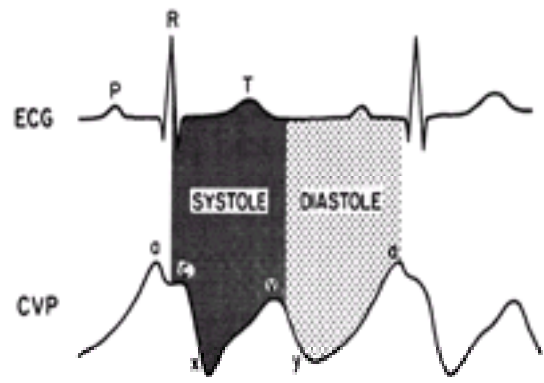

Figure 25-6. The normal central venous pressure trace. (Redrawn with permission from Mark JB: Central venous pressure monitoring: Clinical insights beyond the numbers. J Cardiothorac Vasc Anesth 5:163, 1991.)

The character of the CVP trace depends on many factors, including heart rate, conduction disturbances, tricuspid valve function, normal or abnormal intrathoracic pressure changes, and changes in right ventricular compliance. In patients with atrial fibrillation, a waves are absent. When resistance to the emptying of the right atrium is present, large a waves are often observed. Examples include tricuspid stenosis, right ventricular hypertrophy due to pulmonic stenosis, or acute or chronic lung disease associated with pulmonary hypertension. Large a waves are often observed when right ventricular compliance is impaired.

Tricuspid regurgitation typically produces giant v waves that begin immediately after the QRS complex. Large v waves are often observed when right ventricular ischemia or failure is present or when ventricular compliance is impaired by constrictive pericarditis or cardiac tamponade. Diagnosis of right ventricular ischemia is often difficult. A prominent v wave during CVP monitoring may suggest right ventricular papillary muscle ischemia and tricuspid regurgitation. When right ventricular compliance decreases, the CVP often increases with prominent a and v waves fusing to form an m or w configuration.

Central venous pressure monitoring is helpful in the diagnosis and treatment of pericardial tamponade, where equalization of diastolic filling pressures typically occurs. As the CVP tracing becomes monophasic, the y descent is lost. Equalization of diastolic filling pressures of the CVP, right ventricle, pulmonary artery, and pulmonary artery occlusion pressure is a characteristic of hemodynamically significant pericardial constriction and cardiac tamponade. After treatment, a dramatic drop in filling pressures, restoration of systemic blood pressure, and a normalization of the CVP waveform should occur.

Central venous pressure monitoring is often unreliable for estimating left ventricular filling pressures, especially when cardiopulmonary disease processes alter the normal cardiovascular pressure–volume relationships. CVP monitoring is less invasive and less costly than pulmonary artery monitoring and offers unique understanding of right-sided hemodynamic events and the status of vascular volume.

Pulmonary Artery Monitoring

The development of the flow-directed, balloon flotation PAC was a major advance in hemodynamic monitoring, and it has become an important tool in the quantitative assessment of cardiopulmonary function. The original indication for PAC monitoring was for the management of complicated myocardial infarction. Because right-sided heart pressures are often unreliable determinants of left ventricular filling pressures, pulmonary artery monitoring is commonly used in the perioperative period when caring for patients with pre-existing cardiopulmonary or renal disease or shock, or when surgical interventions or ongoing disease processes are associated with excessive blood or fluid losses or cardiopulmonary dysfunction. Numerous articles have reviewed the various applications and benefits of pulmonary artery monitoring.²³ Use should be guided by the information needed for enhanced diagnosis and therapy.²⁴ Today, PAC monitoring is commonly used in surgical patients to help evaluate and treat hemodynamic alterations, which contribute significantly to the morbidity and mortality inherent to the surgical care of high-risk patients.

The ASA established a task force to examine the evidence supporting the clinical effectiveness of PAC monitoring. Issues such as the timing of PAC monitoring, its effect on treatment decisions, patient selection and case mix, and evidence regarding PAC monitoring contribution to positive or negative outcomes were evaluated using stringent evidence-based methodology. This effort identified many flaws in the body of evidence, which made it difficult to draw meaningful conclusions regarding the effectiveness of PAC monitoring to reduce morbidity or mortality. The consensus opinion implies that PAC monitoring may reduce perioperative complications if critical hemodynamic data obtained during appropriate PAC monitoring are accurately interpreted and appropriate treatment is tailored to the conditions as they change over time.²⁵ Monitoring the hemodynamic status of high-risk patients may reduce cardiac complications (e.g., myocardial ischemia, congestive heart failure, dysrhythmias), renal insufficiency, brain injury, and pulmonary complications.

Pulmonary artery catheters permit the measurement of intracardiac pressures, thermodilution CO (TCO), mixed venous oxygen saturation, intracavitary electrograms, and lung water. This information can help define clinical problems, monitor the progression of hemodynamic dysfunctions, and guide the response of corrective therapy.

The measurement of intracardiac pressures can indirectly assess left ventricular preload, diagnose the existence of pulmonary hypertension, or differentiate cardiac and noncardiac causes of pulmonary edema. PACs allow for the rapid and reproducible measurements of TCO, calculation of oxygen delivery ($CO \times$ arterial O_2 content), and assessment of cardiac work. Hemodynamic measurements are often predicated on the manipulation of preload, afterload, and contractility. Several derived indices of hemodynamic function necessitate measurements commonly obtained from PAC monitoring (Table 25-4).

| Name | Abbreviation | Calculation | Units |
|-------------------------------------|--------------|-------------------------------------|-----------------------------------|
| Cardiac index | CI | CO/BSA | $l \cdot min^{-1} \cdot m^{-2}$ |
| Systemic vascular resistance | SVR | $(MAP-CVP)/CO \times 80$ | $dyne \cdot cm^{-5}$ |
| Pulmonary vascular resistance | PVR | $(MPAP-PCWP)/CO \times 80$ | $dyne \cdot cm^{-5}$ |
| Stroke index | SI | $CI/heart\ rate$ | $cc \cdot beat^{-1} \cdot m^{-2}$ |
| Left ventricular stroke work index | LVSNI | $SI \times (MAP-PCWP) \times 0.136$ | $gm \cdot beat^{-1} \cdot m^{-2}$ |
| Right ventricular stroke work index | RVSNI | $SI \times (MPAP-CVP) \times 0.136$ | $gm \cdot beat^{-1} \cdot m^{-2}$ |

BSA = body surface area; MAP = mean arterial pressure; CVP = central venous pressure; MPAP = mean pulmonary arterial pressure; PCWP = pulmonary capillary wedge pressure.

Table 25-4. DERIVED HEMODYNAMIC VARIABLES

Access to mixed venous blood from the pulmonary artery port provides an indirect assessment of the balance between O_2 delivery and O_2 utilization. Mixed venous oxygen saturation ($S\bar{V}O_2$) measurements are needed to calculate mixed venous oxygen content ($C\bar{V}O_2$). $C\bar{V}O_2$ is an important variable used for calculating intrapulmonary (Eqn. 25-1) or intracardiac shunts (Eqn. 25-2).

$$\frac{C_{CO_2} - C_{aO_2}}{C_{CO_2} - C\bar{V}O_2} = \frac{Q_s}{Q_t} \quad (25-1)$$

$$\frac{S_{aO_2} - S_{RAO_2}}{S_{aO_2} - S\bar{V}O_2} = \frac{Q_p}{Q_s} \quad (25-2)$$

Where C_{CO_2} = capillary O_2 content, C_{aO_2} = arterial O_2 content, $C\bar{V}O_2$ = mixed venous O_2 content, Q_s/Q_t = shunt fraction, S_{aO_2} = arterial O_2 saturation, S_{RAO_2} = right

atrial O_2 saturation, $\overline{SvO_2}$ = mixed venous O_2 saturation, and \dot{Q}_p/\dot{Q}_s = pulmonary-to-systemic shunt.

The validity of PAC monitoring depends on a properly functioning pressure monitoring system, correctly identifying the “true” *pulmonary capillary wedge pressure* (PCWP), and integration of the various factors that affect the relationship of PCWP, and the other cardiac pressures and volumes that are determinants of ventricular function. [Figure 25-7](#) depicts the transduced pressure waves observed as a PAC is floated to the wedged position. Catheter placement is most commonly performed by observing the pressure waves as the catheter is floated from the CVP position through the right heart chambers into the pulmonary artery.

Figure 25-7. Pressure tracing observed during the flotation of a pulmonary artery catheter. (Reproduced with permission from Dizon CT, Barash PG: The value of monitoring pulmonary artery pressure in clinical practice. *Conn Med* 41:622, 1979.)

Pulmonary artery catheter monitoring necessitates an appreciation of the various physiologic determinants of CO and oxygen delivery. The PAC is used to continuously monitor the pulmonary artery pressure and intermittently monitor pulmonary wedge pressure. PCWP is used to assess left ventricular preload indirectly by reflecting changes in left ventricular end-diastolic pressure (LVEDP). [Figure 25-8](#) depicts the relationship between the various pressures in the cardiopulmonary system.

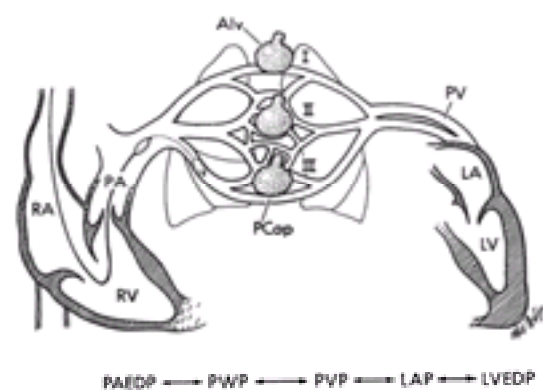

Figure 25-8. The anatomic position of a pulmonary artery catheter in the pulmonary artery. The dashed line positions the inflated balloon in the “wedged” position. (RA = right atrium; RV = right ventricle; PA = pulmonary artery; Alv = alveolus; Pcap = pulmonary capillary; PV = pulmonary vein; LA = left atrium; LV = left ventricle.) I, II, and III characterize the relationship of P_{alveolar} , P_{arterial} , and P_{venous} as described by West. The bottom of the figure shows a progressive correlation of vascular pressures. (Reproduced with permission from Vender JS: Invasive cardiac monitoring. *Crit Care Clin* 4:455, 1988.)

It has been well demonstrated that right-sided pressures often are poor indicators of left ventricular filling, either as absolute numbers or in terms of the direction of change in response to therapy. The correlation of these pressures as estimates of LVEDP (or left ventricular end diastolic volume [LVEDV]) is directly related to their proximity to the left ventricle and the status of ventricular compliance. Assuming an open conduit from the catheter tip to the left ventricle, when the PAC is occluded (“wedged”), the right-sided heart chambers and valves are bypassed. During end-diastole, there is cessation of forward blood flow, and a static fluid column is presumed to exist from the left ventricle to the PAC tip. Ideally, changes in LVEDP are reflected by all proximal pressures (left atrial, pulmonary venous, pulmonary artery end-diastolic pressure [PAEDP], and PCWP). Alterations of internal or external forces applied to the open conduit during PCWP measurements may invalidate the PCWP-LVEDP-LVEDV relationship.

Factors Affecting the Accuracy of Pulmonary Artery Catheter Data

Pulmonary Vascular Resistance. Any disease process or condition that increases pulmonary vascular resistance has the potential to reduce pulmonary blood flow and alter the relationship between PCWP and PAEDP. Pathologic conditions such as acute or chronic lung disease, pulmonary emboli, alveolar hypoxia, acidosis, and hypoxemia, and many vasoactive drugs increase pulmonary vascular resistance and have the potential to modify the PCWP-PAEDP relationship. Tachycardia shortens ventricular diastole and also increases pulmonary vascular resistance.

Alveolar–Pulmonary Artery Pressure Relationships. West *et al*²⁶ described a gravity-dependent difference between ventilation and perfusion in the lung. The variability in pulmonary blood flow is a result of differences in pulmonary artery (PA), alveolar (Palv), and venous pressures (PV) and is categorized into three distinct zones. Only Zone III ($PA > PV > Palv$) meets the criteria for uninterrupted blood flow and a continuous communication with distal intracardiac pressures. Increases in alveolar pressure, decreases in perfusion, or changes in positioning can convert areas of Zone III into either Zone II or I. Flow-directed PACs usually advance to gravity-dependent areas of highest blood flow.

The location of a PAC can be confirmed by a lateral chest film to ascertain that the catheter tip is below the level of the left atrium. The following characteristics suggest that the PAC tip is not in Zone III: $PCWP > PAEDP$, nonphasic PCWP tracing, and inability to aspirate blood from the distal port when the catheter is wedged.

Respiratory Pattern and Airway Pressure. Changes in intrathoracic and intrapleural pressure affect transmural cardiac pressures. Transmural pressure is defined as the net distending pressure of the left ventricle. Changes in intrathoracic pressure affect the PCWP-LVEDP relationship. Positive end-expiratory pressure (PEEP) therapy can induce changes in both intravascular and intrapleural pressures. PEEP increases alveolar pressure, potentially converting Zone III areas to Zone II. If PEEP is transmitted across the alveoli, intrapleural pressure increases. Pulmonary compliance determines the extent of this effect. PEEP alters ventricular distensibility and decreases venous return. This causes a disproportionate increase in PCWP (and LVEDP) compared with changes in LVEDV.

The effect of PEEP therapy is minimal if the levels of PEEP are low (≤ 10 cm) and the PAC is located in Zone III. Higher levels of PEEP influence the PCWP-LVEDP relationship. During high PEEP therapy, esophageal pressure measurements can be made to determine intrapleural pressure. Alternatively, subtracting 1–2 mm Hg from the displayed “wedge” pressure for each 5 cm H_2O of PEEP therapy gives an estimate when PEEP is above 10 cm H_2O .

Intracardiac Factors. Pathologic obstruction at the mitral valve secondary to mitral stenosis, atrial myxoma, or clot can interfere with the ability of left atrial pressure to reflect LVEDP. Similarly, mitral regurgitation, a noncompliant left atrium, or left-to-right intracardiac shunting often is associated with large v waves.

Decreases in left ventricular compliance, aortic regurgitation, or premature closure of the mitral valve may reverse the left atrial pressure–LVEDP pressure gradient. When this occurs, PCWP is not a valid reflection of LVEDV.

[Figure 25-9](#) graphically depicts the relationship between LVEDP and LVEDV. The LVEDP–LVEDV relationship is not linear. A family of LVEDP–LVEDV compliance curves characterizes the effect of changing the stiffness of the left ventricle. Ventricular compliance is a dynamic factor influenced by many physiologic and pathologic variables. The LVEDP-LVEDV compliance curves suggest that at low preloads, larger increases in LVEDV produce smaller changes in LVEDP. Conversely, at higher preloads, a similar change in LVEDV produces a greater pressure change. For a given LVEDV, any decrease in ventricular compliance results in an increase in

LVEDP. This explains the development of hydrostatic pulmonary edema at normal LVEDV. Factors that are associated with changes in ventricular compliance are listed in [Table 25-5](#).

Table 25-5. DECREASED LEFT VENTRICULAR COMPLIANCE: COMMON ETIOLOGIES

Adverse Effects of Pulmonary Catheter Monitoring

Complications from PAC monitoring can result during central venous access, the catheterization procedure, or any time after PAC placement. Central venous access represents an invasive process with inherent risks, some of which are potentially life threatening.

Unintentional puncture of nearby arteries, bleeding, neuropathy, and pneumothorax may result from needle insertion into adjacent structures. Air embolism may occur if a cannula is open to the atmosphere and air is entrained during or after CVP placement. Dysrhythmias are common during the catheterization procedure, with a reported incidence of 4.7–68.9%. Ventricular tachycardia or fibrillation may be induced during catheter advancement. Catheter advancement has been associated with right bundle-branch block and, in patients with pre-existing left bundle-branch block, may precipitate complete heart block. [Table 25-6](#) summarizes the adverse effects as reported by the ASA task force on pulmonary artery catheterization.²⁵

| Complication | Reported Incidence (%) |
|---|------------------------|
| Central venous access | 1.1–13 |
| Arterial puncture | 3.3 |
| Postoperative neuropathy | 0.3–1.1 |
| Pneumothorax | 0.3–4.5 |
| Air embolism | |
| Flotation of pulmonary artery catheter | |
| Major dysrhythmias | 4–68.9 |
| Ventricular tachycardia or fibrillation | 0.3–62.7 |
| Right bundle branch block | 0.1–4.3 |
| Complete heart block (prior left bundle-branch block) | 0–6.3 |
| Complications associated with catheter residence | |
| Pulmonary artery rupture | 0.1–1.5 |
| Positive cultures from catheter tip | 1.4–34.8 |
| Sepsis secondary to catheter residence | 0.7–11.4 |
| Biventricular thrombosis | 0.5 |
| Venous thrombosis | 0.5–66.7 |
| Pulmonary infarction | 0.1–3.6 |
| Mural thrombus | 38–61 |
| Valvular or endocardial vegetations | 2.2–100 |
| Deaths attributed to pulmonary artery catheter | 0.02–1.5 |

Table 25-6. ADVERSE EFFECTS ASSOCIATED WITH PULMONARY ARTERY MONITORING

The rate of iatrogenic deaths associated with PAC monitoring is uncertain. The most dreaded complication associated with PAC monitoring is pulmonary artery rupture. Pulmonary hypertension, coagulopathy, and heparinization are often present in patients who have died of pulmonary artery rupture. Perforations and subsequent hemorrhage can be avoided by restricting “overwedging,” minimizing the number of balloon inflations, and using proper technique during balloon inflations. Sepsis is a potential complication of the continued use of PACs. Although cultures of PAC tips are often positive, the exact incidence of catheter-related sepsis is uncertain. Catheter-related sepsis has a reported incidence of 0.7–11.4%.

Since the advent of PACs, several modifications have been integrated into the design that enhance their monitoring capabilities. The first significant design modification incorporated a thermistor at the tip, permitting the measurement of CO. Other features have been introduced for clinical use or evaluation. These include mixed venous oximetry, measurement of right ventricular ejection fraction, pacing options, and continuous CO monitoring (CCOM).

Mixed Venous Oximetry

Continuous estimates of $\bar{S}\bar{V}O_2$ provide a reflection of total tissue oxygen balance. Oxygen delivery ($\dot{D}O_2$) equals the arterial oxygen content multiplied by the CO ($\dot{D}O_2 = [Hb \times 13.8] \times CO$), where 13.8 represents the volume of oxygen carried by Hb converted to grams per liter. Oxygen consumption ($\dot{V}O_2$) is determined by the difference between arterial and venous oxygen delivery. The relationship between $\bar{S}\bar{V}O_2$, $\dot{V}O_2$, and $\dot{D}O_2$ is demonstrated in the following equation derived from the Fick relationship:

$$\bar{S}\bar{V}O_2 = SaO_2 - \frac{\dot{V}O_2}{Hb \times 13.8} \times CO$$

This equation indicates that changes in $\bar{S}\bar{V}O_2$ vary directly with changes in CO, Hb, and SaO_2 and inversely with $\dot{V}O_2$. The normal $\bar{S}\bar{V}O_2$ is 75%, which denotes tissue oxygen extraction = 25%.

The oximetric PAC uses reflectance spectrophotometry and technology similar to pulse oximetry. Several wavelengths are transmitted through optical fibers embedded in the pulmonary artery. The reflected intensity of light identifies the saturation of blood surrounding the tip of the PAC. Three-wavelength *in vivo* systems correlate well

with simultaneous samples measured by co-oximetry.^{27,28} An example of the utility of mixed venous oximetry is depicted in [Figure 25-10](#).

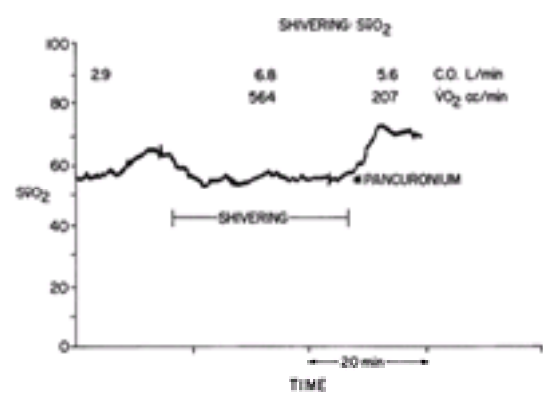

Figure 25-10. This $\overline{SvO_2}$ recording in a postcoronary artery bypass patient demonstrates the effects of shivering and its treatment, and the relationship between $\overline{SvO_2}$, cardiac output (CO), and metabolic rate ($\dot{V}O_2$). Indicator Dilution Applications

Indicator dilution determination of CO is based on a concept proposed by Stewart and tested by Hamilton and colleagues. TCO determination is the most widely used adaptation of the indicator dilution principle, which was first described by Fegler in 1954.²⁹ Today, cooled 5% dextrose or 0.9% saline is used as the indicator. A thermistor located at the PAC tip records the decrease in temperature as the bolus of cooled injectate passes through the pulmonary artery. Computers contend with the complexity of the TCO equation, which includes the following factors: specific heat of the blood and the indicator fluid, the volume of injectate, catheter size, specific gravity of the blood and indicator, the volume of the injectate, and the area of the blood temperature curve. Unlike dye dilution techniques, in which the concentration of indicator increases with each determination, the effect of adding cold injectate on core temperature is insignificant. Comparison studies suggest that using either room-temperature or iced injectates provides accurate estimates of CO. Iced injectate is preferred because it produces a more exacting curve with a better signal-to-noise ratio.³⁰

When properly performed, TCO measurements correlate well with direct Fick or dye dilution estimates of CO. In clinical practice, triplicate determinations are averaged to increase precision. Differences in values of 12–15% are not of clinical significance. TCO estimates vary with the respiratory cycle. This variability can be reduced by performing measurements at peak inspiration or end-expiration. Precision is enhanced by ensuring that the rate of injection and the volume are constant. Most CO computers delay the repeat measurement 30–90 seconds to stabilize the thermal environment of the pulmonary thermistor.

Observation of the thermal curve is helpful. Low-amplitude curves result when the injectate volume is too small, the temperature differential between injectate and blood temperature is small, or when the thermistor is improperly positioned. Tricuspid or pulmonic regurgitation and intracardiac shunts may produce recirculation errors and a falsely elevated TCO.

Adaptations for Continuous Cardiac Output Monitoring

Continuous CO monitoring offers the potential to identify acute changes in ventricular performance as they occur. A properly positioned PAC provides access to the right atrium, right ventricle, and pulmonary artery outflow tract. These locations provide many options for assessment of CCOM. Several thermal techniques are currently used. Pulsed thermodilution uses a coiled right ventricular filament that is randomly heated. A thermistor at the tip of the PAC detects changes in blood temperature and sends the temperature information to a microcomputer that uses stochastic analysis to create a thermodilution curve. CO is computed continuously from a conservation of heat equation.³¹

Another technique applies heat to a thermistor located at the tip of a PAC. The right ventricular outflow subsequently cools the tip. The temperature changes registered are proportional to the decreased temperature produced by right ventricular blood flow. Both of these systems require calibration using standard thermodilution before initiating the CCOM mode. CCOM compares favorably with bolus CO measurements, even under conditions of varying patient temperature and CO.³²

Doppler PAC methodology measures the blood flow velocity in the pulmonary artery. If the diameter of the pulmonary artery can be measured or estimated, then continuous monitoring of the CO is possible.³³

Right Ventricular Ejection Fraction

Calculation of right ventricular ejection fraction and end-diastolic volume may be performed with a special PAC that uses a rapid response thermistor and a sophisticated computer system. This system analyzes the exponential decay of the pulmonary artery temperature over several cardiac cycles and calculates the ejection fraction by subtracting the mean residual fraction from the CO. Studies have demonstrated good correlation with *in vitro* techniques and clinical utility for detecting intraoperative right ventricular ischemia.^{34,35} and ³⁶ Right ventricular ejection fraction monitoring has been recommended when impairment of right ventricular function is suspect. Accuracy requires proper placement. Atrial fibrillation and tricuspid regurgitation can affect the accuracy of the thermal decay methodology.

Clinical Benefits of Pulmonary Artery Monitoring

The debate regarding the clinical benefit of PAC monitoring has persisted since the mid-1980s. Controversy was initially stimulated by two articles suggesting that PACs may worsen outcome.^{37,38} The publication of the Study to Understand Prognosis and Preferences for Outcomes and Risks of Treatment (SUPPORT) in 1996 suggested that patients managed with PACs had increased 30-day mortality rates and longer intensive care unit and hospital stays.³⁹ This study design had several limitations that make interpretation of the data difficult. The SUPPORT protocol did not define treatment interventions to be used in response to the data provided by the PAC, and patients who received PACs were more critically ill than those who did not. The SUPPORT study illustrates the need for a large-scale prospective trial, in which patients are randomized to a control or PAC group, to determine the clinical benefits of PAC monitoring.

Inadequate understanding and application by physician users have been implicated as conditions that limit the benefit of PAC monitoring. To optimize clinical outcome and reduce complications, the care provider must be able to interpret and use the data provided by the PAC. A questionnaire that measured physician knowledge of the technical and theoretical aspects of PAC monitoring was administered to critical care specialists in the United States and Europe. These surveys revealed knowledge of pulmonary artery catheterization is not uniformly good among intensive care unit physicians, with only half of respondents able to read the PCWP correctly from a clearly marked tracking.^{40,41} Changes in training and credentialing have been proposed to improve these deficiencies in knowledge.^{42,43} In experienced and knowledgeable hands, the PAC can add valuable information with limited risk.

NONINVASIVE TECHNIQUES FOR CARDIAC OUTPUT

The quest for technically simple, noninvasive methods for accurately estimating CO continues. Two methods are available for clinical use.

Impedance Plethysmography

Impedance plethysmography is based on determining the pulsatile changes in resistance occurring during ventricular ejection. Four electrodes are applied to the neck and thorax and a small electric current is applied. Impedance measurements (dZ/dT) are made using two thoracic electrode pairs. Changes in impedance correlate with stroke volume. CO is estimated by determining stroke volume and ventricular ejection time.⁴⁴ Electrode placement is an important source of error. Other factors influencing bioimpedance measurements include intrathoracic fluid shifts and changes in hematocrit. More than 150 validation studies have been published, and both poor and good correlations between impedance plethysmography and a reference method have been reported.⁴⁵ Although impedance plethysmography has not gained wide acceptance, the technique offers clinicians a simple, quick method to determine CO with minimal direct patient risk.

Doppler Ultrasonography

Continuous-wave or pulsed-wave Doppler ultrasonography can measure the velocity of blood in the ascending or descending aorta or outflow tract of the pulmonary artery. CO is calculated by multiplying the time-weighted average velocity of blood flow by an estimate of aortic or pulmonary artery cross-sectional area that can be directly measured or predicted from a nomogram. Accuracy and precision depend on the estimate of the vessel diameter and the alignment of the Doppler probe. Velocity measurements are most accurate when the Doppler probe and the blood flow are parallel. If the alignment exceeds 25 degrees, velocity measurements lose precision. Suprasternal, transtracheal, and transesophageal probes have been designed for clinical use.^{46,47} The development of esophageal Doppler probes allows for continuous, minimally invasive estimation of CO, and may allow for optimization of intravascular volume status without the use of a CVP or PAC.⁴⁸

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

The use of transesophageal echocardiography (TEE) in the perioperative period has increased significantly since its first application in humans was reported by Frazen in 1976. Rapid technological advances have occurred since then, including a reduction in transducer size, the development of biplane and multiplane probes, and the use of pulsed-wave, continuous-wave, and color flow Doppler. Improvements in computer design and image acquisition have allowed for a more comprehensive examination of the heart and surrounding structures. TEE appears to offer distinct advantages over other monitors of cardiovascular function, and can provide the anesthesiologist with unique diagnostic information in the operating room.

Ultrasound transducers use piezoelectric crystals to transmit and receive high-frequency sound waves. As emitted ultrasound waves are propagated through the surrounding tissues, the energy is absorbed, scattered, or reflected back to the transducer. The amount of ultrasound energy reflected back to the transducer depends on differences in acoustic impedance between two tissues. The greater the difference in density, the greater the reflection. Because sound waves travel through soft tissue at a constant velocity, the time delay for the ultrasound beam to be reflected back to the transducer can be used to calculate the precise distance between the transducer and the object being interrogated.

Modern TEE machines offer a number of imaging techniques. In *M-mode*, or motion mode, all of the structures along a narrow ultrasound beam are plotted on the x-axis vs. time on the y-axis. M-mode allows only a few millimeters of the heart to be visualized at any one time. *Two-dimensional (2-D) mode* uses multiple scanning lines to create a two-dimensional image of a cross-section of the heart. This image is updated 30–60 times per second, which produces a real-time display of cardiac motion.

Doppler technology provides information about blood flow in the heart and major vessels. The *Doppler effect* is based on the principle that moving objects (red blood cells) change the frequency of the emitted ultrasound beam. If an object is moving toward the transducer, the ultrasound beam is compressed, which increases the frequency of the transmitted signal. An object moving away from the transducer lowers the frequency of the transmitted ultrasound beam. This information allows the calculation of blood flow velocity within the cardiovascular system. Current TEE machines use three Doppler systems: pulsed-wave, continuous-wave, and color flow Doppler. *Pulsed-wave Doppler* uses a single crystal to emit and receive short bursts of ultrasound at a known frequency (pulse repetition frequency). By measuring the time required for the transmitted ultrasound bursts to return to the transducer, the velocity of blood flow at precise locations in the heart can be measured. A major limitation of pulsed-wave Doppler is that high-velocity flows cannot be accurately quantified. The maximal velocity that can be measured is limited to one half of the pulse repetition frequency; this is known as the Nyquist limit. *Continuous-wave Doppler* uses two crystals (one to transmit, one to receive) to measure blood flow velocity continuously. This allows for accurate measurement of high-velocity flows, but does not permit precise localization. *Color flow Doppler* uses pulsed-wave technology to measure blood flow velocity at multiple sites. Blood flow toward the transducer is coded red and flow away from the transducer is coded blue. Rapidly accelerating or turbulent flow is coded green. By superimposing this color map on a 2-D image of the heart, the direction and velocity of blood flow in the heart can be easily imaged.

Monitoring Applications

There are a number of important monitoring applications for TEE in the perioperative period. In 1996, the ASA and the Society of Cardiovascular Anesthesiologists published practice guidelines to define the proper indications for performing TEE in the operative setting.⁴⁹ Indications were divided into three categories.

Category I indications are supported by the strongest evidence or expert opinion; TEE frequently is useful in improving clinical outcomes and is often indicated, depending on patient risk and practice setting. Category II indications are supported by weaker evidence and expert consensus; TEE may be useful in improving clinical outcomes, depending on individual circumstances. Category III indications have little current scientific or expert support, and TEE is infrequently useful in improving clinical outcomes. These indications are summarized in [Table 25-7](#).

Table 25-7. INDICATIONS FOR PERIOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography is used extensively as a monitor of ventricular function. TEE appears to provide more accurate estimates of left ventricular preload than pulmonary artery catheterization. In echocardiography, preload is determined by measuring end-diastolic area. Studies in patients undergoing cardiac or vascular surgery revealed that end-diastolic area calculated by TEE correlated well with left ventricular preload, whereas pulmonary artery diastolic pressure correlated poorly with left ventricular preload.^{50,51} Left atrial and left ventricular pressures may also be calculated using Doppler measurements of flow across the mitral valve, or from the pulmonary veins into the left atrium. TEE estimates of intracardiac filling pressures correlate well with data obtained from PACs.⁵² Left ventricular contractility can be estimated using a variety of techniques. Ejection fraction can be determined by measuring left ventricular end-diastolic area (EDA) and end-systolic area (ESA):

$$\text{ejection fraction area} = \frac{\text{EDA} - \text{ESA}}{\text{EDA}} \times 100.$$

Stroke volume can be calculated by measuring the Doppler velocity of flow across an area of the heart (aortic valve, pulmonary artery, left ventricular outflow tract) and multiplying this value times the area through which the flow occurs. The stroke volume times heart rate yields CO. The use of biplane or multiplane probes appears to increase the accuracy of CO measurements.⁵³

Transesophageal echocardiography may provide a more meaningful reference standard for myocardial ischemia than ECG. Within seconds of the onset of myocardial ischemia, abnormal inward motion and thickening of the affected myocardial segment occurs. Wall motion abnormalities precede changes in the ECG or PAC. Clinical studies suggest that many episodes of ischemia detected by TEE are missed by standard intraoperative ECG monitoring.^{54,55} However, not all wall motion abnormalities are due to ischemia. Ventricular pacing, conduction abnormalities, translational motion of the heart, stunned myocardium, and changes in loading conditions can all mimic myocardial ischemia on TEE.

Transesophageal echocardiography is the only intraoperative monitor that provides information on the structure and function of the mitral, aortic, tricuspid, and pulmonic valves. The severity of stenotic or regurgitant valvular disease can be determined using Doppler studies. One of the most important indications for TEE in the operating room is in the assessment of patients requiring valvular surgery. The use of TEE before cardiopulmonary bypass provides new information or prompts changes in valve surgery in 9–13% of cases.⁴⁹ In patients undergoing mitral valve repair, postcardiopulmonary bypass TEE revealed persistent valvular dysfunction in

6–11% of patients, leading to second pump runs in 3–10% of cases.⁴⁹

Transesophageal echocardiography may be used to determine the etiology of acute hypotension in the perioperative period. Left ventricular failure or dysfunction can be differentiated from other common causes of severe hypotension, such as hypovolemia or decreased systemic vascular resistance. Unusual causes of acute hypotension, including pericardial tamponade, pulmonary embolism, and aortic dissection, can be rapidly diagnosed with TEE. The early detection of the cause of hemodynamic instability allows for the appropriate therapy to be instituted (volume expansion, inotropes, vasopressors).

Transesophageal echocardiography is moderately invasive and is associated with major and minor complications. Major complications (esophageal trauma, dysrhythmias, hemodynamic instability) occur in 0.2–0.5% of examinations.⁴⁹ Minor complications (lip injuries, dental injuries, hoarseness, dysphagia) occur in 0.1–13% of cases, and may be related to endotracheal intubation rather than TEE.⁴⁹ Complication rates may be reduced when examinations are performed by experienced practitioners. Most complication rates have been reported from studies in awake patients; some complications may be less frequent in anesthetized surgical patients.

MONITORING NEUROLOGIC FUNCTION

The best assessment of neurologic function is a thorough neurologic examination that evaluates the integration of brain and spinal cord function. However, anesthesia, sedation, and muscle relaxants, as well as existing neuropathology or trauma, may significantly impair the sensitivity or even the ability to perform a standard neurologic examination in the operating room. Therefore, monitoring neurologic function has become an important component of anesthesia care. Intraoperative neurologic monitoring often guides anesthesia and surgical decision making. Many intraoperative factors have the potential to influence spontaneous or evoked neural activity. General anesthesia can influence synaptic transmission and neural activity directly or by altering physiologic factors such as blood flow or blood pressure.

Intracranial Pressure Monitoring

Intracranial pressure (ICP) monitoring was initially used in trauma, where the relationship between uncontrolled ICP elevation and fatality has been firmly established.⁵⁶ ICP can be monitored by insertion of a subarachnoid bolt, a ventricular catheter, or an epidural transducer, or by insertion of a fiberoptic sensor in the cranial cavity. Each of these techniques requires a burr hole for intracranial access.

The cerebrospinal fluid (CSF) pressure wave is pulsatile and oscillates with the cardiac and respiratory cycle. Normal ICP is less than 15 mm Hg. Continuous recordings of the ICP in neurotrauma victims demonstrate three distinct pathologic waveforms. A waves (plateau waves) are found in patients with elevated baseline ICP and consist of a further elevation of ICP for periods from 5–20 minutes; A waves result from abrupt increases in regional cerebral blood volume where cerebral blood flow is decreased due to brain swelling, venous obstruction, or obstruction of CSF flow. B and C waves are of lesser magnitude and are related to respiratory pattern and blood pressure. Unlike A waves, they are not thought to be useful in guiding therapy or predicting outcome.

Intracranial pressure monitoring assumes that *cerebral perfusion pressure* (CPP = MAP – ICP) is uniformly distributed and that intracranial hypertension results in ischemia, displacement, compression, or herniation of the brain. ICP monitoring does not measure neural function or neural recovery.

Subarachnoid Devices

It is possible to monitor ICP using hollow stainless steel bolts or intraventricular catheters that are connected to a fluid-filled transducer system or a gravity manometer. Both methods are associated with the potential for infection or inaccuracy due to damping. Although the subarachnoid bolt is easiest to place and has a lower infection rate, the ventricular catheter allows CSF removal or insertion of a small volume of fluid to test the compliance of the cranial cavity.

Epidural Devices

Epidural sensors reduce the potential for infection because the dura is not breached. Two systems for epidural monitoring of ICP are in common use. The Ladd epidural transducer system uses a pressure-sensitive pneumatic switch that deforms as the dura changes conformation. Similarly, a fiberoptic system for ICP monitoring has been designed, which can be inserted epidurally or passed through an intraventricular catheter to sense ICP changes. Fiberoptic ICP monitoring is accurate and versatile.⁵⁷

Electroencephalogram

The electroencephalogram (EEG) represents the spontaneous electrical activity of the superficial cerebral cortex as recorded from either the scalp or surface electrodes. The EEG signal originates from postsynaptic excitatory and inhibitory potentials produced by the pyramidal cells located in the outer cerebral cortex. In the operating room, the EEG signal can often be recorded to assess cortical activity. Signal processing requires the amplification of small voltages (10–100 mV), which are 1000 times smaller than ECG signals. Conventional EEG analysis uses scalp electrodes positioned at standardized points referenced to cranial dimensions. The voltage difference between a pair of EEG electrodes is amplified and compared with measurements using a reference electrode. This method, differential amplification, reduces artifacts. The resulting signal is then passed through electronic filters, which reduce or remove unwanted frequencies, and is then displayed as voltage over time. The EEG is usually characterized by activity in four frequency bands: beta (>12 Hz), alpha (8–12 Hz), theta (4–8 Hz), and delta (<4 Hz).

In unanesthetized patients, the EEG trace demonstrates background rhythms regulated by “pacemaker neurons” of the lower brain structures and the local electrical activity resulting from cortical neurons underlying the active electrode. During anesthesia, the background alpha rhythm predominates. With deeper anesthesia or during ischemia, EEG activity generally decreases in both amplitude and frequency. A total of 50% of the brain's oxygen consumption has been attributed to the energy requirement for the generation of EEG activity.

Electroencephalographic monitoring has been advocated for the intraoperative detection of cerebral ischemia during carotid endarterectomy; during deliberate hypotension; for the intraoperative or perioperative assessment of pharmacologic interventions; for identification of epileptic foci; or for the assessment of coma or brain death.⁵⁸

Deep anesthesia, cerebral ischemia, or other pathologic states abolish or reduce normal neural EEG activity (alpha and beta rhythms), and slower frequencies (delta and theta) predominate. Sleep or surgical anesthesia typically increases amplitude (synchronization), whereas arousal characteristically decreases amplitude (desynchronization). Deep anesthesia may depress the EEG by directly effecting the cortical activity or by depression of pacemaker regulation. High concentrations of isoflurane or desflurane can cause periods of electrical silence interspersed with brief episodes of activity. Similar effects are seen by many intravenous sedative drugs such as barbiturates. This pattern is termed *burst suppression*. Increasing depth of anesthesia often results in EEG slowing with increases in amplitude, leading to burst suppression. At the highest levels of anesthesia, the EEG can become isoelectric, mimicking the effect of hypothermia or brain hypoxia. EEG interpretation requires experienced observers and the ability to integrate the changes with anesthetic, physiologic, and surgical events.

Processing Electroencephalographic Data

Several signal-processing techniques have been used to improve the ability of clinicians to interpret changes in the EEG and evaluate trends. The EEG signal is usually digitized, processed, and then graphically displayed for interpretation. Real-time analysis using Fourier transformation to identify amplitudes and frequencies of interest or a periodic analysis are often performed to convert voltage/time data to power spectral information, where power vs. frequency information is graphically displayed over epochs (*e.g.*, the *compressed spectral array*).

The *spectral edge frequency* is often calculated and displayed to summarize the changes in the power spectrum. The spectral edge is the frequency that is just above 95% of the power contained in the raw EEG. Monitoring the spectral edge has been considered useful in detection of cerebral ischemia and anesthetic depth.⁵⁹ Other descriptors such as the peak power frequency or the median power frequency have been used to describe EEG data under anesthesia.⁶⁰

Today, there are many instruments that process EEG data to create graphic displays of brain electrical function. Instrumentation and software for mapping the frequency spectrum of the standard 16 EEG leads can produce pictorial images of brain electrical activity over time. Brain mapping may provide insight into the distribution of electrical activity associated with the administration of anesthetic agents. Intraoperative brain mapping remains controversial because of the potential for mapping artifact.⁶¹

Bispectral Index

The bispectral index (BIS) is a variable derived from the EEG that is a measure of the hypnotic effect of anesthetic agents. The BIS is the first processed EEG descriptor that predicts depth of consciousness. Previous EEG parameters, such as the spectral edge frequency, do not change in a linear manner with increasing depth of anesthesia. Furthermore, different anesthetic agents have differing effects on the processed EEG.

The calculation of the BIS integrates four different processed EEG descriptors into a single variable. These four parameters were selected on the basis of EEG data collected from thousands of anesthetics. The EEG data were correlated with the clinical state of the patient (level of consciousness, response to surgical incision). Each parameter has a particular stage of anesthesia where it performs most accurately. The BetaRatio parameter reflects light sedation, the SynchronFastSlow detects surgical levels of anesthesia, and the burst suppression ratio (BSR) and QUASI predominate during deep levels of anesthesia.⁶² The parameters are then ranked and combined to yield a single number, the BIS. The range of values for the BIS is from 0 to 100, with decreasing numbers indicating deeper levels of sedation or anesthesia. BIS values of less than 60 appear to predict absence of consciousness.

Clinical studies have demonstrated that the BIS can reliably predict the level of sedation, loss of consciousness, and the probability of recall using a variety of anesthetic agents (thiopental, propofol, midazolam, isoflurane, and sevoflurane).^{63,64,65} and ⁶⁶ The BIS does not appear to be as reliable in predicting movement in response to a noxious stimulation. Motor responses to painful stimuli may be mediated by subcortical structures, which are not measured by the BIS monitor. The use of the BIS can facilitate faster emergence and improved recovery from general anesthesia by allowing more precise titration of anesthetic effect.⁶⁷

Evoked Potential Monitoring

Stimulation of neural structures to evoke responses is useful for monitoring the functional integrity of brain stem, visual, auditory, or peripheral neural pathways. Evoked potentials (EPs) represent small electrical signals generated in neural pathways after periodic stimulation. In the cortex and subcortex, EPs are smaller than the background EEG, and it is necessary to remove the random background electrical activity to record EP data. Computer signal averaging and filtering permits display of the EP voltages over time. EPs are usually quantitated by the time from stimulation (latency) and the amplitude of the peaks generated by the neural structures of interest. Three sensory pathways are available for intraoperative monitoring.⁶⁸

Brain stem auditory evoked responses (BAERs) are monitored by stimulation of the cochlea using pulsed sound waves in the ear. Three to five waves are usually recorded using electrodes placed near the ear and cortex. BAERs are useful in assessing brain stem function in comatose patients and during surgical procedures of the cerebellopontine angle, floor of the fourth ventricle, or procedures in proximity to the fifth, seventh, or eighth cranial nerves.⁶⁹ Unlike other EPs, the BAERs are relatively resistant to the effects of anesthesia.

Visual evoked potentials (VEPs) are produced by flashing light to stimulate the retina and recording the EPs over the occipital cortex. VEPs assess the integrity of the visual pathway and have been used during resection of pituitary tumors, craniopharyngiomas, or surgery in the vicinity of the optic tracts. Unlike BAERs, VEPs are technically difficult to obtain during anesthesia, and questions have arisen about their usefulness in surgery.

Somatosensory evoked potentials (SSEPs) are produced by stimulating peripheral nerves and recording responses from electrodes monitoring the transmission of the EPs through the sensory pathway. The nerves usually stimulated are the median, ulnar, peroneal, or posterior tibial. Surface electrodes are placed to record the signal from peripheral nerves, plexuses, nerve roots, the dorsal columns, the brain stem lemniscal pathways to the thalamus, and the sensory cortex.

Median nerve SSEPs have been used to monitor cerebral function in patients undergoing neurosurgical procedures or those with cerebral ischemia. In these patients, examination of the timing and amplitude of the response measured over the contralateral scalp at 20 milliseconds (N20) represents the cortical response to stimulation. Similarly, examination of the negative waves occurring 11–14 milliseconds interrogates spinal roots, spinal cord, and brain stem.

Monitoring the responses of upper or lower extremity nerves may assist in evaluating spinal cord function during instrumentation of the spine or during thoracoabdominal surgery, where spinal cord ischemia is a possible risk factor. Deterioration of spinal cord function decreases the amplitude and increases the latency of the SSEP waveform. Monitoring of SSEPs is thought to be a sensitive indicator of the spinal cord's functional integrity. Despite the fact that SSEP monitoring does not evaluate the function of the motor pathway, it appears to be useful during spinal surgery, notably for correction of scoliosis.⁷⁰ Intraoperative SSEPs should be regarded as an extension of the sensory neurologic examination during anesthesia care, but may not totally replace the "wake-up" test. During anesthesia, monitoring both the area of risk and the contralateral pathways helps identify changes resulting from surgery as opposed to those due to other global variables, such as the effect of anesthesia.

Motor evoked potentials (MEPs) provide a means of assessing descending motor pathways during neurosurgical, orthopedic, or vascular procedures. MEPs can be obtained by transcranial electrical stimulation, transcranial magnetic stimulation, or direct spinal cord stimulation.⁷¹ Attenuation of transcranially elicited MEPs by commonly used anesthetic techniques has limited their usefulness during surgery. Further investigation with MEPs is needed to define fully their use during surgery.⁷²

Facial nerve stimulation is commonly performed during procedures in the posterior fossa. Intentional stimulation or surgical irritation of the facial nerve can be evaluated visually or by evaluating the electromyogram. Although facial nerve function is rather insensitive to anesthetic influences, muscle relaxants need to be limited to provide adequate monitoring conditions.

Noninvasive Monitoring of Cerebral Hemodynamics

Transcranial Doppler monitoring of cerebral blood velocity offers anesthesiologists the potential to assess alterations in regional cerebral perfusion in patients at risk for cerebral ischemia or cerebral emboli. Low-frequency ultrasound can penetrate areas of the cranium and detection of the reflected Doppler signal can permit estimation of blood flow velocity. The Doppler signals are transformed by computer to calculate and display systolic, diastolic, and mean blood velocity (V_{bf}). V_{bf} serves as an index of cerebral blood flow in the region interrogated.

Three interrogation sites have been described. The temporal bone is used to determine the V_{bf} of the middle, anterior, and posterior cerebral arteries. The orbit permits measurement from the ophthalmic artery and portions of the internal carotid artery. The foramen magnum portal interrogates V_{bf} in the intracranial vertebral and basilar arteries. Transcranial Doppler can detect intracranial air or particulate embolism, and monitoring beat-to-beat changes in V_{bf} correlates with changes in regional cerebral blood flow.⁷³ Interest in using transcranial Doppler as an early warning of critical reductions in cerebral perfusion during anesthesia has been reported.⁷⁴ Unfortunately, the methodology cannot be used in all patients, and the instrumentation requires training with respect toinsonation technique and interpretation of the sonograms displayed.

Similarly, *infrared spectroscopy* has been adapted to monitor cerebral oxygen delivery. This methodology is possible because infrared light (650–1100 nm) penetrates the scalp and skull so that reflective pulse oximetry is feasible. In the brain, venous oximetry signals predominate over arterial signals and the output of these instruments correlates best with cerebral S_VO₂. Cerebral S_VO₂ and the regional cerebral Hb oxygen saturation monitored by near-infrared cranial spectroscopy are sensitive indicators of changing regional cerebral oxygen saturation resulting from systemic hypoxia, regional cerebral oligemia, or anemia.^{75,76} These devices are still being investigated for general clinical applications.

TEMPERATURE MONITORING

The ability to monitor body temperature is a standard of anesthesia care. The continual observation of temperature changes in anesthetized patients allows for the detection of accidental heat loss or malignant hyperthermia. Humans maintain their core temperature by balancing heat production from metabolism and the many environmental factors that supply heat or cool the body. Regional temperature information from skin, muscle, the body cavities, spinal cord, and brain are integrated in the central nervous system. Conceptually, thermoregulation involves the integration of "set points," which, when exceeded, trigger temperature-dissipating, temperature-conserving, or heat-producing mechanisms. Both general and regional anesthesia inhibit afferent and efferent control of thermoregulation.^{77,78} In addition, the operating room environment and surgical exposure often contribute to excessive heat losses. Heat loss is common during surgery because the surgical environment transfers heat from the patient and anesthesia reduces heat production and diminishes the capability of patients to monitor and maintain thermoregulation.

Heat is produced as a consequence of cellular metabolism. In adults, thermoregulation involves the control of basal metabolic rate, muscular activity, sympathetic arousal, vascular tone, and hormone activation balanced against exogenous factors that determine the need for the body to create heat or to adjust the transfer of heat to the environment.

Heat losses may result from radiation, conduction, convection, and evaporation. Radiation refers to the infrared rays emanating from all objects above absolute temperature. Conduction refers to the transfer of heat from contact with objects. Convection refers to the transfer of heat from air passing by objects. Evaporation

represents the heat loss resulting when water vaporizes. For every gram of water evaporated, 0.58 kcal of heat is lost.

Perioperative hypothermia predisposes patients to increases in metabolic rate (shivering) and cardiac work, decreases in drug metabolism and cutaneous blood flow, and impairments of coagulation. Clinical studies have demonstrated that patients in whom intraoperative hypothermia develops are at a higher risk for development of postoperative myocardial ischemia and wound infection compared with patients who are normothermic in the perioperative period.^{79,80} Anesthesiologists frequently monitor temperature and attempt to maintain central core temperature at near-normal values in all patients undergoing anesthesia.

Central core temperatures can be estimated using probes that can be placed into the bladder, distal esophagus, ear canal, trachea, nasopharynx, or rectum.⁸¹ Pulmonary artery blood temperature is also a good estimate of central core temperature.

Temperature is usually measured using electrical probes containing calibrated thermistors or thermocouples that serve as temperature transducers. Thermistors respond to temperature changes by changing their electrical resistance. Thermocouples are constructed by passing current through a circuit where the electrodes are made of two dissimilar metals. The current measured is directly proportional to the temperature difference between the two metal junctions. Thermocouple temperature probes maintain one junction at a known temperature and place the second junction on the temperature probe tip. Skin temperature can also be monitored using liquid crystal thermometry. Although convenient, temperature strips do not correlate with core temperature measurements.⁸²

Thermoregulatory responses are based on a physiologically weighted average reflecting changes in the mean body temperature. Mean body temperature is estimated by the following equation:

$$\text{Mean temperature} = 0.85 T_{\text{core}} + 0.15 T_{\text{skin}}$$

Skin temperature monitoring has been advocated to identify peripheral vasoconstriction, but is not adequate to determine alterations in mean body temperature that may occur during surgery. Core temperature sites have been established as reliable indicators of changes in mean temperature. During routine noncardiac surgery, temperature differences between these sites are small. When anesthetized patients are being cooled, changes in rectal temperature often lag behind those of other probe locations, and the adequacy of rewarming is best judged by measuring temperature at several locations.

FUTURE TRENDS IN MONITORING

Diagnostic and therapeutic advances in medicine have had a great impact on the strategies and techniques available for intraoperative monitoring. Today's anesthesia practice has narrowed the distinction between laboratory medicine and patient monitoring. Technologic advances in instrument design, computerization, and engineering have made it possible to have ready access to serum chemistries, hematologic profiles, assessment of coagulation, and arterial blood gas measurements. Modern monitoring systems have the potential to transfer processed and raw data from the operating room to information management systems, which offer the potential for creating meaningful paperless anesthesia records and enhanced archiving of the conduct of anesthesia care as depicted by real-time monitoring trends.

The U.S. Department of Health and Human Services proposed implementation of patient record systems in 1996.⁸³ Proprietary systems for automated anesthesia records are now in the marketplace. These offer file sharing so that information that is traditionally viewed as patient monitoring can also be used for billing, ordering supplies, and quality improvement. Although computerization of the hospital environment has direct and indirect costs, the benefits to physicians, patients, insurers, and hospital administrators indicate that, like in other business environments, information management is coming to operating room monitoring and anesthesiology.^{84,85} The clinical and administrative data that can be obtained from anesthesia work stations integrated with hospital information systems should enhance the quality of care and improve the intraoperative monitoring of anesthetized patients.

There are no absolute indications for spinal or epidural anesthesia. However, there are clinical situations in which patient preference, patient physiology, or the surgical procedure makes central neuraxial block the technique of choice. There is also growing evidence that these techniques may improve outcome in selected situations. Spinal and epidural anesthesia have been shown to blunt the “stress response” to surgery,¹ to decrease intraoperative blood loss,^{2,3} to lower the incidence of postoperative thromboembolic events,^{4,3,4} and ⁵ and to decrease morbidity and mortality in high-risk surgical patients.⁶ In addition, both spinal and epidural techniques can be used to extend analgesia into the postoperative period or to provide analgesia to nonsurgical patients. Thus, these techniques are an indispensable part of modern anesthetic practice, and every anesthesiologist should be adept at performing them.

ANATOMY

Proficiency in spinal and epidural anesthesia requires a thorough understanding of the anatomy of the spine and spinal cord. The anesthesiologist must be familiar with the surface anatomy of the spine but must also develop a mental picture of the three-dimensional anatomy of deeper structures. In addition, one must appreciate the relationship between the cutaneous dermatomes, the spinal nerves, the vertebrae, and the spinal segment from which each spinal nerve arises.

Vertebrae

The spine consists of 33 vertebrae (7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal) (Fig. 26-1). With the exception of C1, the cervical, thoracic, and lumbar vertebrae consist of a body anteriorly, two pedicles that project posteriorly from the body, and two laminae that connect the pedicles (Fig. 26-2). These structures form the vertebral canal, which contains the spinal cord, spinal nerves, and epidural space. The laminae give rise to the transverse processes that project laterally and the spinous process that project posteriorly. These bony projections serve as sites for muscle and ligament attachments. The pedicles contain a superior and inferior vertebral notch through which the spinal nerves exit the vertebral canal. The superior and inferior articular processes arise at the junction of the lamina and pedicles and form joints with the adjoining vertebrae. The first cervical vertebra differs from this typical structure in that it does not have a body or a spinous process.

Figure 26-1. Posterior (A) and lateral (C) views of the human spinal column. Note the inset (B), which depicts the variability in vertebral level at which the spinal cord terminates.

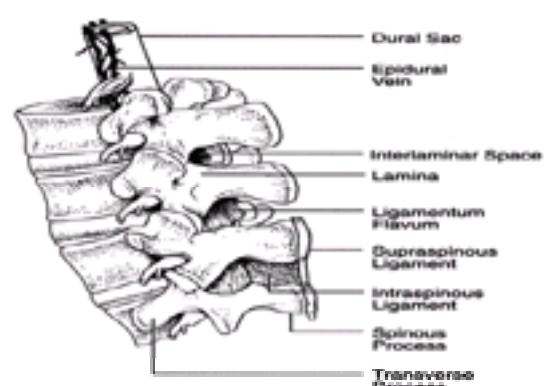

Figure 26-2. Detail of the lumbar spinal column and epidural space. Note that the epidural veins are largely restricted to the anterior and lateral epidural space

The five sacral vertebrae are fused together to form the wedge-shaped sacrum, which connects the spine with the iliac wings of the pelvis (Fig. 26-1). The 5th sacral vertebra is not fused posteriorly, giving rise to a variably shaped opening known as the sacral hiatus. Occasionally other sacral vertebrae do not fuse posteriorly, giving rise to a much larger sacral hiatus. The sacral cornu are bony prominences on either side of the hiatus and aid in identifying it. The sacral hiatus provides an opening into the sacral canal, which is the caudal termination of the epidural space. The four rudimentary coccygeal vertebrae are fused together to form the coccyx, a narrow, triangular bone that abuts the sacral hiatus and can be helpful in identifying it. The tip of the coccyx can often be palpated in the proximal gluteal cleft, and by running one's finger cephalad along its smooth surface, the sacral cornu can be identified as the first bony prominence encountered.

Identifying individual vertebrae is important for correctly locating the desired interspace for epidural and spinal blockade. The spine of C7 is the first prominent spinous process encountered while running the hand down the back of the neck. The spine of T1 is the most prominent spinous process and immediately follows C7. The 12th thoracic vertebra can be identified by palpating the 12th rib and tracing it back to its attachment to T12. A line drawn between the iliac crests crosses the body of L5 or the L4–L5 interspace.

Ligaments

The vertebral bodies are stabilized by five ligaments that increase in size between the cervical and lumbar vertebrae (Fig. 26-2). From the sacrum to T7, the supraspinous ligament runs between the tips of the spinous processes. Above T7 this ligament continues as the ligamentum nuchae and attaches to the occipital protuberance at the base of the skull. The interspinous ligament attaches between the spinous processes and blends posteriorly with the supraspinous ligament and anteriorly with the ligamentum flavum. The ligamentum flavum is a tough, wedge-shaped ligament composed of elastin. It consists of right and left portions that span adjacent vertebral laminae and fuse in the midline to varying degrees.^{7,8} The ligamentum flavum is thickest in the midline measuring 3–5 mm at the L2–L3 interspace of adults. This ligament is also farthest from the spinal meninges in the midline, measuring 4–6 mm at the L2–L3 interspace.⁷ As a result, midline insertion of an epidural needle is least likely to result in unintended meningeal puncture. The anterior and posterior longitudinal ligaments run along the anterior and posterior surfaces of the vertebral bodies.

Epidural Space

The epidural space is the space that lies between the spinal meninges and the sides of the vertebral canal (Fig. 26-3). It is bounded cranially by the foramen magnum, caudally by the sacrococcygeal ligament covering the sacral hiatus, anteriorly by the posterior longitudinal ligament, laterally by the vertebral pedicles, and posteriorly by both the ligamentum flavum and vertebral lamina. The epidural space is not a closed space but communicates with the paravertebral space by way of the intervertebral foramina. The epidural space is shallowest anteriorly where the dura may in some places fuse with the posterior longitudinal ligament. The space is deepest posteriorly, although the depth varies because the space is intermittently obliterated by contact between the dura mater and the ligamentum flavum or vertebral lamina. Contact between the dura mater and the pedicles also interrupts the epidural space laterally. Thus, the epidural space is composed of a series of discontinuous compartments that become continuous when the potential space separating the compartments is opened up by injection of air or liquid (Fig. 26-3).⁸

Figure 26-3. The compartments of the epidural space (*stippled areas*) are discontinuous. Areas where no compartments are indicated represent a potential space where the dura mater normally abuts the sides of the vertebral canal. (Reprinted with permission from Hogan Q: Lumbar epidural anatomy: A new look by cryomicrotome section. *Anesthesiology* 75:767, 1991.)

The most ubiquitous material in the epidural space is fat, which is principally located in the posterior and lateral epidural space. A rich network of valveless veins (Batson's plexus) courses through the anterior and lateral portions of the epidural space, with few if any veins present in the posterior epidural space (Fig. 26-2).^{9,10} The epidural veins anastomose freely with extradural veins including the pelvic veins, the azygos system, and the intracranial veins. The epidural space also contains lymphatics and segmental arteries running between the aorta and the spinal cord.

Meninges

The spinal meninges consist of three protective membranes (dura mater, arachnoid mater, and pia mater) that are continuous with the cranial meninges (Fig. 26-4).

Figure 26-4. The spinal meninges of the dog demonstrating the pia mater (PM) in apposition to the spinal cord, the subarachnoid space (SS), the arachnoid mater (AM), trabeculae (*arrow*), and the dura mater (DM). The separation between the arachnoid mater and the dura mater demonstrates the subdural space. The subdural space is only a potential space *in vivo* but is created here as an artifact of preparation. (Reprinted with permission from Peters A, Palay SL, Webster H [eds]: *The Fine Structure of the Nervous System: The Neurons and Supporting Cells*. Philadelphia, WB Saunders, 1976.)

Dura Mater

The dura mater is the outermost and thickest meningeal tissue. The spinal dura mater begins at the foramen magnum, where it fuses with the periosteum of the skull, forming the cephalad border of the epidural space. Caudally, the dura mater ends at approximately S2 where it fuses with the filum terminale. The dura mater extends laterally along the spinal nerve roots and becomes continuous with the connective tissue of the epineurium at approximately the level of the intervertebral foramina. The dura mater is composed of randomly arranged collagen fibers and elastin fibers arranged longitudinally and circumferentially.¹¹ The dura mater is largely acellular

except for a layer of cells that forms the border between the dura and arachnoid mater.

There is controversy regarding the existence and clinical significance of a midline connective tissue band, the plica medianis dorsalis, running from the dura mater to the ligamentum flavum. Anatomic studies using epiduroscopy¹² and epidurography¹³ have demonstrated the presence of the plica medianis dorsalis and have led to speculation that this tissue band may on occasion be responsible for difficulty in inserting epidural catheters and for unilateral epidural block. However, using cryomicrotome sections to investigate the epidural space, Hogan failed to find evidence of a substantial connection between the dura mater and the ligamentum flavum.⁸ He speculated that the injection of either air or contrast required for the earlier studies may have compressed epidural contents (e.g., fat) and produced an artifact mimicking a connective tissue band. In addition, Hogan has shown in a clinical study that there is no significant impediment to spread of injectate across the midline.¹⁴ Thus, the plica medianis dorsalis does not appear to be clinically relevant with respect to clinical epidural anesthesia.

The inner surface of the dura mater abuts the arachnoid mater. There is a potential space between these two membranes called the subdural space (Fig. 26-4). Occasionally, drug intended for either the epidural space or the subarachnoid space is injected into the subdural space.¹⁵ Subdural injection has been estimated to occur in 0.82% of intended epidural injections.¹⁶ The radiology literature suggests that the incidence of subdural injection during intended subarachnoid injection may be as high as 10%.¹⁷

Arachnoid Mater

The arachnoid mater is a delicate, avascular membrane composed of overlapping layers of flattened cells with connective tissue fibers running between the cellular layers. The arachnoid cells are interconnected by frequent tight junctions and occluding junctions. These specialized cellular connections likely account for the fact that the arachnoid mater is the principal physiologic barrier for drugs moving between the epidural space and the spinal cord.¹⁸

In the region where the spinal nerve roots traverse the dura and arachnoid membranes, the arachnoid mater herniates through the dura mater into the epidural space to form arachnoid granulations. As with the cranial arachnoid granulations, the spinal arachnoid granulations serve as a site for material in the subarachnoid space to exit the central nervous system (CNS). Although some have postulated that the arachnoid granulations are a preferred route for drugs to move from the epidural space to the spinal cord, the available experimental data suggest that this is not the case.¹⁹

The subarachnoid space lies between the arachnoid mater and the pia mater and contains the cerebrospinal fluid (CSF). The spinal CSF is in continuity with the cranial CSF and provides an avenue for drugs in the spinal CSF to reach the brain. In addition, the spinal nerve roots and rootlets run in the subarachnoid space.

Pia Mater

The spinal pia mater is adherent to the spinal cord and is composed of a thin layer of connective tissue cells interspersed with collagen. Trabeculae connect the pia mater with the arachnoid mater and the cells of these two meninges blend together along the trabeculae. Unlike the arachnoid mater, the pia mater is fenestrated in places so that the spinal cord is in direct communication with the subarachnoid space. The pia mater extends to the tip of the spinal cord where it becomes the filum terminale, which anchors the spinal cord to the sacrum. The pia mater also gives rise to the dentate ligaments, which are thin connective tissue bands extending from the side of the spinal cord through the arachnoid mater to the dura mater. These ligaments serve to suspend the spinal cord within the meninges.

Spinal Cord

In the first-trimester fetus, the spinal cord extends from the foramen magnum to the end of the spinal column. Thereafter, the vertebral column lengthens more than the spinal cord so that at birth the spinal cord ends at approximately the level of the third lumbar vertebra. In the adult, the caudad tip of the spinal cord typically lies at the level of the first lumbar vertebra. However, in 30% of people the spinal cord may end at T12, whereas in 10% it may extend to L3 (Fig. 26-1).²⁰ A sacral spinal cord has been reported in an adult.²⁰ Flexion of the vertebral column causes the tip of the spinal cord to move slightly cephalad.

The spinal cord gives rise to 31 pairs of spinal nerves, each composed of an anterior motor root and a posterior sensory root. The nerve roots are in turn composed of multiple rootlets. The portion of the spinal cord that gives rise to all of the rootlets of a single spinal nerve is called a cord segment. The skin area innervated by a given spinal nerve and its corresponding cord segment is called a dermatome (Fig. 26-5). The intermediolateral gray matter of the T1–L2 spinal cord segments contains the cell bodies of the preganglionic sympathetic neurons. These sympathetic neurons run with the corresponding spinal nerve to a point just beyond the intervertebral foramen, where they exit to join the sympathetic chain ganglia.

Figure 26-5. Human sensory dermatomes.

The spinal nerves and their corresponding cord segments are named for the intervertebral foramen through which they run. In the cervical region, the spinal nerves are named for the vertebra forming the caudad half of the intervertebral foramen; for example, C4 emerges through an intervertebral foramen formed by C3 and C4. In the thoracic and lumbar regions, the nerve roots are named for the vertebrae forming the cephalad half of the intervertebral foramen; for example, L4 emerges through an intervertebral foramen formed by L4 and L5. Because the spinal cord ends between L1 and L2, the thoracic, lumbar, and sacral nerve roots run increasingly longer distances in the subarachnoid space to get from their spinal cord segment of origin to the intervertebral foramen through which they exit. Those nerves that extend beyond the end of the spinal cord to their exit site are collectively known as the cauda equina (Fig. 26-1).

TECHNIQUE

Spinal and epidural anesthesia should be performed only after appropriate monitors are applied and in a setting where equipment for airway management and resuscitation are immediately available. Before positioning the patient, all equipment for spinal block should be ready for use (e.g., local anesthetics mixed and drawn up, needles uncapped, prep solution available). Preparing all equipment ahead of time minimizes the time required to perform the block and thereby enhances patient comfort.

Needles

Spinal and epidural needles are named for the design of their tips (Fig. 26-6). The Whitacre and Sprotte spinal needles have a “pencil-point” tip with the needle hole on the side of the shaft. The Greene and Quincke needles have beveled tips with cutting edges. The pencil-point needles require more force to insert than the bevel-tip needles but provide a better tactile “feel” of the various tissues encountered as the needle is inserted. In addition, the bevel has been shown to cause the needle to be deflected from the intended path as it passes through tissues, whereas pencil-point needles are not deflected.²¹

Figure 26-6. Some of the commercially available needles for spinal and epidural anesthesia. Needles are distinguished by the design of their tips.

Epidural needles have a larger diameter than spinal needles to facilitate the injection of fluid or air when using the “loss-of-resistance” technique to identify the epidural space. In addition, the larger diameter allows for easier insertion of catheters into the epidural space. The Tuohy epidural needle has a curved tip to help control the direction the catheter moves in the epidural space. The Hustead needle tip is also curved, although somewhat less than the Tuohy needle. The Crawford needle tip is straight, making it less suitable for catheter insertion.

The outside diameter of both epidural and spinal needles is used to determine their gauge. Larger-gauge (*i.e.*, smaller-diameter) spinal needles are less likely to cause postdural puncture headaches (PDPH), but are more readily deflected than smaller-gauge needles. Epidural needles are typically sized 16–19 gauge and spinal needles 22–29 gauge. Spinal needles smaller than 22 gauge are often easier to insert if an introducer needle is used. The introducer is inserted into the interspinous ligament in the intended direction of the spinal needle and the spinal needle is then inserted through the shaft of the introducer. The introducer prevents the spinal needle from being deflected or bent as it passes through the interspinous ligament.²¹ Needles of the same outside diameter may have different inside diameters. This is important because inside diameter determines how large a catheter can be inserted through the needle and determines how rapidly CSF appears at the needle hub during spinal needle insertion.

All spinal and epidural needles come with a tight-fitting stylet. The stylet prevents the needle from being plugged with skin or fat and, importantly, prevents dragging skin into the epidural or subarachnoid spaces, where the skin may grow and form dermoid tumors.

Sedation

If the patient desires, light sedation is appropriate before placement of spinal or epidural block. In general, the patient should not be heavily sedated because successful spinal and epidural anesthesia requires patient participation to maintain good position, evaluate block height, properly evaluate an epidural test dose, and indicate paresthesias to the anesthesiologist if the needle contacts neural elements. Once the block is placed and adequate block height assured, the patient can be sedated as deemed appropriate.

Spinal Anesthesia

Position

Careful attention to patient positioning is critical to successful spinal puncture. Poor positioning can turn an otherwise easy spinal anesthetic into a challenge for both the anesthesiologist and the patient. Spinal needles are most often inserted with the patient in the lateral decubitus position, and this technique is described in detail in this section. However, both the prone jackknife and sitting positions offer advantages under specific circumstances. The sitting position is sometimes used in obese patients because it is often easier to identify the midline with the patient sitting. In addition, the sitting position allows the anesthesiologist to restrict spinal block to the sacral dermatomes (saddle block) when using hyperbaric local anesthetic solutions. Usually, spinal block is performed in the prone jackknife position only when this is the position to be used for surgery. The use of hypobaric local anesthetic solutions with the patient in the prone jackknife position produces sacral block for perirectal surgery.

In the lateral decubitus position, the patient lies with the operative side down when hyperbaric local anesthetic solutions are used and with the operative side up when hypobaric solutions are used, thus ensuring that the earliest and most dense block occurs on the operative side. The back should be at the edge of the table so that the patient is within easy reach. The patient's shoulders and hips are both positioned perpendicular to the bed to help prevent rotation of the spine. The knees are drawn to the chest, the neck is flexed, and the patient is instructed to actively curve the back outward. This spreads the spinous processes apart and maximizes the size of the interlaminar foramina. It is useful to have an assistant who can help the patient maintain this position. Using the iliac crests as a landmark, the L2–L3, L3–L4, and L4–L5 interspaces are identified and the desired interspace chosen for needle insertion. Interspaces above L2–L3 are avoided to decrease the risk of hitting the spinal cord with the needle. Some find it helpful to mark the spinous processes flanking the desired interspace with a skin marker obviating the need to reidentify the intended interspace after the patient is prepared and draped.

The patient is prepared with an appropriate antiseptic solution and draped. All antiseptic solutions are neurotoxic, and care must be taken not to contaminate spinal needles or local anesthetics with the preparation solution. How the patient is draped is a matter of personal preference, but the author finds that preparing and draping out a large area (*e.g.*, T12–S1) with towels is preferable to using a commercial one-piece drape with a limited center hole. Draping a large area permits easier identification of a rotated or inadequately flexed back and allows the anesthesiologist to move readily to another interspace if this becomes necessary.

Midline Approach

For the midline approach to the subarachnoid space, the skin overlying the desired interspace is infiltrated with a small amount of local anesthetic to prevent pain when inserting the spinal needle. The anesthesiologist should avoid raising too large a skin wheal because this can obscure palpation of the interspace, especially in obese patients. Additional local anesthetic (1–2 ml) is then deposited along the intended path of the spinal needle to a depth of 1–2 inches. This deeper infiltration provides additional anesthesia for spinal needle insertion and helps identify the correct path for the spinal needle.

The spinal needle or introducer needle is inserted in the middle of the interspace with a slight cephalad angulation of 10–15 degrees (*Fig. 26-7*). The needle is then advanced, in order, through the subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space, dura mater, and finally arachnoid mater. The ligaments produce a characteristic “feel” as the needle is advanced through them, and the anesthesiologist should develop the ability to distinguish a needle that is advancing through the high-resistance ligaments from one that is advancing through lower-resistance paraspinous muscle. This allows early detection and correction of needles that are not advancing in the midline. Penetration of the dura mater produces a subtle “pop” that is most easily detected with the pencil-point needles. Detection of dural penetration prevents inserting the needle all the way through the subarachnoid space and contacting the vertebral body. In addition, learning to detect dural penetration allows the practitioner to insert the spinal needle quickly without having to stop every few millimeters and remove the stylet to look for CSF at the needle hub.

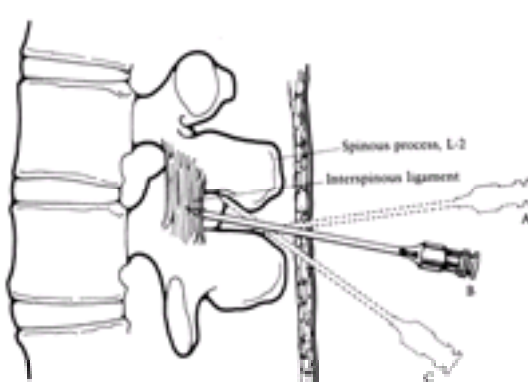

Figure 26-7. Midline approach to the subarachnoid space. The spinal needle is inserted with a slight cephalad angulation and should advance in the midline without contacting bone (*B*). If bone is contacted, it may be either the caudad (*A*) or the cephalad spinous process (*C*). The needle should be redirected slightly cephalad and

reinserted. If bone is encountered at a shallower depth, then the needle is likely walking up the cephalad spinous process. If bone is encountered at a deeper depth, then the needle is likely walking down the inferior spinous process. If bone is repeatedly contacted at the same depth, then the needle is likely off the midline and walking along the lamina. (Reprinted with permission from Mulroy MF: *Regional Anesthesia: An Illustrated Procedural Guide*. Boston, Little, Brown, 1989.)

Once the needle tip is believed to be in the subarachnoid space, the stylet is removed to see if CSF appears at the needle hub. With small-diameter needles (26–29 gauge), this usually requires 5–10 seconds, but may require ≥ 31 min in some patients. Gentle aspiration may speed the appearance of CSF. If CSF does not appear, the needle orifice may be obstructed by a nerve root, and rotating the needle 90 degrees may result in CSF flow. Alternatively, the needle orifice may not be completely in the subarachnoid space, and advancing an additional 1–2 mm may result in brisk CSF flow. This is particularly true of pencil-point needles, which have their orifice on the side of the needle shaft proximal to the needle tip. Finally, failure to obtain CSF suggests that the needle orifice is not in the subarachnoid space and the needle should be reinserted.

If bone is encountered during needle insertion, the anesthesiologist must develop a reasoned, systematic approach to redirecting the needle. Simply withdrawing the needle and repeatedly reinserting it in different directions is not appropriate. When contacting bone, the depth should be immediately noted and the needle redirected slightly cephalad. If bone is again encountered at a greater depth, then the needle is most likely walking down the inferior spinous process and should be redirected more cephalad until the subarachnoid space is reached. If bone is encountered again at a shallower depth, then the needle is most likely walking up the superior spinous process and should be redirected more caudad. If bone is repeatedly encountered at the same depth, then the needle is likely off the midline and walking along the vertebral lamina (Fig. 26-7).

When redirecting a needle, it is important to withdraw the tip into the subcutaneous tissue. If the tip remains embedded in one of the vertebral ligaments, attempts at redirecting the needle will simply bend the shaft and not reliably change needle direction. If an introducer needle is used, it also must be withdrawn into the subcutaneous tissue before being redirected. Changes in needle direction should be made in small increments because even small changes in needle angle at the skin may result in fairly large changes in position of the needle tip when it reaches the spinal meninges at a depth of 4–6 cm. Care should be exercised when gripping the needle to ensure that it does not bow. Insertion of a curved needle causes it to veer off course.

If the patient experiences a paresthesia, it is important to determine whether the needle tip has encountered a nerve root in the epidural space or in the subarachnoid space. When the paresthesia occurs, immediately stop advancing the needle, remove the stylet, and look for CSF at the needle hub. The presence of CSF confirms that the needle encountered a cauda equina nerve root in the subarachnoid space and the needle tip is in good position. Given how tightly packed the cauda equina nerve roots are, it is surprising that all spinal punctures do not produce paresthesias. If CSF is not visible at the hub, then the paresthesia probably resulted from contact with a spinal nerve root traversing the epidural space. This is especially true if the paresthesia occurs in the dermatome corresponding to the nerve root that exits the vertebral canal at the same level that the spinal needle is inserted. In this case, the needle has most likely deviated from the midline and should be redirected toward the side opposite the paresthesia. Occasionally, pain experienced when the needle contacts bone may be misinterpreted by the patient as a paresthesia, and the anesthesiologist should be alert to this possibility.

Once the needle is correctly inserted into the subarachnoid space, it is fixed in position and the syringe containing local anesthetic is attached. CSF is gently aspirated to confirm that the needle is still in the subarachnoid space and the local anesthetic slowly injected ($0.5 \text{ ml} \cdot \text{s}^{-1}$). After completing the injection, a small volume of CSF is again aspirated to confirm that the needle tip remained in the subarachnoid space while the local anesthetic was deposited. This CSF is then reinjected and the needle, syringe, and any introducer removed together. If the surgical procedure is to be performed in the supine position, the patient is helped onto his or her back. To prevent excessive cephalad spread of hyperbaric local anesthetic, care should be taken to ensure that the patient's hips are not raised off the bed as he or she turns.

Once the block is placed, strict attention must be paid to the patient's hemodynamic status with blood pressure or heart rate supported as necessary. Block height should also be assessed early by pin-prick or temperature sensation. Temperature sensation is tested by wiping the skin with alcohol and may be preferable to pin prick because it is not painful. If, after a few minutes, the block is not rising high enough or is rising too high, the table may be tilted as appropriate to influence further spread of hypobaric or hyperbaric local anesthetics.

Paramedian Approach

The paramedian approach to the epidural and subarachnoid spaces is useful in situations where the patient's anatomy does not favor the midline approach (e.g., inability to flex the spine or heavily calcified interspinous ligaments). This approach can be used with the patient in any position and is probably the best approach for the patient in the prone jackknife position.

The spinous process forming the lower border of the desired interspace is identified. The needle is inserted ~1 cm lateral to this point and is directed toward the middle of the interspace by angling it ~45 degrees cephalad with just enough medial angulation (~15 degrees) to compensate for the lateral insertion point. The first significant resistance encountered should be the ligamentum flavum. Bone encountered before the ligamentum flavum is usually the vertebral lamina of the cephalad vertebra and the needle should be redirected accordingly. An alternative method is to insert the needle perpendicular to the skin in all planes until the lamina is contacted. The needle is then walked off the superior edge of the lamina and into the subarachnoid space. The lamina provides a valuable landmark that facilitates correct needle placement; however, repeated needle contact with the periosteum can be painful.

Lumbosacral Approach

The lumbosacral (or Taylor) approach to the subarachnoid and epidural spaces is simply a paramedian approach directed at the L5–S1 interspace, which is the largest interlaminar space. This approach may be useful when anatomic constraints make other approaches unfeasible. The patient may be positioned laterally, prone or sitting, and the needle inserted at a point 1 cm medial and 1 cm inferior to the posterior superior iliac spine. The needle is angled cephalad 45–55 degrees and just medial enough to reach the midline at the level of the L5 spinous process. As with the paramedian approach, the interspinous ligament is bypassed and the first significant resistance felt should be the ligamentum flavum.

Continuous Spinal Anesthesia

Inserting a catheter into the subarachnoid space increases the utility of spinal anesthesia by permitting repeated drug administration as often as necessary to extend the level or duration of spinal block. A common and reasonable recommendation for subsequent dosing or “topping up” of continuous spinal blocks is to administer half the original dose of local anesthetic when the block has reached two-thirds of its expected duration.

The technique is similar to that described for “single shot” spinal anesthesia except that a needle large enough to accommodate the desired catheter must be used. After inserting the needle and obtaining free-flowing CSF, the catheter is simply threaded into the subarachnoid space a distance of 2–3 cm. It is often easier to insert the catheter if it is directed cephalad or caudad instead of lateral. If the catheter does not easily pass beyond the needle tip, rotating the needle 180 degrees may be helpful or another interspace may be used. The catheter should never be withdrawn back into the needle shaft because of the risk of shearing the catheter off into the subarachnoid space.

A variety of catheters and needles are available for continuous spinal anesthesia. Commonly, 18-gauge epidural needles and 20-gauge catheters are used. However, needles and catheters this size carry a higher risk of causing PDPH, especially in young patients. Because of this risk, smaller needle and catheter combinations have been developed with catheters ranging in size from 24 to 32 gauge. Although smaller catheters decrease the risk of PDPH, they have also been associated with multiple reports of neurologic injury, specifically, cauda equina syndrome (see section on [Complications](#)). For this reason, the U.S. Food and Drug Administration has advised against using any catheter smaller than 24 gauge for continuous spinal anesthesia.

Epidural Anesthesia

For the novice, correct placement of an epidural needle can be technically more challenging than spinal needle placement because there is less room for error. However, with experience, epidural needle placement is often easier than spinal needle placement because the larger-gauge needles used for epidural anesthesia are less likely to be deflected from their intended path and they produce much better tactile feel of the interspinous and flaval ligaments. In addition, the loss-of-resistance technique provides a much clearer end point when entering the epidural space than does the subtle “pop” of a spinal needle piercing the dura mater.

Patient preparation, positioning, monitors, and needle approaches for epidural anesthesia are the same as for spinal anesthesia. Unlike spinal anesthesia, epidural anesthesia may be performed at any intervertebral space. However, at vertebral levels above the termination of the spinal cord, the epidural needle may accidentally puncture the spinal meninges and damage the underlying spinal cord. To prevent accidental meningeal puncture, the anesthesiologist must learn to identify the

interspinous ligaments and the ligamentum flavum by their feel. In addition, epidural needles must be advanced slowly and, most importantly, under control.

After proper positioning, sterile skin preparation, and draping, the desired interspace is identified and a local anesthetic skin wheal is raised at the point of needle insertion. Because epidural needles are relatively blunt, it is sometimes helpful to pierce the skin with a ³18-gauge hypodermic needle before inserting the epidural needle. For epidural anesthesia using the midline approach, the epidural needle is inserted through the subcutaneous tissue and into the interspinous ligament. The interspinous ligament has a characteristic “gritty” feel, much like inserting a needle into a bag of sand. This is especially true of younger patients. If the interspinous ligament is not clearly identified, the needle may not be in the midline. After engaging the interspinous ligament, the needle is advanced slowly through it until an increase in resistance is felt. This increased resistance represents the ligamentum flavum.

The epidural needle must now traverse the ligamentum flavum and stop within the epidural space before puncturing the spinal meninges. Numerous techniques for identifying the epidural space have been used successfully; however, the loss of resistance to fluid has the advantage of simplicity, reliability, and speed. In addition, use of fluid instead of air for loss of resistance decreases the risk of PDPH in the event of accidental meningeal puncture.²²

A glass syringe or a specially designed low, resistance plastic syringe is filled with 2–3 ml of saline and a small (0.1–0.3 ml) air bubble. The syringe is attached to the epidural needle and the plunger pressed until the air bubble is visibly compressed. If the needle tip is properly embedded within the ligamentum flavum, it should be possible to compress the air bubble without injecting fluid. In this way, the air bubble serves as a gauge of the appropriate amount of pressure to exert on the syringe plunger. If the air bubble cannot be compressed without injecting fluid, then the needle tip is most likely not in the ligamentum flavum. In this case, the needle tip may still be in the interspinous ligament, or it may be off the midline in the paraspinal muscles. To differentiate between these possibilities, the anesthesiologist can carefully advance the needle and syringe a few millimeters in an effort to engage the ligamentum flavum. If it is still not possible to compress the air bubble, the needle should be withdrawn into the subcutaneous tissue, and reinserted.

Once the ligamentum flavum is identified, the needle is slowly advanced with the nondominant hand while the dominant hand maintains constant pressure on the syringe plunger (Fig. 26-8). As the needle tip enters the epidural space, there is a sudden and dramatic loss of resistance as the saline is rapidly injected. Saline injection into the epidural space can be moderately painful, and patients should be forewarned. If the needle is advancing obliquely through the ligamentum flavum, it is possible to enter into the paraspinal muscles instead of the epidural space. In this case the loss of resistance is less dramatic. To help verify that the needle has entered the epidural space, 0.5 ml of air can be drawn into the syringe and injected. In the epidural space there is virtually no resistance to air injection, whereas in the paraspinal muscles air injection encounters demonstrable resistance.

Figure 26-8. Proper hand position when using the loss-of-resistance technique to locate the epidural space. After embedding the needle tip in the ligamentum flavum, a syringe with 2–3 ml saline and an air bubble is attached. The left hand rests securely on the back and the fingers of the left hand grasp the needle firmly. The left hand advances the needle slowly and under control by rotating at the wrist. The fingers of the right hand maintain constant pressure on the syringe plunger but do not aid in advancing the needle. If the needle tip is properly engaged in the ligamentum flavum, it should be possible to compress the air bubble without injecting the saline. As the needle tip enters the epidural space, there will be a sudden loss of resistance and the saline is suddenly injected. (Reprinted with permission from Mulroy MF: *Regional Anesthesia: An Illustrated Procedural Guide*. Boston, Little Brown, 1989.)

After entering the epidural space, the needle is advanced no further. Because the dura mater abuts the ligamentum flavum, the dura will now be tented over the needle tip, and advancing the needle any more than necessary heightens the risk of accidental meningeal puncture (*i.e.*, “wet tap”). When the syringe is disconnected from the needle, it is common to have a small amount of fluid flow from the needle hub. This is usually the saline flowing back out of the epidural space, but could be CSF if the needle accidentally entered the subarachnoid space. CSF can often be distinguished by the fact that it is warm, whereas the saline is room temperature. CSF also tests positive for glucose. In addition, accidental meningeal puncture usually results in much larger volumes of CSF rapidly escaping from the epidural needle.

If a single-shot technique is to be used, a local anesthetic test dose should be administered to help rule out undetected subarachnoid or intravenous (iv) needle placement. After a negative test dose, the desired volume of local anesthetic should be administered in small increments (*e.g.*, 5 ml) at a rate of 0.5–1 ml · s⁻¹. Slow, incremental injection decreases the risk of pain during injection and allows detection of adverse reactions to accidental iv or subarachnoid placement before the entire dose is administered.

Continuous Epidural Anesthesia

Use of a catheter for epidural anesthesia affords much greater flexibility than the single-shot technique because the catheter can be used to prolong a block that is too short, extend a block that is too low, or provide postoperative analgesia. Potential disadvantages include catheter migration into an epidural vein or the subarachnoid space, or out an intervertebral foramen. Catheter use is also more likely to result in unilateral epidural block, a clinical fact that has been shown to result from catheter tips ending up in the anterior epidural space or migrating out an intervertebral foramen.^{14,23}

An ever-changing selection of epidural catheters is commercially available. They differ in diameter, stiffness, location of injection holes, presence or absence of a stylet, construction material, and so forth. Whichever catheter is chosen, it is important to verify that it passes easily through the epidural needle before the needle is placed in the epidural space. Epidural catheters are usually inserted through either Tuohy or Hustead needles because their curved tips help direct the catheter away from the dura mater. The needle bevel should be directed either cephalad or caudad, although the direction of the bevel does not guarantee that the catheter will travel in that direction. The catheter typically encounters resistance as it reaches the curve at the tip of the needle, but steady pressure usually results in passage into the epidural space. If the catheter will not pass beyond the needle tip, it is possible that the needle opening is not completely in the epidural space, or that some structure in the epidural space is preventing catheter insertion (*e.g.*, epidural fat). In this instance, the needle can be carefully advanced 1–2 mm more or rotated 180 degrees and the catheter reinserted. Although either of these maneuvers may result in successful catheter placement, they also increase the risk of accidental meningeal puncture. Alternatively, the procedure can be repeated at another interspace or with a different needle approach (*e.g.*, paramedian). Occasionally, a catheter will advance only a short distance past the needle tip. This raises the possibility that the needle tip is not in the epidural space and needs to be repositioned. In this case, the catheter should not be withdrawn back into the epidural needle because of the risk that the catheter tip will be sheared off by the bevel's sharp edge. Rather, the needle and catheter should be pulled out in tandem and the procedure repeated.

The catheter should be advanced only 3–5 cm into the epidural space. Placing a longer length of catheter in the epidural space increases the risk that it will enter an epidural vein, puncture the spinal meninges, exit an intervertebral foramen, wrap around a nerve root, or end up in some other disadvantageous location. Once the catheter is appropriately positioned in the epidural space, the needle is slowly withdrawn with one hand as the catheter is stabilized with the other. After the needle is removed, the length of catheter in the epidural space is confirmed by subtracting the distance between the skin and the epidural space from the length of catheter below the skin. Documenting this distance is important when trying to determine if catheters used in the postoperative period have been dislodged.

An epidural test dose must be administered through the catheter to test for iv or subarachnoid placement before incrementally delivering the entire epidural drug dose. In addition, because of the risk of undetected iv or subarachnoid migration of the catheter over time, additional test doses must be administered before each additional therapeutic (“top-up”) dose is given through the catheter. As with continuous spinal anesthesia, a reasonable guideline for top-up doses is to administer half the initial local anesthetic dose at an interval equal to two-thirds the expected duration of the block.

Epidural Test Dose

The epidural test dose is designed to identify epidural needles or catheters that have entered an epidural vein or the subarachnoid space. Failure to do so may result in intravascular injection of toxic doses of local anesthetic or total spinal block. Aspirating the catheter or needle to check for blood or CSF is helpful if positive, but the

incidence of false-negative aspirations is too high to rely on this technique alone.²⁴

The most common test dose is 3 ml of local anesthetic containing 5 mg · ml⁻¹ epinephrine (1:200,000). The dose of local anesthetic should be sufficient that subarachnoid injection results in clear evidence of spinal anesthesia. Intravenous injection of this dose of epinephrine typically produces an average 30 beats · min⁻¹ heart rate increase between 20 and 40 seconds after injection.^{25,26} Heart rate increases may not be as evident in patients taking b-adrenergic blockers; reflex bradycardia usually occurs in these patients.^{25,27} In b-blocked patients, systolic blood pressure increases of ³20 mm Hg may be a more reliable indicator of intravascular injection.^{25,27}

Isoproterenol has also been used to detect intravascular injection.²⁸ In addition, air injection combined with precordial Doppler ultrasonography to detect the characteristic murmur has been used successfully to test for iv placement of epidural catheters.²⁴ These techniques have been developed for use in laboring women where the sensitivity of epinephrine as a test dose is disturbingly low because maternal heart rate increases during contractions are often as large as those produced by epinephrine.²⁹ The clinical indications for these alternative tests of intravascular injection await additional, larger studies.

Combined Spinal-Epidural Anesthesia

Combined spinal-epidural anesthesia (CSEA) is a useful technique by which a spinal block and an epidural catheter are placed simultaneously. This technique is growing in popularity because it combines the rapid onset, dense block of spinal anesthesia with the flexibility afforded by an epidural catheter. There are special epidural needles with a separate lumen to accommodate a spinal needle available for CSEA (Fig. 26-6). However, the technique is easily performed by first placing a standard epidural needle in the epidural space and then inserting an appropriately sized spinal needle through the shaft of the epidural needle and into the subarachnoid space. The desired local anesthetic is injected into the subarachnoid space, the spinal needle removed, and a catheter placed in the epidural space via the epidural needle. The catheter can then be used to extend the height or duration of intraoperative block or to provide postoperative epidural analgesia.

An interesting pharmacologic aspect of CSEA is the observation that after the peak spinal block height is established, both saline and local anesthetic injected into the epidural space are effective at pushing the block level higher.^{30,31} and ³² This observation has been interpreted to indicate that the mechanism by which the epidural top-up increases block height is due to a volume effect (*i.e.*, compression of the spinal meninges forcing CSF cephalad) as well as a local anesthetic effect.

A potential risk of this technique is that the meningeal hole made by the spinal needle may allow dangerously high concentrations of subsequently administered epidural drugs to reach the subarachnoid space. Anecdotal case reports and *in vitro* animal studies suggest that this may be a legitimate concern.^{29,33,34} and ³⁵ Although CSEA shows great promise, additional, prospective studies are necessary to identify the relative risks and limitations of the technique.

PHARMACOLOGY

Successful spinal or epidural anesthesia requires a block that is high enough to block sensation at the surgical site and lasts for the duration of the planned procedure. However, because interindividual variability is considerable (Fig. 26-9 and Fig. 26-10), reliably predicting the height and duration of central neuraxial block that will result from a particular local anesthetic dose is difficult. Thus, recommendations regarding local anesthetic choice and dose must be viewed as approximate guidelines. The clinician must understand the factors governing spinal and epidural block height and duration to individualize local anesthetic choice and dose for each patient and procedure.

Figure 26-9. Peak spinal block height following 10- and 15-mg doses of hypobaric, isobaric, and hyperbaric tetracaine solutions injected at L3–L4 with patients in the lateral horizontal position. Note that dose has no influence on block height and that there is considerable interindividual variability in peak block height, especially with the hypobaric solution. (Adapted with permission from Brown DT, Wildsmith JA, Covino BG, Scott DB: Effect of baricity on spinal anaesthesia with amethocaine. Br J Anaesth 52:589, 1980.)

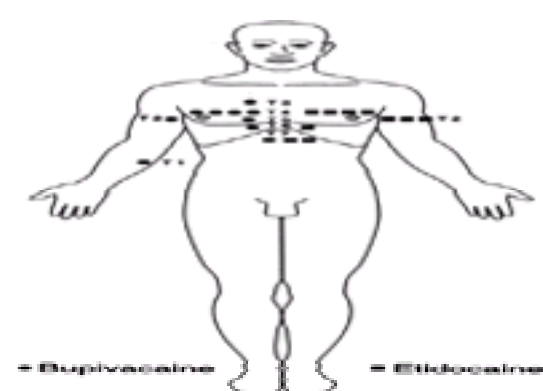

Figure 26-10. Peak epidural block height following 20 ml of 0.75% bupivacaine and 1.5% etidocaine injected via a catheter at the L1–L2 interspace. Note that despite a well controlled technique, the interindividual variability in block height is considerable and demonstrates the difficulty in accurately predicting block height in an individual patient. (Adapted with permission from Sinclair CJ, Scott DB: Comparison of bupivacaine and etidocaine in extradural blockade. Br J Anaesth 56:147, 1984.)

Spinal Anesthesia

Table 26-1 lists some common surgical procedures that are readily performed under spinal anesthesia, and the block height that is usually sufficient to ensure patient comfort. Also listed are techniques appropriate to achieve the desired block height. The rationales for these recommendations are detailed in the following sections.

| Surgical Procedure | Suggested Block Height | Technique | Comments |
|---|------------------------|---|--|
| Prostate | L3–L2 | Hypobaric solution/sitting position Hypobaric solution/semi-lith position Isobaric solution/horizontal position | Patients must remain in relative head up or head down position when using hypobaric and hyperbaric solutions to maintain restricted spinal filling for procedure |
| Lower extremity hip | T10 | Isobaric solution | Hypobaric and hyperbaric solutions are also suitable but may produce higher blocks than necessary |
| Transurethral resection of the prostate Vaginal cesarean | T10–T11 | Hypobaric solution/horizontal position | Isobaric solution limited at L2–L3 interspace may also be suitable |
| Thoracotomy Pituitary procedures Appendectomy | T4–T5 | Hypobaric solution/horizontal position | Upper abdominal procedures usually require some combined general anesthesia to prevent vagal or reflex and pain-brain reflexes on diaphragm, esophagus, and thorax |

Table 26-1. REPRESENTATIVE SURGICAL PROCEDURES APPROPRIATE FOR SPINAL ANESTHESIA

Baricity and Patient Position. The height of spinal block is thought to be determined by the cephalad spread of local anesthetic in the CSF. Table 26-2 lists some of the many variables that have been proposed to influence the spread of local anesthetics in the subarachnoid space. Many of these variables have been shown to be of negligible clinical importance. Of those factors that do exert significant influence on local anesthetic spread, the baricity of the local anesthetic solution relative to patient position is probably the most important. Baricity is defined as the ratio of the density (mass/volume) of the local anesthetic solution divided by the density of CSF, which averages $1.0003 \pm 0.0003 \text{ g} \cdot \text{ml}^{-1}$ at 37°C. Solutions that have the same density as CSF have a baricity of 1.0000 and are termed *isobaric*. Solutions that are more dense than CSF are termed *hyperbaric*, whereas solutions that are less dense than CSF are termed *hypobaric*.

Table 26-2. FACTORS THAT HAVE BEEN SUGGESTED AS POSSIBLE DETERMINANTS OF SPREAD OF LOCAL ANESTHETIC SOLUTIONS WITHIN THE SUBARACHNOID SPACE

Table 26-3 lists the baricity of local anesthetic solutions commonly used for spinal anesthesia. For practical purposes, solutions with a baricity <0.9990 can be expected reliably to behave hypobarically in all patients. Hypobaric solutions are typically prepared by mixing the local anesthetic solution in distilled water. Solutions with a baricity of ≈ 1.0015 can be expected reliably to behave hyperbarically. Hyperbaric solutions are typically prepared by mixing the local anesthetic in 5–8% dextrose. The baricity of the resultant solution depends upon the amount of dextrose added; however, dextrose concentrations between 1.25% and 8% result in equivalent block heights.^{36,37} Lower dextrose concentrations have been shown to have a concentration-dependent effect on block height with 0.33% producing a block to T9.5 on average, 0.83% producing a block to T7.2, and 8% producing a block to T3.6.³⁸

| | Baricity* |
|--------------------------------------|-----------|
| HYPERBARIC | |
| Tetracaine: 0.5% in 5% dextrose | 1.0155 |
| Bupivacaine: 0.75% in 8.25% dextrose | 1.0227 |
| Lidocaine: 8% in 7.8% dextrose | 1.0268 |
| Prilocaine: 10% in water | 1.0304 |
| ISOBARIC | |
| Tetracaine: 0.5% in normal saline | 0.9997 |
| Bupivacaine: 0.75% in saline | 0.9998 |
| Lidocaine: 0.5% in saline | 0.9983 |
| Lidocaine: 2% in saline | 0.9986 |
| HYPobaric | |
| Tetracaine: 0.2% in water | 0.9922 |
| Bupivacaine: 0.5% in water | 0.9946 |
| Lidocaine: 0.5% in water | 0.9983 |

* Measured at 37°C, except for hypobaric 0.5% lidocaine measured at 25°C. At 37°C, this solution's baricity is less.
† These solutions are slightly hypobaric but are used clinically as if they were isobaric.
Data from Horlocker TT, Wedel DJ. Density, specific gravity, and baricity of spinal anesthetic solutions at body temperature. Anesth Analg 76:1015, 1993; Lambert EJ, Cousins D. Hyperbaric, hypobaric, and isobaric spinal anesthesia. Residents Staff Physicians 33:79, 1987; Greene NM. Distribution of local anesthetic solutions within the subarachnoid space. Anesth Analg 64:715, 1985; and Bodily N, Carpenter H, Greene B. Lidocaine 0.5% spinal anesthesia: A hyperbaric solution for short-acting paravertebral surgery. Can J Anaesth 30:770, 1983.

Table 26-3. BARICITY OF SOLUTIONS COMMONLY USED FOR SPINAL ANESTHESIA

Baricity is important in determining local anesthetic spread and thus block height because gravity causes hyperbaric solutions to flow downward in CSF to the most dependent regions of the spinal column, whereas hypobaric solutions tend to rise in CSF. In contrast, gravity has no effect on the distribution of truly isobaric solutions. Thus, the anesthesiologist can exert considerable influence on block height by choice of anesthetic solution and proper patient positioning. Spinal block can be restricted to the sacral and low lumbar dermatomes (“saddle block”) by administering a hyperbaric local anesthetic solution with the patient in the sitting position³⁹ or by administering a hypobaric solution with the patient in the prone jackknife position. Similarly, high thoracic to midcervical levels of anesthesia can be reached by administering hyperbaric solutions with the patient in the horizontal and Trendelenburg positions^{40,41} or by administering hypobaric solutions with the patient in a semisitting position. However, this use of hypobaric solutions is not recommended because the high block achieved and the diminished venous return associated with the upright posture can lead to significant cardiovascular compromise.

The sitting, Trendelenburg, and jackknife positions have marked influences on the distribution of hypobaric and hyperbaric solutions because these positions accentuate the effect of gravity. However, most spinal anesthetics are administered as hyperbaric solutions injected while patients are in the horizontal lateral position, after which they are turned to the horizontal supine position. In this situation the influence of gravity is more subtle because the dependent areas of the spinal column do not deviate as much from the horizontal. While the patient is turned laterally, gravity has a small but measurable effect on local anesthetic distribution in that hyperbaric solutions produce a denser, longer-lasting block on the dependent side whereas hypobaric solutions will have the opposite effect.⁴² This makes hypobaric solutions ideal for unilateral procedures performed in the lateral position (e.g., hip surgery). Hyperbaric solutions can be used to advantage for unilateral procedures performed in the supine position if the operative side is dependent during drug injection and the patient is left in the lateral position for at least 6 minutes.⁴² Despite differences in block density and duration, peak block height will be comparable between the dependent and nondependent sides.

When the patient is turned supine after hyperbaric drug injection in the lateral position, the normal spinal curvature influences subsequent movement of the injected solution. Hyperbaric solutions injected at the height of the lumbar lordosis will tend to flow cephalad to pool in the thoracic kyphosis and caudad to pool in the sacrum (Fig. 26-11). Pooling of hyperbaric local anesthetic solutions in the thoracic kyphosis has been evoked to explain the clinical observation that hyperbaric solutions tend to produce blocks with an average height in the midthoracic region (Fig. 26-9). In addition, hyperbaric solutions have also been observed to produce blocks with a bimodal distribution, that is, one group of patients with blocks centered in the low thoracic region and a second group of patients with blocks centered in the high thoracic region.^{43,44} The presumed explanation for this observation is that the lumbar lordosis produces “splitting” of the local anesthetic solution with some portion flowing caudad toward the sacrum and the remainder flowing cephalad into the thoracic kyphosis. The cephalad extent of the block then depends on what fraction of the injected drug flows cephalad. Consistent with this hypothesis, eliminating the lumbar lordosis by maintaining the hips flexed has been shown to significantly reduce⁴⁴ or eliminate⁴³ the bimodal distribution of blocks without affecting maximal block height.

Figure 26-11. In the horizontal supine position, hyperbaric local anesthetic solutions injected at the height of the lumbar lordosis (*circle*) flow down the lumbar lordosis to pool in the sacrum and in the thoracic kyphosis. Pooling in the thoracic kyphosis is thought to explain the fact that hyperbaric solutions produce blocks with an average height of T4–T6.

Obviously, gravity influences the distribution of hyperbaric and hypobaric solutions only until they are sufficiently diluted in CSF so that they become isobaric. At this point, the local anesthetic solution no longer moves in response to changes in patient position and the block is said to be “fixed.” The time required for a local anesthetic solution to become fixed may be considerable. Povey *et al* showed that hyperbaric bupivacaine injected in the sitting position produces a saddle block that is restricted to the lumbar segments for as long as the subjects remained sitting.^{39,40} However, even 60 minutes after bupivacaine injection, the block spread to midthoracic levels after the patients were turned supine. Similarly, Bodily *et al*⁴⁵ found that hypobaric lidocaine administered in the jackknife position rose as many as six dermatomes when patients were allowed to sit upright in the recovery room as long as 60 minutes after lidocaine injection. Whether it is also possible to affect spread so long after injecting hyperbaric or hypobaric solutions in the horizontal position is unclear. Nonetheless, these findings demonstrate that in some situations it may be possible to exert influence on block height by adjusting patient position for at least 60 minutes after local anesthetic injection.

In contrast to the situation with hyperbaric solutions, patient position has no effect on the distribution of isobaric solutions because these solutions are not influenced by gravity. Consequently, isobaric solutions tend not to spread as far from the site of injection and produce blocks with an average height in the low thoracic region^{37,46} (Fig. 26-9). The obvious caveat is that the local anesthetic solution must be truly isobaric in the patient in whom it is used. Because of the interindividual variability in CSF density, it is difficult reliably to produce isobaric local anesthetic solutions. Nonetheless, as indicated in Table 26-3, several local anesthetic solutions are used as if they were isobaric. It is noteworthy that whereas isobaric solutions produce an average block height that is lower than that of comparable hyperbaric solutions,^{37,46,47} and⁴⁸ the “isobaric” solutions produce blocks with a much greater variability in height.^{49,50} and⁵¹ Logan *et al* have termed plain bupivacaine “an unpredictable spinal anesthetic agent.”⁴⁹ The greater variability in spread may stem in part from the fact that these solutions are actually slightly hypobaric, and their spread has been shown to be affected by patient position.^{52,53} Temperature-related changes in baricity may also play a role in the variability in distribution of these nearly isobaric solutions. For example, Stienstra and van Poorten⁵⁴ have shown that the distribution of plain bupivacaine is significantly altered by changes in temperature of the injected solution. In addition, McClure *et al*⁵⁵ have shown that increasing the volume and decreasing the concentration of isobaric tetracaine also increases the variability in block height. These and other unknown factors may play a role in the unpredictability of these nearly isobaric solutions. Although unpredictability is cause for concern, the lower average block height achieved offers potential advantages for surgical procedures below the umbilicus because of the decreased incidence of cardiovascular side effects associated with lower blocks. The isobaric solution that most reliably produces a low thoracic block is 10 mg of tetracaine crystals diluted in 1 or 2 ml room temperature saline and injected in the horizontal position.⁵⁵

Dose, Volume, and Concentration. Studies aimed at determining the effect of these three interdependent variables on block height, are difficult to conduct and interpret because it is not possible to change one variable without simultaneously changing another. Nonetheless, it is possible to draw some conclusions regarding the effect of these variables on block height. Several studies with isobaric tetracaine and bupivacaine solutions have found that neither injected volume nor drug concentration affects block height when dose is held constant.^{55,56,57,58} and⁵⁹ Drug dose does appear to play a small role in determining block height with isobaric bupivacaine. Two studies have found that 10 mg of isobaric bupivacaine results in significantly lower blocks than does 15 or 20 mg, but there is no difference in block height between the two higher doses.^{60,61} In contrast, two studies that examined the effect of different doses of isobaric tetracaine found that doses between 5 and 15 mg had no effect on block height, producing blocks with an average height of T9–T10.^{46,62}

Drug dose and volume appear to be relatively unimportant in predicting the spread of hyperbaric local anesthetic solutions injected in the horizontal position. Increasing the dose and volume of hyperbaric tetracaine while holding concentration constant does not affect block height when doses between 7.5 and 15 mg are used.^{46,62,63} Similarly, increasing the dose and volume of hyperbaric 0.5% bupivacaine does not increase block height when doses between 10 and 20 mg are used.^{64,65} However, doses of hyperbaric 0.5% bupivacaine <10 mg have been shown to result in blocks that are ~2.5 dermatomes lower than those achieved with doses >10 mg.⁶⁴ The fact that bupivacaine dose affects block height only at the extreme low end of the usual dose range is consistent with the experience with isobaric bupivacaine reported previously. The fact that drug dose is relatively unimportant in determining block height with hyperbaric solutions likely results from an overwhelming effect of baricity and patient position in determining spread of these solutions.

Injection Site. The site of injection can have an important effect on block height in some situations. In particular, sensory block height resulting from isobaric 0.5% bupivacaine is reduced by 2 dermatomes per interspace when comparing different groups of patients who received injections at the L2–L3, L3–L4, or L4–L5 interspaces.^{66,67} In an even more convincing study, this group of investigators performed repeated blocks in the same patient and found that by moving from the L3–L4 to the L4–L5 interspace mean block height could be reduced from T6 to T10 when using isobaric 0.5% bupivacaine.⁶⁸ In contrast, Sundnes *et al*⁶⁴ found no relationship between injection site and block height when using a hyperbaric bupivacaine solution, presumably because of the overwhelming effect of gravity and patient position on distribution of hyperbaric local anesthetics. Whether isobaric and hyperbaric solutions of other local anesthetics behave similarly is not clear.

Patient Characteristics. Data from Carpenter and colleagues suggest that the most important patient variable governing block height may be lumbosacral CSF volume.⁶⁹ In their study, the correlation coefficient for linear regression of lumbosacral CSF volume and peak block height was a compelling 0.91, with larger CSF volumes resulting in lower blocks. This study was performed in young adults (age 33 ± 4 years) using hyperbaric lidocaine, thus, it is unclear if the findings can be extrapolated to other local anesthetics or patient ages. Also, although they are mechanistically important, the clinical application of these data will be limited unless and until a simple method is developed to predict accurately lumbosacral CSF volume.

Patient age, weight, and height have all been suggested to have an effect on block height; however, none of these variables is an important or reliable predictor of block height.⁷⁰ Studies investigating the effect of age on block height in adults are conflicting, with some studies indicating that age does not correlate with block height⁷¹ and others that it does.^{51,72} However, even in the studies that reported a correlation between age and block height, the correlation was not strong enough to serve as a reliable predictor of block height in the clinical setting. For example, the range of block heights reported by Cameron *et al*⁵¹ for spinal block with isobaric bupivacaine was the same for patients in their seventh decade (T11–T2) as it was for patients in their ninth decade.

Patient height and vertebral column length are also poor predictors of the extent of sensory blockade in adults, at least within the range of heights commonly encountered.^{73,74} and⁷⁵ It is possible that extremes in height might decrease cephalad spread of sensory block. Similarly, weight is a poor predictor of block height in nonobese adults, although block height does appear to be somewhat higher in obese patients receiving isobaric local anesthetics.^{66,76,77}

Onset

Most patients can sense the onset of spinal block within a very few minutes after drug injection regardless of the local anesthetic used. However, there is a significant difference among drugs in the time to reach peak block height. Lidocaine and mepivacaine tend to reach peak block height between 10 and 15 minutes, whereas tetracaine and bupivacaine may require >20 minutes before peak block height is reached.

Duration

Spinal blocks do not end abruptly after a fixed time. Rather, they recede gradually from the most cephalad dermatome to the most caudad. As a result, surgical anesthesia lasts significantly longer at sacral levels than at thoracic levels. Therefore, when discussing the duration of spinal block it is necessary to distinguish between duration at the surgical site and the time required for the block to resolve completely. The former is important for providing adequate surgical anesthesia, and the latter for ensuring a timely recovery. A thorough understanding of the factors that govern block duration is necessary if the clinician is to choose techniques that result in an appropriate duration of spinal blockade.

Local Anesthetic. The principal determinant of spinal block duration is the local anesthetic drug used. Procaine is the shortest-acting local anesthetic for subarachnoid use, lidocaine and mepivacaine are agents of intermediate duration, and bupivacaine and tetracaine are the longest-acting drugs available for use in the United States. Table 26-4 lists the range of times required for sensory block to regress two dermatomes and to resolve completely with the local anesthetics most commonly used for spinal anesthesia. Although drug choice is the principal determinant of block duration, the factors discussed in the following sections can be used to alter block duration as necessary for a particular clinical situation. These variables are responsible for the wide range of block duration found in Table 26-4.

| Drug | Dose (mg) [†] | Duration of Sensory Block [‡] | | |
|-------------|------------------------|--|---------------------------|--|
| | | Two-Dermatome Regression (min) | Complete Resolution (min) | Prolongation by Adrenergic Agonists (%) [§] |
| Procaine | 50-200 | 30-50 | 90-120 | 30-50 |
| Lidocaine | 25-100 | 40-100 | 140-240 | 20-50 |
| Bupivacaine | 5-20 | 90-140 | 200-300 | 20-50 |
| Tetracaine | 5-20 | 90-140 | 200-300 | 50-100 |

*The lowest doses are used primarily for very restricted blocks (e.g., saddle block), but they become too dilute to be effective.
[†]Duration is influenced by dose and block height. The duration of surgical anesthesia obviously depends on the surgical site.
[‡]The effect of adrenergic agonists depends on the dose and choice of agonist. Prolongation is greatest at lumbar and sacral dermatomes and least at thoracic dermatomes.

Table 26-4. DOSE AND DURATION OF LOCAL ANESTHETICS USED FOR SPINAL ANESTHESIA

Drug Dose. Increasing local anesthetic dose clearly increases the duration of spinal block.^{60,61,63,78,79} For example, Brown *et al*⁴⁶ demonstrated that duration of sensory block at L1 after 15 mg tetracaine was ~20% greater than after 10 mg. Sheskey *et al*⁶¹ demonstrated a ~40% increase in block duration at L2 when comparing 10 mg bupivacaine with 15 mg. Similarly, Axelsson *et al*⁷⁸ found that duration of sensory block at L2 was nearly doubled when comparing 10 mg bupivacaine with 20 mg.

Block Height. If drug dose is held constant, higher blocks tend to regress faster than lower blocks.⁷⁹ Consequently, isobaric local anesthetic solutions usually produce longer blocks than hyperbaric solutions using the same dose. The conventional wisdom is that greater cephalad spread results in relatively lower drug concentration in the CSF and spinal nerve roots. As a result, it takes less time for local anesthetic concentration to decrease below the minimally effective concentration.

Adrenergic Agonists. Adrenergic agonists, such as epinephrine, phenylephrine, and more recently, clonidine, are added to local anesthetics in an effort to prolong the duration of spinal anesthesia. Their effectiveness depends upon the local anesthetic with which they are combined. In addition, they are more effective at prolonging block in the lumbar and sacral dermatomes than in thoracic dermatomes.

Epinephrine is typically administered in doses of 0.2–0.3 mg and phenylephrine in doses of 2–5 mg. There is evidence to suggest a relationship between the dose of vasoconstrictor added and the duration of spinal anesthesia; however, the relationship is not strong.^{80,81,82} and ⁸³ At the maximal doses used clinically, phenylephrine (5 mg) prolongs spinal block to a greater degree than epinephrine (0.5 mg).^{84,85} At lower doses, epinephrine (0.2–0.3 mg) and phenylephrine (2–3 mg) appear to be equally effective in prolonging spinal block.^{83,86} Thus, both choice of adrenergic agonist and dose administered appear to play a role in determining block duration.

Clonidine has been added to intrathecal local anesthetics in a dose of 75–150 µg.^{87,88} At this dose, it is at least as effective as moderate doses of phenylephrine and epinephrine at prolonging sensory block, but has been associated with greater decreases in blood pressure in some,⁸⁷ but not all studies.⁸⁸ Clonidine also prolongs spinal block when administered orally.^{89,90} and ⁹¹

Tetracaine is the local anesthetic whose effects are most dramatically prolonged by addition of adrenergic agonists. The duration of tetracaine spinal block may be increased 70–100% at lumbar and sacral dermatomes by addition of phenylephrine. Epinephrine may prolong tetracaine spinal anesthesia by 40–60%. Clonidine prolongs tetracaine spinal block by 50–70%, with the larger effect occurring at lumbar dermatomes.

Bupivacaine spinal block is also prolonged by adrenergic agonists, although the effect is somewhat less than that seen with tetracaine (Table 26-4). Epinephrine in doses of 0.2 mg prolongs bupivacaine spinal block by 20–30%, but only in lumbar dermatomes. Larger doses of epinephrine (0.3–0.5 mg) prolong sensory block in thoracic dermatomes as well by 30–50%. Clonidine prolongs bupivacaine spinal block by 30–50%.

The effect of adrenergic agonists on the duration of lidocaine spinal block is controversial. Some clinical studies have demonstrated that adrenergic agonists clearly prolong lidocaine spinal block,^{81,92,93} and ⁹⁴ whereas others have concluded that adrenergic agonists do not produce clinically useful prolongation.^{95,96} This discrepancy may be explained, in part, by the fact that spinal block duration is so variable that studies using small numbers of patients may lack sufficient statistical power to detect real differences in mean block duration between groups. This problem was obviated in an interesting study by Chiu *et al.*,⁹⁷ who used a crossover study design to demonstrate that 0.2 mg of epinephrine significantly prolonged lidocaine sensory block in lumbar and sacral dermatomes. Thus, the available data suggest that adding epinephrine to lidocaine will result in a somewhat longer block, at least in lumbar and sacral dermatomes, than would be achieved if epinephrine were not added.

The mechanism by which adrenergic agonists prolong spinal block is not clear. Originally, epinephrine and phenylephrine were added to local anesthetics with the intent of reducing local spinal cord blood flow and thereby slowing the rate of drug elimination from the spinal cord and CSF. There are animal studies that support this mechanism^{98,99} and others that do not.^{100,101} Animal studies with clonidine indicate that it does reduce regional spinal cord blood flow.¹⁰² There are no human studies that have investigated the effect of intrathecal adrenergic agonists on spinal cord blood flow. However, there are human studies that demonstrate that epinephrine decreases the rate of local anesthetic clearance from the CSF^{103,104} and also slows the rate at which subarachnoid local anesthetic appears in the plasma.⁹² These findings are consistent with a vasoconstrictor-mediated decrease in drug clearance from the spinal cord; however, they are not proof that this is the only or even the principal mechanism by which adrenergic agonists prolong spinal anesthesia.

Adrenergic agonists are potent analgesic agents in their own right when administered into the subarachnoid space.¹⁰⁵ Analgesia results from inhibition of nociceptive afferents, an effect that is mediated by stimulation of α -adrenergic receptors in the spinal cord dorsal horn. In addition, large intrathecal doses of α -adrenergic agonists have been shown to produce flaccidity in animal models by hyperpolarizing motor neurons.¹⁰⁶ Thus, prolongation of motor and sensory block by adrenergic agonists may be due, in part, to direct inhibitory effects of these drugs on sensory and motor neurons.

Epidural Anesthesia

Any procedure that can be performed under spinal anesthesia can also be performed under epidural block, and requires the same block height (Table 26-1). As with spinal anesthesia, there is a great deal of individual variability in spread (Fig. 26-10) and duration of epidural block (Table 26-5). Therefore, to choose the most appropriate local anesthetic and dose for a particular clinical situation, the anesthesiologist must be familiar with the variables that affect spread and duration of epidural anesthesia.

| Drug* | Duration of Sensory Block | | |
|-----------------------|--------------------------------|---------------------------|---------------------------------|
| | Two-Dermatome Regression (min) | Complete Resolution (min) | Prolongation by Epinephrine (%) |
| Chlorprocaine 2% | 45-60 | 100-150 | 40-60 |
| Lidocaine 2% | 60-100 | 160-220 | 40-60 |
| Mepivacaine 2% | 60-100 | 160-220 | 40-60 |
| Bupivacaine 0.5-1.0% | 90-180 | 240-420 | No |
| Etidocaine 1-1.5% | 120-240 | 300-600 | No |
| Bupivacaine 0.5-0.75% | 120-240 | 300-600 | No |

*These concentrations are recommended for surgical anesthesia; more dilute concentrations are appropriate for epidural analgesia.

Table 26-5. LOCAL ANESTHETICS USED FOR SURGICAL EPIDURAL BLOCK

Block Spread

Injection Site. Unlike spinal anesthesia, epidural anesthesia produces a segmental block that spreads both caudally and cranially from the site of injection (Fig. 26-12).

Thus, injection site is arguably the most important determinant of the spread of epidural block.

Figure 26-12. Spread of epidural sensory block over time after injection of various local anesthetic solutions at the L2–L3 interspace. All solutions contained epinephrine 1:200,000. Sensory block spreads both cephalad and caudad from the site of injection with time. Note the delay in onset of block at the L5 and S1 dermatomes with all solutions tested. (Reprinted with permission from Bromage PR: Epidural Analgesia. Philadelphia, WB Saunders, 1978.)

Caudal epidural blocks are largely restricted to sacral and low lumbar dermatomes. Low thoracic levels can be reached with caudal injections if large volumes are used (e.g., 30 ml). However, the block at thoracic dermatomes tends to be patchy and short-lived following caudal injection.¹⁰⁷ Lumbar local anesthetic injections with volumes of 10 ml often extend caudad to include all sacral dermatomes, although the onset of block in the L5 and S1 roots is often delayed and may be patchy.¹⁰⁸ Twenty-milliliter volumes produce better-quality sacral anesthesia following lumbar injection. The slow onset at L5 and S1 is thought to result from their larger diameter and consequent slower drug penetration. Lumbar injections can be extended to midthoracic levels (T4–T6) when 20-ml volumes of local anesthetic are used. Thoracic injections produce a symmetric segmental band of anesthesia, the width of which depends on the dose of local anesthetic administered. When using a mid- to upper thoracic injection site, it is prudent to reduce the local anesthetic doses by ~30–50% relative to lumbar doses to prevent excessive cephalad spread. It is generally not feasible to produce surgical anesthesia in low lumbar and sacral dermatomes with midthoracic or higher injection sites. Thoracic epidural block is ideally suited for anesthesia of the chest and abdomen.

Dose, Volume, and Concentration. Within the range typically used for surgical anesthesia, drug concentration is relatively unimportant in determining block spread. However, drug dose and volume are important variables determining both spread and quality of epidural block. If drug concentration is held constant, increasing the volume of local anesthetic (and thereby the dose) results in significantly greater average spread and greater block density. However, the relationship is nonlinear. For example, doubling the volume and dose of 1.5% lidocaine or 0.75% bupivacaine from 10 to 20 ml has been shown to increase spread by only three to four spinal segments.^{108,109}

Volume appears to be important in determining block spread independent of drug dose, but again the relationship is nonlinear. Erdemir *et al* showed that tripling the injected volume of lidocaine from 10 to 30 ml, while holding dose constant (300 mg) increased the cephalad extent of block by only 4.3 dermatomes.¹¹⁰ This tendency toward greater spread is thought to be explained by the observation that increasing the volume of solution injected into the epidural space increases cephalad distribution.¹¹¹

Position. When a single-shot technique is used, maintaining patients in the lateral position during and after epidural injection of surgical doses of local anesthetics does not seem to have a clinically important effect on spread of the block from side to side.¹¹² Similarly, studies examining the effect of patient position on cephalad spread of epidural block have found that the effect of posture on spread is not clinically important.¹¹³ Ponthold *et al*,¹¹⁴ however, demonstrated that maintaining a 30-degree head-up position significantly increased the frequency of adequate block at the L5 and S1 nerve roots even though there was no effect on the cephalad extent of anesthesia.

Patient Characteristics

Age. Most,^{108,109,115,116,117} and ¹¹⁸ but not all¹¹⁹ studies that have examined the effect of age on epidural block have demonstrated greater spread in older patients. However, the effect of age is probably clinically significant only when comparing adults whose ages differ by three or more decades. Even so, the difference in block height is not likely to be more than three or four dermatomes.

Greater spread in older patients is thought to be related to a less compliant epidural space and diminished ability for epidural solutions to leak out of intervertebral foramina.^{111,120} Both of these age-related changes would be expected to result in more extensive spread of solutions in the epidural space.

Height and Weight. The correlation between patient height^{108,109,118,119} or weight^{118,119} and spread of epidural block is weak and of little clinical significance except perhaps in patients who are extremely tall, extremely short, or morbidly obese.

Pregnancy. Studies examining the effect of pregnancy on spread of epidural block are conflicting. Some studies have demonstrated greater spread at term¹²¹ and during early pregnancy,¹²² suggesting that greater spread during pregnancy is not simply the result of anatomic changes associated with pregnancy. However, other studies have not found a significant difference in spread of epidural block between pregnant and nonpregnant women.^{123,124}

Atherosclerosis. Atherosclerosis has been suggested as an important determinant of the spread of epidural block.¹²¹ However, subsequent studies have failed to find any relationship between block spread and atherosclerosis.^{109,115,125}

Given the myriad factors that have some effect on spread of epidural anesthesia, how should anesthesiologists choose an appropriate local anesthetic dose for a single-shot epidural block? A useful recommendation is to assume that a 20-ml volume of all local anesthetics intended for surgical anesthesia will produce a midthoracic block on average after lumbar injection. If there are multiple reasons to expect that the block may spread excessively in an individual patient (e.g., advanced age, obesity, very short stature, high injection site) or if the procedure does not require a high block, then the dose is reduced accordingly. If there are multiple reasons to expect that the spread may be reduced from the average, then the volume is increased accordingly.

Obviously, choice of the appropriate local anesthetic dose is obviated if an epidural catheter is used. In this situation, the anesthesiologist should begin with a lower dose than he or she anticipates will be needed and administer additional local anesthetic as necessary to extend the block to the desired level.

Onset

The onset of epidural block with all local anesthetics can usually be detected within 5 minutes in the dermatomes immediately surrounding the injection site. The time to peak effect differs somewhat among local anesthetics. Shorter-acting drugs usually reach their maximum spread in 15–20 minutes, whereas longer acting drugs require 20–25 minutes. Increasing the dose of local anesthetic speeds the onset of both motor and sensory block.

Duration

Local Anesthetic. As with spinal anesthesia, choice of local anesthetic is the most important determinant of the duration of epidural block. Chloroprocaine is the shortest-duration drug used for epidural anesthesia, lidocaine and mepivacaine provide blocks of intermediate duration, and bupivacaine, ropivacaine, and etidocaine produce the longest-lasting epidural blocks. Table 26-5 lists local anesthetics commonly used for epidural block and approximate duration of surgical anesthesia. Of note, tetracaine and procaine are not generally used for epidural block because of the poor-quality block they produce.

When used epidurally, some local anesthetics exhibit considerable separation in both the intensity and duration of sensory and motor block. Etidocaine produces the most intense motor block and is unusual among local anesthetics in that motor block may considerably outlast sensory block.¹²⁶ The phenomenon of the postoperative patient who is in pain yet still unable to move his legs has led some anesthesiologists to abandon etidocaine for epidural use. This is unfortunate, because etidocaine's superior muscle relaxation is sometimes beneficial during surgery. Bupivacaine has the opposite sensorimotor profile in that low concentrations of bupivacaine produce

sensory block that is relatively more intense than motor block. This separation of sensory and motor block underlies the common practice of using dilute bupivacaine solutions for epidural analgesia since the laboring patient may be comfortable yet still able to move about.

Dose. Increasing the dose of local anesthetic administered results in increased duration^{108,127,128} and ¹²⁹ and density^{108,128,129} of epidural block.

Age. Studies that have evaluated the effect of age on epidural block duration are inconclusive. Veering *et al*¹¹⁷ found that duration of epidural block with plain bupivacaine was not significantly affected by age. Nydahl *et al*¹¹⁶ found that epidural block using bupivacaine with epinephrine was actually shorter in older patients. In contrast, Park *et al*¹¹⁵ found that epidural block using lidocaine with epinephrine was slightly but significantly longer in older patients. Additional studies are necessary to clarify the effect of age on duration of epidural block.

Adrenergic Agonists. Epinephrine, in a concentration of $5 \text{ mg} \cdot \text{ml}^{-1}$ (1:200,000) is the most common adrenergic agonist added to epidural local anesthetics. It has been shown to prolong the duration of lidocaine and mepivacaine epidural block by as much as 80%.¹³⁰ The mechanism by which epinephrine prolongs epidural block is not clear. Vasoconstrictors have been assumed to prolong block by producing local vasoconstriction and thus decreased local anesthetic clearance from the epidural space. The fact that epinephrine reduces peak plasma concentrations of some local anesthetics after epidural injection is considered to be supportive evidence of this mechanism. However, iv infusion of epinephrine also decreases peak plasma concentration of epidurally administered local anesthetics, presumably by increasing their volume of distribution.¹³¹ Thus, it is unclear what role local vasoconstriction plays in epinephrine's ability to prolong epidural block. As discussed earlier for spinal anesthesia, prolongation of motor and sensory block may be due, in part, to direct inhibitory effects of epinephrine on sensory and motor neurons.

Epinephrine does not significantly prolong the duration of anesthesia when added to the concentrated solutions of bupivacaine,^{132,133} etidocaine,^{128,133} or ropivacaine¹³⁴ that usually are used for surgical anesthesia. However, epinephrine does appear to prolong analgesia and improve the quality of block when added to more dilute solutions of these local anesthetics, such as those used for labor analgesia.^{135,136} and ¹³⁷

Summary

The extent and duration of both spinal and epidural block are influenced by a number of variables, some of which are under the control of the anesthesiologist. Understanding the impact of these variables will allow the anesthesiologist rationally to select the most appropriate drug and dose for any clinical situation. However, even the most experienced anesthesiologist will still have blocks that are not adequate for the planned procedure. The frequency of failed blocks can be kept to a minimum if the clinician aims to produce blocks that are a little higher and a little longer than seems necessary. It is often easier to deal with a block that is too high or too long than to cover up for a block that is too low or too brief.

PHYSIOLOGY

Neurophysiology

The physiology of local anesthetic neural blockade is discussed in detail in [Chapter 17](#). This section briefly presents aspects of the physiology of neural blockade that are unique to spinal and epidural anesthesia.

Site of Action

The site of action of spinal and epidural anesthesia is not precisely known. After epidural administration, local anesthetic is found in the spinal nerves within the epidural space, in spinal nerve rootlets within the CSF, and in the spinal cord. Similarly, after intrathecal administration in animals, local anesthetic is found in all sites between the spinal nerve rootlets and the interior of the spinal cord.^{138,139} Thus, neural blockade can potentially occur at any or all points along the neural pathways extending from the site of drug administration to the interior of the spinal cord.

In an interesting study in humans, Boswell *et al* demonstrated that patients are able to feel paresthesias during direct electrical stimulation of the spinal cord under spinal anesthesia.¹⁴⁰ Cortical evoked potentials from direct spinal cord stimulation were also maintained under spinal anesthesia, although amplitudes were decreased. In contrast, paresthesias and cortical evoked potentials from tibial nerve stimulation were abolished by spinal anesthesia. These investigators concluded that neural pathways in the spinal cord were largely intact during spinal anesthesia and that the spinal nerve rootlets were the principal site of neural blockade.

The site of epidural block is less well localized. Monkey studies suggest that epidural block occurs largely at sites in the spinal meninges, including the cauda equina nerve roots, dorsal root entry zone, and the long tracts of spinal cord white matter.¹⁴¹ However, these findings are not entirely consistent with the segmental onset of epidural anesthesia ([Fig. 26-12](#)) or with the limited segmental blocks that can be produced with small doses of lumbar epidural local anesthetics in humans. These clinical observations are most readily explained by block of the segmental spinal nerves as they traverse the epidural or paravertebral spaces. In reality, epidural block likely occurs at both extradural and subdural sites with extradural radicular block predominating early and subdural spinal block predominating later. This supposition is consistent with human studies by Urban who rigorously examined the anatomic pattern of analgesia that occurred during onset and regression of epidural block.¹⁴² He concluded that local anesthetics initially acted upon radicular structures, followed later by actions within the spinal cord.

Human studies demonstrate that somatosensory evoked potentials are maintained during epidural anesthesia, although amplitudes are decreased and latencies increased. This contrasts with spinal block, in which evoked potentials are completely eliminated, and supports the clinical impression that epidural block is generally less dense than that achieved with spinal anesthesia.

Differential Nerve Block

Differential block refers to a clinically important phenomenon in which nerve fibers subserving different functions display varying sensitivity to local anesthetic blockade. *In vivo* sympathetic nerve fibers appear to be blocked by the lowest concentration of local anesthetic, followed in order by fibers responsible for pain, touch, and motor function. This observation has led to the widely held belief that differences in sensitivity to local anesthetic blockade are explained solely by differences in fiber diameter, with smaller-diameter neurons exhibiting greater sensitivity than larger-diameter neurons. Although the mechanism for differential block in spinal and epidural anesthesia is not known, it is clear that fiber diameter is not the only, or perhaps even the most important factor contributing to differential block.^{143,144}

Differential block occurs with both peripheral nerve blocks and central neuraxial blocks. In the peripheral nervous system, differential block is a temporal phenomenon, with sympathetic block occurring first, followed in time by sensory and motor block. In contrast, with spinal and epidural anesthesia, differential block is manifest as a spatial separation in the modalities blocked. This is seen most clearly with spinal anesthesia, where the level of sympathetic block may extend to as many as two to six dermatomes higher than the level at which pin-prick sensation is absent,¹⁴⁵ which in turn extends two to three dermatomes higher than the level of motor block. This spatial separation is believed to result from a gradual decrease in local anesthetic concentration within the CSF as a function of distance from the site of injection. With epidural anesthesia, similar zones of differential sensory and sympathetic block are found.¹⁴⁶

Perhaps the most troublesome consequence of differential block is the occasional patient who has intact touch and proprioception at the surgical site despite adequate blockade of pain sensation. Even the most stoic patients are likely to find this unpleasant and may lie in fear that the procedure will soon become painful. In no instance should the anesthesiologist downplay the distress this may cause patients. Reassurance and judicious sedation as necessary are usually sufficient to overcome this problem.

Central Effects of Neuraxial Block

Another important neurophysiologic aspect of central neuroaxial block is that it produces sedation,¹⁴⁷ potentiates the effect of sedative, hypnotic drugs^{148,149} and ¹⁵⁰ and markedly decreases anesthetic requirement.¹⁵¹ The mechanisms underlying these effects are not known, but "deafferentation," (*i.e.*, the loss of ascending sensory input to the brain) is commonly invoked as causative.

Cardiovascular Physiology

Cardiovascular side effects, principally hypotension and bradycardia, are arguably the most important and common physiologic changes during spinal and epidural anesthesia. Understanding the homeostatic mechanisms responsible for control of blood pressure and heart rate is essential for understanding and treating the cardiovascular changes associated with spinal and epidural anesthesia.

Spinal Anesthesia

Blockade of sympathetic efferents is the principal mechanism by which spinal anesthesia produces cardiovascular derangements. As would be expected, the incidence of significant hypotension or bradycardia is related in general to the extent of sympathetic blockade, which in turn parallels block height.^{152,153} However, the severity of cardiovascular changes has been shown not to correlate with peak block height in one study¹⁵⁴ and to correlate poorly in another (Fig. 26-13).¹⁵² Additional risk factors associated with hypotension include age >40–50 years, concurrent general anesthesia, obesity, hypovolemia, and addition of phenylephrine to the local anesthetic.^{152,155}

Figure 26-13. The relationship between peak block height and change in systolic blood pressure (SBP) during spinal anesthesia. Although there is a statistically significant correlation between block height and decrease in systolic blood pressure, the interindividual variability is so great that the relationship has little predictive value. This is reflected in the R^2 of 0.07 for the linear regression line. (Reprinted with permission from Carpenter RL, Caplan RA, Brown DL *et al*: Incidence and risk factors for side effects of spinal anesthesia. *Anesthesiology* 76:906, 1992.)

Hypotension during spinal anesthesia is the result of both arterial and venodilation. Venodilation increases volume in capacitance vessels, thereby decreasing venous return and right-sided cardiac filling pressures.^{154,156,157} and ¹⁵⁸ This fall in preload is thought to be the principal cause of decreased cardiac output during high spinal anesthesia. Arterial dilation during spinal anesthesia results in significant decreases in total peripheral resistance (Fig. 26-14).^{157,159} Thus, the hypotension that accompanies 30–40% of spinal anesthetics may be the result of reductions in afterload, reductions in cardiac output, or both (Fig. 26-14).

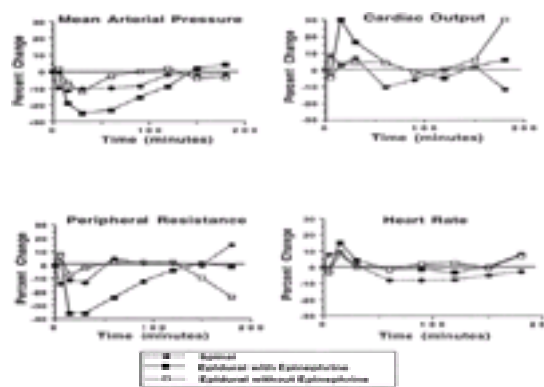

Figure 26-14. The cardiovascular effects of spinal and epidural anesthesia in volunteers with T5 blocks. The effects of spinal anesthesia and epidural anesthesia without epinephrine were generally comparable and are both qualitatively and quantitatively different from the effects of epidural anesthesia with epinephrine. (Modified and reprinted with permission from Bonica JJ, Kennedu WF Jr, Ward RJ, Tolas AG: A comparison of the effects of high subarachnoid and epidural anesthesia. *Acta Anaesthesiol Scand [Suppl]* 23:429, 1966.)

Heart rate does not change significantly during spinal anesthesia in most patients (Fig. 26-14). However, clinically significant bradycardia occasionally occurs, with a reported incidence of 10–15%. As with hypotension, the risk of bradycardia increases with increasing block height.¹⁵² Additional risk factors associated with bradycardia include age <50 years, American Society of Anesthesiologists Class 1 physical status, and concurrent use of β blockers.^{152,155} The mechanism responsible for bradycardia is not clear. Blockade of the sympathetic cardioaccelerator fibers originating from T1–T4 spinal segments is often suggested as the cause. The fact that bradycardia is more common with high blocks supports this mechanism. However, significant bradycardia sometimes occurs with blocks that are seemingly too low to block cardioaccelerator fibers. Diminished venous return has also been proposed as a cause of bradycardia during spinal anesthesia. Intracardiac stretch receptors have been shown reflexively to decrease heart rate when filling pressures fall.¹⁶⁰ Consistent with this mechanism, Jacobsen *et al* demonstrated a significant reduction in left ventricular volumes and heart rate during hypotensive episodes in two patients during epidural anesthesia.¹⁶¹ They concluded that central volume depletion elicited a vagally mediated reflex slowing of heart rate. Similarly, Baron *et al* demonstrated that vagal activity is enhanced by decreased venous return during epidural anesthesia.¹⁶² However, this mechanism does not operate at all times in all patients. Anzai and Nishikawa demonstrated significant heart rate increases in 40 patients who had their filling pressures suddenly decreased by body tilt during spinal anesthesia.¹⁵⁸ In reality, both blockade of cardioaccelerator fibers and decreased filling pressures as well as other unrecognized factors likely contribute to bradycardia during spinal anesthesia.

Although bradycardia is usually of moderate severity and well tolerated, there have been reports of sudden, unexplained, severe bradycardia and asystole during both spinal and epidural anesthesia.^{163,164} In addition, multiple case reports document that spinal anesthesia can also produce second- and third-degree heart block^{165,166} and ¹⁶⁷ and that pre-existing first-degree block may be a risk factor for progression to higher-grade blocks during spinal anesthesia.¹⁶⁵ These reports document the need for careful and continued vigilance of patients with central neuraxial blockade. Prompt, and occasionally aggressive, treatment of the cardiovascular changes that accompany the blockade may be required.

Epidural Anesthesia

The hemodynamic changes produced by epidural anesthesia depend largely on whether or not epinephrine is added to the local anesthetic solution (Fig. 26-14).¹⁶⁸ High epidural block with non-epinephrine-containing solutions results in decreased stroke volume, cardiac output, total peripheral resistance, and arterial pressure. The magnitude of these changes is usually less than that seen with comparable levels of spinal block.¹⁶⁸ As with spinal anesthesia, these hemodynamic changes are believed to result from venous and arterial dilation induced by sympathetic blockade. In contrast, when epinephrine-containing solutions are used for epidural anesthesia, stroke volume and cardiac output increase significantly (Fig. 26-14).¹⁶⁸ However, peripheral resistance falls dramatically, resulting in a decrease in arterial pressure greater than that seen with non-epinephrine-containing solutions. β_2 -Adrenergic-mediated vasodilatation produced by low doses of absorbed epinephrine accounts for the greater decrease in peripheral vascular resistance and blood pressure. Decreased peripheral resistance may also contribute to the marked increase in cardiac output.¹⁶⁹

Treating Hemodynamic Changes

Treatment of hypotension secondary to spinal and epidural block must be aimed at the root causes: decreased cardiac output, decreased peripheral resistance, or both. Bolus crystalloid administration has often been advocated as a means of restoring venous return and thus cardiac output during central neuraxial blockade. However, the effectiveness of this therapy in normovolemic patients is controversial. Prehydrating patients with 500–1500 ml of crystalloid does not reliably prevent hypotension, but it has been shown to decrease the incidence of hypotension during spinal anesthesia in some,^{170,171} but not all¹⁵³ studies. Similarly, prehydration with crystalloid has been shown not to be effective in preventing hypotension during spinal anesthesia for cesarean section.¹⁷² Thus, although judicious crystalloid preloading of patients before central neuraxial blocks may benefit some patients, this practice cannot be relied on to prevent clinically significant hypotension in all or

even most patients. The reason for this is that increasing preload can only increase stroke volume, which has limited ability to restore blood pressure if heart rate or systemic vascular resistance remains low. In this regard, colloids offer an interesting alternative to crystalloids for preloading before placing central neuraxial blocks. Marhofer *et al* have shown that 500 ml 6% hetastarch actually increases the systemic vascular resistance index in elderly patients having spinal anesthesia, 1500 ml crystalloid significantly decreases the systemic vascular resistance index.¹⁷³

Vasopressors are a more reliable approach to treating hypotension secondary to central neuraxial blockade. Drugs with both α - and β -adrenergic activity have been shown to be superior to pure α agonists for correcting the cardiovascular derangements produced by spinal and epidural anesthesia.^{174,175} Ephedrine is the drug most commonly used to treat hypotension. Ephedrine boluses of 5–10 mg increase blood pressure by restoring cardiac output and peripheral vascular resistance. Dopamine, in low to moderate doses, has also been shown to correct the hemodynamic changes induced by central neuraxial block.^{176,177} Dopamine may be preferable to ephedrine for long-term infusion because tachyphylaxis can develop to repeated ephedrine boluses. Pure α -adrenergic agonists, most commonly phenylephrine, are also used to correct hypotension during spinal anesthesia. However, α agonists increase blood pressure largely by increasing systemic vascular resistance, sometimes at the expense of a further decrease in cardiac output.¹⁷⁵ In addition, phenylephrine boluses have been shown to produce transient left ventricular dysfunction during epidural anesthesia with non-epinephrine-containing local anesthetics.¹⁷⁸ A potential, but as yet unstudied, role for α agonists may be to treat hypotension that occurs during epidural anesthesia with epinephrine-containing local anesthetics. Because the principal derangement in this situation is a marked decrease in systemic vascular resistance, α agonists may be an appropriate choice for treating hypotension in this setting.

Deciding when to treat hemodynamic derangements during spinal and epidural anesthesia is perhaps more difficult than deciding how to treat them. There are no studies that clearly define the lower limit of acceptable blood pressure or heart rate for any group of patients. In the absence of such data, several authors have recommended treating blood pressure if it decreases more than 25–30% below baseline or, in normotensive patients, if systolic pressure falls below 90 mm Hg. Recommendations regarding bradycardia suggest initiating treatment if heart rate falls below 50–60 $\text{beat} \cdot \text{min}^{-1}$. These recommendations are reasonable, although not universally applicable. Ultimately, anesthesiologists must decide what is an acceptable blood pressure and heart rate for an individual patient based on that patient's underlying medical condition.

Respiratory Physiology

Spinal and epidural blocks to midthoracic levels have little effect on pulmonary function in patients without pre-existing lung disease. Drugs used perioperatively for sedation during spinal or epidural block likely have a larger impact on pulmonary function than the block *per se*. In particular, lung volumes, resting minute ventilation, dead space, arterial blood gas tensions, and shunt fraction show little or no change during spinal or epidural anesthesia. Interestingly, the ventilatory response to hypercapnia is actually increased by spinal and epidural block.^{179,180}

High blocks associated with abdominal and intercostal muscle paralysis can impair ventilatory functions requiring active exhalation. For example, expiratory reserve volume, peak expiratory flow, and maximum minute ventilation may be significantly reduced by high spinal and epidural blocks. The negative impact of high blocks on active exhalation suggests caution when using spinal or epidural anesthesia in patients with obstructive pulmonary disease who may rely on their accessory muscles of respiration to maintain adequate ventilation.

Patients with high spinal or epidural blocks may complain of dyspnea despite normal or elevated minute ventilation. This likely results from the patient's inability to feel the chest wall move while breathing. This is understandably frightening to the patient, but reassurance is usually effective in alleviating their fear. The anesthesiologist must also be alert to the possibility that the complaint of dyspnea stems from incipient respiratory failure secondary to respiratory muscle paralysis. A normal speaking voice, as opposed to a faint gasping voice, suggests ventilation is normal.

Gastrointestinal Physiology

The gastrointestinal effects of spinal and epidural anesthesia are largely the result of sympathetic blockade. The abdominal organs derive their sympathetic innervation from T6 to L2. Blockade of these fibers results in unopposed parasympathetic activity by way of the vagus nerve. Consequently, secretions increase, sphincters relax, and the bowel becomes constricted. Some surgeons believe this improves surgical exposure. Nausea is a common complication of spinal and epidural anesthesia. The etiology is unknown, but an increased incidence of nausea during spinal anesthesia is associated with blocks higher than T5, hypotension, opioid administration, and a history of motion sickness.^{152,155}

Endocrine-Metabolic Physiology

Surgery produces numerous endocrine and metabolic changes, including increased protein catabolism and oxygen consumption as well as increases in circulating concentrations of catecholamines, growth hormone, renin, angiotensin, thyroid-stimulating hormone, β -endorphin, glucose, and free fatty acids, among others.¹ These endocrine–metabolic changes have collectively been termed the *surgical stress response*.

The mechanisms responsible for the stress response are complex and incompletely understood. However, afferent sensory information from the surgical site plays an important role in initiating and maintaining these changes.¹ Not surprisingly, spinal and epidural anesthesia have been shown to inhibit many of the endocrine–metabolic changes associated with the stress response. The inhibitory effect is greatest with lower abdominal and lower extremity procedures and least with upper abdominal and thoracic procedures.¹ The salutary effect of spinal and epidural anesthesia is believed to result from blockade of the afferent sensory information that helps initiate the stress response.

Although some aspects of the surgical stress response may be beneficial, it is generally viewed as maladaptive and possibly a contributor to postoperative morbidity and mortality.¹ Despite the ability of central neuraxial block to decrease the stress response, there is as yet no clear evidence that this results in decreased morbidity or mortality.

COMPLICATIONS

Backache

Although postoperative backache occurs after general anesthesia, it is more common after epidural and spinal anesthesia.¹⁸¹ Compared with spinal anesthesia, back pain after epidural anesthesia is more common (11% vs. 30%) and of longer duration.¹⁸² Back pain has been cited in one study as the most common reason for patients to refuse repeat epidural block.¹⁸² The etiology of backache is not clear, although needle trauma, local anesthetic irritation, and ligamentous strain secondary to muscle relaxation have been offered as explanations.

Postdural Puncture Headache

Postdural puncture headache (PDPH) is a common complication of spinal anesthesia, with a reported incidence as high as 25% in some studies. The risk of PDPH is less with epidural anesthesia, but it occurs in up to 50% of young patients after accidental meningeal puncture with large-diameter epidural needles. The headache is characteristically mild or absent when the patient is supine, but head elevation rapidly leads to a severe fronto-occipital headache, which again improves upon returning to the supine position. Occasionally cranial nerve symptoms (*e.g.*, diplopia, tinnitus) and nausea and vomiting are also present. The headache is believed to result from the loss of CSF through the meningeal needle hole, resulting in decreased buoyant support for the brain. In the upright position, the brain sags in the cranial vault, putting traction on pain-sensitive structures. Traction on cranial nerves is believed to cause the cranial nerve palsies occasionally seen.

The incidence of PDPH decreases with increasing age (Fig. 26-15) and with the use of small-diameter spinal needles with noncutting tips.^{183,184} Inserting cutting needles with the bevel aligned parallel to the long axis of the meninges has also been shown to decrease the incidence of PDPH.^{184,185} Some authors have suggested that parallel insertion spreads dural fibers, whereas perpendicular insertion cuts the fibers, resulting in a larger meningeal hole. However, the collagen fibers of the dura mater are arranged randomly; therefore, as many fibers are cut with parallel insertion as with perpendicular insertion. A more likely explanation arises from the fact that the dura mater is under longitudinal tension. Thus, a slit-like hole oriented perpendicular to this longitudinal tension tends to be pulled open, whereas a hole oriented parallel to this tension is pulled closed. Some studies have suggested that women are at greater risk of development of PDPH. However, if age differences are accounted for, there does not appear to be a sex difference in the incidence of PDPH.¹⁸⁴ Folklore aside, remaining supine after meningeal puncture does not decrease the incidence of PDPH. Finally, use of fluid instead of air for loss of resistance during attempted epidural anesthesia does not alter the risk of accidental meningeal puncture, but does markedly decrease the risk of subsequent development of PDPH.²²

Figure 26-15. The incidence of postdural puncture headache decreases as patient age increases. When using beveled needles, the incidence is higher than average at any given age if the needle is inserted perpendicular to the spinal meninges and lower if inserted parallel to the spinal meninges. (Modified and reprinted with permission from Lybecker H, Møller JT, May O, Nielsen HK: Incidence and prediction of post-dural puncture headache: A prospective study of 1021 spinal anesthetics. *Anesth Analg* 70:389, 1990.)

Postdural puncture headache usually resolves spontaneously in a few days to a week for most patients. However, there are reports of PDPH persisting for months after meningeal puncture. Initial treatment is appropriately conservative if this meets the patient's needs. Bed rest and analgesics as necessary are the mainstay of conservative treatment. Caffeine has also been shown to produce short-term symptomatic relief.¹⁸⁶

Epidural blood patch is an alternative for patients who are unable or unwilling to await spontaneous resolution of PDPH. It is believed that a clot forms over the meningeal hole, thereby preventing further CSF leak while the meningeal rent heals. Ten to 20 milliliters of autologous blood is aseptically removed and injected into the epidural space at or near the interspace at which the meningeal puncture occurred. This is effective in relieving symptoms within 1–24 hours in 85–95% of patients; ~90% of patients who fail an initial blood patch respond to a second patch. The most common side effects of blood patch are backache and radicular pain, although transient bradycardia and cranial nerve palsies have also been reported.

The timing of epidural blood patch has been controversial. Early studies suggested that prophylactic blood patch in patients at high risk for PDPH was ineffective.¹⁶⁸ This led several authors to suggest that blood patch should not be performed before symptoms of PDPH develop. Subsequent studies that used larger volumes of blood in the epidural space (15–20 ml) have shown that prophylactic blood patch is effective in preventing PDPH in patients in whom the meninges were accidentally punctured during attempted epidural anesthesia.^{187,188} Prophylactic blood patch is not appropriate for most patients, but is worth considering in high-risk outpatients for whom a return trip to the hospital for epidural blood patch would be difficult.

Epidurally administered fibrin glue has also been shown to be an effective alternative to blood administration for treatment of PDPH.¹⁸⁹ Whether it is superior to blood requires further study, but it may be an attractive alternative for some patients. In the future, it may be necessary to drop the term *blood patch* in favor of *meningeal patch*.

Hearing Loss

Lamberg *et al* demonstrated that a transient (1–3 days) mild decrease in hearing acuity (>10 dB) is common after spinal anesthesia patients with an incidence of roughly 40% and a 3:1 female:male predominance.¹⁹⁰ Similarly, Gültekin *et al*¹⁹¹ demonstrated a 45% incidence of hearing impairment in patients undergoing prilocaine spinal anesthesia, but a much lower incidence (18%) in patients having bupivacaine spinal anesthesia. The mechanism of hearing loss in these studies is unclear, but the marked female predominance, the absence of PDPH, and the difference in incidence between prilocaine and bupivacaine suggests that CSF leak is not the cause.

Systemic Toxicity

The toxicity of local anesthetics is discussed in detail in [Chapter 17](#). Systemic toxicity does not occur with spinal anesthesia because the drug doses used are too low to cause toxic reactions even if injected intravenously. Both CNS and cardiovascular toxicity may occur during epidural anesthesia. CNS toxicity may result from local anesthetic absorption from the epidural space, but more commonly occurs after accidental intravascular injection of local anesthetic. Because the plasma concentrations of local anesthetics required to produce serious cardiovascular toxicity are very high, this complication likely results only from accidental intravascular local anesthetic injection. An adequate iv test dose and incremental injection of local anesthetics are the most important methods to prevent both CNS and cardiovascular toxicity during epidural anesthesia.

Total Spinal

Total spinal anesthesia occurs when local anesthetic spreads high enough to block the entire spinal cord and occasionally the brain stem during either spinal or epidural anesthesia. Profound hypotension and bradycardia are common secondary to complete sympathetic blockade. Respiratory arrest may occur as a result of respiratory muscle paralysis or dysfunction of brain stem respiratory control centers. Management includes vasopressors, atropine, and fluids as necessary to support the cardiovascular system, plus oxygen and controlled ventilation. If the cardiovascular and respiratory consequences are managed appropriately, total spinal block will resolve without sequelae.

Neurologic Injury

Serious neurologic injury is a rare but widely feared complication of epidural and spinal anesthesia. Multiple large series of spinal and epidural anesthesia report that neurologic injury occurs in ~0.03–0.1% of all central neuraxial blocks, although in most of these series the block was not clearly proven to be causative.¹⁹² Persistent paresthesias and limited motor weakness are the most common injuries, although paraplegia and diffuse injury to cauda equina roots (cauda equina syndrome) do occur rarely. Injury may result from direct needle trauma to the spinal cord or spinal nerves, from spinal cord ischemia, from accidental injection of neurotoxic drugs or chemicals, from introduction of bacteria into the subarachnoid or epidural space, or very rarely from epidural hematoma.¹⁹²

Local anesthetics intended for epidural and intrathecal use can themselves be neurotoxic in concentrations used clinically.¹⁹³ In particular, hyperbaric 5% lidocaine has been implicated as a cause of multiple cases of cauda equina syndrome after subarachnoid injection through small-bore (“microspinal”) catheters during continuous spinal anesthesia.¹⁹⁴ Hyperbaric solutions injected through these high-resistance catheters have been shown to produce very little turbulence and thus poor mixing of the local anesthetic with CSF.¹⁹⁵ Nerve injury is believed to result from pooling of toxic concentrations of undiluted lidocaine around dependent cauda equina nerve roots. Consequently, the U.S. Food and Drug Administration has banned the use of these small-gauge catheters for continuous spinal anesthesia. Although the combination of microspinal catheters and high concentrations of lidocaine has clearly been implicated in causing cauda equina syndrome, this complication has also occurred when larger (20-gauge) catheters,¹⁹⁴ 2% lidocaine,¹⁹⁶ and 0.5% tetracaine were used.¹⁹⁴ A common thread in all of these reports has been the apparent maldistribution of the local anesthetic in the CSF. Maldistribution should be suspected whenever spinal block is unexpectedly restricted, and maneuvers, such as altering patient position or drug baricity, should be used to improve drug distribution before additional drug is injected through a continuous spinal catheter. If these maneuvers fail to improve drug distribution, an alternative anesthetic technique should be used.

The mechanism by which local anesthetics produce cauda equina syndrome is not yet clear; however, *in vitro* evidence suggests that local anesthetics produce excitotoxic damage by depolarizing neurons and increasing intracellular calcium concentrations.¹⁹⁷ It is also unclear as yet whether adjuncts, such as epinephrine, added to local anesthetics contribute to cauda equina syndrome. However, based on animal studies, it has been argued that epinephrine should not be added to intrathecal lidocaine.¹⁹⁸ Rather, if prolonged duration of spinal anesthesia is necessary, a longer-acting drug like bupivacaine should be used.

Transient Radicular Irritation. In addition to cauda equina syndrome, transient radicular irritation (TRI) has emerged as a concern after central neuraxial blockade. TRI is defined as pain, dysesthesia, or both in the legs or buttocks after spinal anesthesia, and was first proposed as a recognizable entity by Schneider *et al*.¹⁹⁹ All local anesthetics have been shown to cause TRI, although the risk appears to be greater with lidocaine than other local anesthetics.^{200,201,202,203,204,205} and ²⁰⁶

In a large epidemiologic study of nearly 2000 patients, Freedman *et al* characterized the clinical picture of TRI.²⁰⁷ They found that patients receiving lidocaine were significantly more likely to have TRI than patients receiving spinal tetracaine or bupivacaine, although TRI did occur with these latter drugs as well. Additional risk factors for TRI included surgery in the lithotomy position (with lidocaine, but not bupivacaine or tetracaine), outpatient status, and obesity. Variables shown not to

increase the risk of TRI included lidocaine dose, type of spinal needle, addition of epinephrine to lidocaine, paresthesia, hypotension, and blood-tinged CSF. In a separate study, Sakura *et al* has shown that the addition of phenylephrine is a risk factor for TRI when 0.5% tetracaine is used for spinal anesthesia.²⁰⁸

Pain from TRI is not trivial with most patients rating it as moderate (visual analogue scale = 4–7/10). The pain usually resolved spontaneously within 72 hours, but a very few patients required 6 months.²⁰⁷

The mechanism responsible for TRI is unknown, but it would be inappropriate to conclude that TRI is simply a milder manifestation of cauda equina syndrome. Differences in clinical presentation, risk factors, and the like suggest that these are not simply two points along a continuum of the same process.

Spinal Hematoma

Spinal hematoma is a rare but potentially devastating complication of spinal and epidural anesthesia, with an incidence estimated to be <1 in 150,000. Patients most commonly present with numbness or lower extremity weakness, a fact that can make early detection difficult in patients receiving perioperative spinal local anesthetics for pain control. Early detection is critical since a delay of more than 8 hours in decompressing the spinal cord reduces the odds of good recovery.²⁰⁹

Coagulation defects are the principal risk factor for epidural hematoma. This raises the legitimate question as to how to treat patients who are or who will be anticoagulated. This issue has been addressed in a Consensus Statement from the American Society for Regional Anesthesia (www.asra.com/consensus/intro.shtml). In brief, patients taking antiplatelet drugs (*e.g.*, nonsteroidal anti-inflammatory drugs [NSAIDs]) or receiving subcutaneous unfractionated heparin for deep vein thrombosis prophylaxis are not viewed as being at increased risk of spinal hematoma. Patients receiving fractionated low-molecular-weight heparin (*e.g.*, enoxaprin) are considered to be at increased risk of spinal hematoma. Patients who are “fully anticoagulated” (*i.e.*, have an elevated prothrombin time or partial thromboplastin time) at the time of block placement or epidural catheter removal are considered to be at increased risk of spinal hematoma. Similarly, patients receiving thrombolytic or fibrinolytic therapy are at increased risk of neuraxial bleeding. For those patients who may have an epidural or intrathecal catheter placed, its removal is nearly as great a risk for spinal hematoma as its insertion, and the timing of removal and anticoagulation should be coordinated. In addition, drugs and regimens not considered to put patients at increased risk for neuraxial bleeding when used alone (*e.g.*, mini dose unfractionated heparin and NSAIDs) may in fact increase the risk when combined.

CONTRAINDICATIONS

The only absolute contraindication to spinal or epidural anesthesia is patient refusal. However, several pre-existing conditions increase the relative risk of these techniques, and the anesthesiologist must carefully weigh the expected benefits before proceeding. Some conditions that increase the apparent risk of central neuraxial block include the following:

1. Hypovolemia or shock increases the risk of hypotension.
2. Increased intracranial pressure increases the risk of brain herniation when CSF is lost through the needle, or if a further increase in intracranial pressure follows injection of large volumes of solution into the epidural or subarachnoid spaces.
3. Coagulopathy or thrombocytopenia increase the risk of epidural hematoma.
4. Sepsis increases the risk of meningitis.
5. Infection at the puncture site increases the risk of meningitis.

Pre-existing neurologic disease, particularly diseases that wax and wane (*e.g.*, multiple sclerosis), have been considered a contraindication to central-neuraxial block by some authors. However, there is no evidence to suggest that spinal or epidural anesthesia alters the course of any pre-existing neurologic disease. Recommendations to avoid regional anesthesia in these patients stem largely from a medicolegal concern that the anesthetic may be incorrectly blamed for any subsequent worsening of the patient's pre-existing condition. Although this is a legitimate concern, it is not a reason to avoid central-neuraxial block if this is an otherwise appropriate choice.

SPINAL OR EPIDURAL ANESTHESIA?

Spinal and epidural anesthesia each have advantages and disadvantages that may make one or the other technique better suited to a particular patient or procedure. Controlled studies comparing both techniques for surgical anesthesia have consistently found that spinal anesthesia takes less time to perform, produces more rapid onset of better-quality sensorimotor block, and is associated with less pain during surgery.¹⁸² Despite these important advantages of spinal anesthesia, epidural anesthesia offers advantages, too. Chief among them are the lower risk of PDPH, less hypotension if epinephrine is not added to the local anesthetic, the ability to prolong or extend the block using an indwelling catheter, and the option of using an epidural catheter to provide postoperative analgesia.

GENERAL PRINCIPLES

Regional anesthesia of the extremities and of the trunk is a useful alternative to general anesthesia in many situations. Peripheral nerve blocks have attracted renewed interest because of their salutary role in reducing postoperative pain¹ and shortening outpatient recovery.²

Local Anesthetic Drug Selection and Doses

The pharmacology of local anesthetics is reviewed at length in [Chapter 17](#). Although high concentrations of drug are needed to produce rapid onset of anesthesia in the epidural space, lower concentrations (e.g., 1% lidocaine, 0.25% or 0.5% bupivacaine) are more appropriate on peripheral nerves because of concerns about local and systemic toxicity. Local toxicity of these anesthetics appears to be concentration dependent.^{3,4} Lower concentrations are also indicated because larger volumes are often required to anesthetize poorly localized peripheral nerves or to block a series of nerves. The use of a high-concentration solution presents the patient with a high total-milligram dose of local anesthetic, which may produce toxic blood levels.

The absorption of drug and the duration of anesthesia vary with the dose, drug, location injected, and presence of vasoconstrictors. The highest blood levels of local anesthetic occur after intercostal blockade, followed by epidural, caudal, and brachial plexus blockade. Similarly, the duration depends on the blood supply of the area of injection. Equivalent doses of local anesthetic may produce only 3–4 hours of anesthesia when placed in the epidural space, but 24–36 hours when placed on the sciatic nerve. In general, the addition of epinephrine 1:200,000 is advantageous in prolonging the duration of blockade and in reducing the systemic blood levels of local anesthetic. Its use is not appropriate in the vicinity of “terminal” blood vessels, such as in the digits or penis, or when using an intravenous (iv) regional technique. The recommended doses and drugs in this chapter assume the addition of epinephrine to the solution.

Nerve Localization

The blockade techniques associated with reliable proximity of nerves to bones or arteries are the easiest technically to perform (e.g., epidural, intercostal, axillary). Less reliable landmarks, such as the psoas compartment or obturator foramen, require either large volumes of local anesthetic solution or the establishment of a distinct localization of the desired nerve to provide adequate anesthesia. Paresthesias are the traditional sign of successful localization. There is potential for intraneural injection if paresthesias are obtained. This is usually signaled by a complaint from the patient of a “cramping” or “aching” pain during the initial injection. If this occurs, the needle should be immediately withdrawn by a few millimeters and a small test injection repeated. Even without intraneural injection, residual neuropathy of peripheral nerves appears more likely if paresthesias are obtained. Selander *et al*⁵ have reported a 2.8% incidence of residual ulnar neuropathy when paresthesias were used to locate nerves, compared with a 0.8% incidence with the transarterial technique of axillary blockade. Other larger series have reported a much lower incidence of dysesthesia since short bevel needles have been used,⁶ and it appears premature to abandon the paresthesia technique.⁷ A third problem with this technique is the inevitable discomfort associated with it; patient education and sedation must be handled appropriately (see later).

The use of a nerve stimulator is an alternative nerve localization technique. A low-current electrical impulse applied to a peripheral nerve produces stimulation of motor fibers and identifies the proximity of the nerve without actual needle contact or patient discomfort (or cooperation). This technique is particularly suited to the patient who is uncooperative as a result of inebriation or heavy sedation. Because the nerve stimulator does not actually contact the nerve, its use may reduce the chance for nerve injury, although it still may occur.⁷ Its use does not improve the success rate of regional anesthesia, at least in a training program,⁸ because a familiarity with the anatomy and technique is necessary to bring the needle into proximity with the nerve. Nevertheless, this is a useful adjunct to regional anesthesia, and some comments about appropriate use of this device are warranted.

The ideal stimulator should have a variable-amperage output. This allows a high current to be delivered in the exploration phase and then a progressively lower current to document proximity of the nerve. Whereas 1 mA can be used to produce the first motor twitch, actual injection of anesthetic should be delayed until stimulation is produced by as little as 0.3–0.5 mA. At that point, 2–3 ml of local anesthetic should be sufficient to abolish motor twitch, indicating that it is appropriate to inject the remainder of the proposed dose. The accuracy of the localization can be improved by the use of insulated needles. A plastic sheath along the shaft allows the current flow to be concentrated at the tip and is more likely to produce stimulation only when the tip is near the nerve fiber rather than after the tip has moved past its target. Current flow can also be improved by using the positive (red) pole of the stimulator as the ground (or reference) electrode and the negative (black) lead as the connection to the needle itself. Despite these steps, the stimulator is still only an adjunct to nerve localization and not a reliable substitute for good technique.

Equipment

Although reusable syringes and needles can be manufactured to a higher standard, their cost and concern about infection generally lead to a preference for disposable equipment. There are a large number of high-quality disposable kits available on the market, and many of the major manufacturers customize their packages at the request of large institutions willing to commit to purchasing a sufficient volume. The use of disposable trays places the burden of sterilization on the manufacturer, although the liability for checking the sterility of contents always remains with the user.

Needles used for regional techniques are often modified from standard injection needles ([Fig. 27-1](#)). For peripheral blockade, the “short bevel” or “B bevel” is often used. This shorter angulation of the bevel (16–20 degrees versus conventional 12–13 degrees) was introduced by Selander *et al*⁹ and has been shown in animals to produce less injury to nerves, perhaps by pushing the nerve away rather than piercing it when contact is made. Other modifications, such as the “pencil-point” insulated needle, have been introduced in attempts to reduce nerve injury. Another feature of regional blockade needles is the addition of a “security bead” to the shaft. This small bead is added approximately 6 mm from the juncture of the shaft and the hub and prevents the shaft of the needle from retracting below the skin in the event that it becomes separated from the hub. These two modifications are useful features for peripheral nerve blockade.

Figure 27-1. Regional anesthesia needles. Characteristic features of needles used for peripheral nerve blockade include the “security bead” on the shaft just below its juncture with the hub (*top*) and the shorter bevel angle compared with standard Quincke-type needle points (*bottom*). Further modifications to enhance the use of a nerve stimulator include the attachment for the electrode and the insulated shaft (*middle*).

Special syringes are also useful for performing peripheral nerve blockades. Plastic and glass are equally useful. With respect to size, a 10-ml syringe is usually a good compromise. Large volumes are usually required for peripheral nerve blockade, so that 3- and 5-ml syringes are rarely adequate. Larger than 10-ml volume often presents such bulk and weight that fine control is hampered. If a larger syringe is used, it is usually advisable to have an assistant manipulate the syringe and have it attached to the needle by a short length of extension tubing. The use of finger rings (the “control syringe”) is helpful in controlling injection, facilitating aspiration, and allowing the operator to refill the syringe with one hand (Fig. 27-2). Luer-Lok adapters for the syringe-hub connection are also advantageous. Although friction fittings produce tight seals, the amount of force required for attaching or removing the syringe may displace a needle that has been meticulously maneuvered into the appropriate close contact with a nerve.

Figure 27-2. The three-ring (“control”) syringe. Use of this adaptation to the plunger of a standard 10-ml syringe allows greater control of injection, easier aspiration, and the opportunity to refill the syringe with one hand. Plastic adapters are available for disposable syringes as demonstrated; glass syringes are supplied with a metal plunger and ring attached. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

The selection of antiseptic solutions is usually a local preference. Organic iodine preparations are the current standard for skin asepsis. They are usually nonirritating to tissues and carry the added advantage of a distinct color. Colorless preparation solutions are dangerous because of the possibility of confusion with (or contamination of) local anesthetic solutions. Colored alcohol solutions are acceptable skin cleansers for many of the simple infiltrations that do not require extensive preparation. For major deep blockade, a wide area of skin preparation is more desirable, and the borders of the clean area can be extended by draping on four sides with sterile towels. Regional anesthesia does not require the same degree of sterile preparation and gowning as indicated for surgery, but strict attention to asepsis is desirable to reduce the chance of infection.

Common Complications

Systemic toxicity of local anesthetics is the most serious concern.¹⁰ This syndrome and the problems of allergy and other unique toxicities are addressed in [Chapter 17](#). Central nervous system excitation and myocardial depression are the two most common hazards associated with high blood levels of local anesthetics. No peripheral nerve blockade using significant quantities of local anesthetic should be performed without oxygen and appropriate resuscitation equipment immediately available. This includes blockades using small quantities of anesthetic but near cerebral vessels, such as stellate ganglion or cervical plexus blockade. With peripheral nerve blockade, careful use of a test dose and small incremental injections are appropriate if intravascular injection is a risk. Toxicity can also occur owing to slow absorption of high doses. Patients should be observed carefully for 20–30 minutes following injection because peak levels occur at this time.

Peripheral neuropathy usually results from intraneural local anesthetic injection or needle trauma, although there are other causes.¹¹ Careful attention should be paid to positioning the patient with numb extremities. Postoperative follow-up is important in confirming that neurologic function has returned to normal. If a deficit is detected, early neurologic assessment is critical in determining whether a pre-existing neuropathy was involved. Fortunately, most of these syndromes resolve uneventfully, but full recovery of some peripheral injuries requires several months as a result of slow regeneration of injured peripheral nerves. Sympathetic concern and involvement of the anesthesiologist in arranging physical therapy during recovery help reduce patient dissatisfaction.

Other minor complications such as pain at the site of injection and local hematoma formation are not uncommon but are usually of short duration and respond to reassurance by the anesthesiologist. Hematoma around a peripheral nerve is not of the same significance as that in the epidural or subarachnoid space. Again, expressed concern and help with local therapy and analgesics alleviate patient dissatisfaction.

PATIENT PREPARATION

Patient Selection

In general, all patients scheduled for extremity, thoracic, abdominal, or perineal surgery should be considered candidates for a regional anesthetic technique. This can be used as the only anesthetic, as a supplement to provide analgesia and muscle relaxation along with general anesthesia, or as the initial step for provision of prolonged postoperative analgesia such as with intercostal blockade or continuous epidural anesthesia. Patient refusal can be an impediment to regional anesthesia, although this is frequently a “relative” refusal. Often, the patient’s real objections to “being awake” or “being aware” can be managed by the use of sedatives and amnestic drugs. True, unwavering refusal of “any needles” is a contraindication to regional anesthesia, although gentle attempts at patient education should be offered. Other contraindications include local infection and severe systemic coagulopathy. The presence of pre-existing neurologic disease is often discussed. Some data are available in the case of spinal anesthesia, but the use of peripheral nerve blockade in this situation is unclear. A classic example is whether an arm blockade should be used for a scheduled ulnar nerve transposition at the elbow. Although some physicians avoid any procedure that may confuse the picture of postoperative neuropathy, others believe that if there is a clear difference in the potential injury and the pre-existing disease, regional techniques are appropriate. There are no clear answers in this regard, and full patient education and cooperation are most appropriate. Finally, the level of patient anxiety is an important consideration. Extreme apprehension regarding surgery necessitates heavy sedation, and the advantages of regional anesthesia in providing rapid recovery, alertness, and protection of airway reflexes may be negated. The use of regional anesthesia in these situations is a matter of judgment and experience.

Premedication and Sedation

The best preparation for a regional technique is careful patient education. Calm, gentle explanation of the technique as it is performed reduces most patient anxiety to a manageable level. In most cases, however, supplemental medication is also useful. In addition to the general comments about premedication discussed in earlier chapters, regional anesthesia techniques have some special requirements. First, sedation must be adjusted to the required level of patient cooperation. If paresthesias are to be sought, medication must be light enough to allow the patient to identify and report nerve contact. Although a mild dose of opioid (50–100 µg of fentanyl or equivalent) will help ease the discomfort of nerve localization, patient responsiveness must be maintained. This does not preclude the use of an amnestic agent. Small

doses of propofol or midazolam may provide excellent amnesia at levels of consciousness that still allow cooperation. They are also excellent supplements in the outpatient setting, where short duration of effect is desired. If paresthesias are not needed, as in intercostal blockade, heavy sedation may allow greater patient tolerance of the injections. Although intramuscular premedication was common with hospitalized patients, careful titration of iv drugs at the time of the blockade has essentially replaced this practice as the most effective way to adjust the level of sedation to individual patient needs and sensitivities.

Monitoring

Although current discussions of "monitoring" typically include mechanical and electrical devices, repetitive assessment of the patient's mental status when receiving local anesthetics is of paramount importance. The anesthesiologist must maintain frequent verbal contact with these patients and ideally have an uninvolved assistant available to assess the level of consciousness at all times. There are no electrical or mechanical devices that detect rising blood levels of local anesthetic; close observation for peak levels owing to iv (within 2 minutes) and subcutaneous (~20 minutes) absorption is essential. An electrocardiogram is appropriate to detect the pulse rise seen with epinephrine when it is included in a test dose. It is also useful if systemic toxicity occurs with bupivacaine. Other pulse counters such as mechanical meters and pulse oximeters are also useful when monitoring the pulse rate change with epinephrine. Blood pressure monitoring should be performed, as with use of any anesthetic. A baseline pressure should be obtained whenever any sympathetic blockade is performed and at frequent intervals thereafter. Beyond these specific comments, the standards for monitoring and record keeping on any patient undergoing regional anesthesia are the same as for patients undergoing any general anesthetic.

Discharge Criteria

Concern is occasionally expressed about discharging patients from postanesthesia care units when an extremity is still anesthetized. If regional anesthesia is administered to provide prolonged analgesia, numbness may be expected to persist for 10 (with intercostal anesthesia) to 24 (with sciatic blockade) hours after bupivacaine or ropivacaine administration. Patients with numb extremities have been successfully discharged from the postanesthesia care unit to the floors as long as their mental alertness is adequate. Outpatients may be discharged home with numb arms or legs as long as the patient is reliable and adequate instruction about care of the insensitive extremity is provided.

SPECIFIC TECHNIQUES

The remainder of this chapter is devoted to the details of the performance of specific types of blockade, arranged by sections of the body. No attempt has been made to describe every regional technique practiced, but to focus on those of clinical usefulness to the anesthesiologist. The common methods are described, in recognition that several alternative approaches have been advocated in each case.

Head and Neck

Regional anesthesia of the head and neck has limited surgical application. Concern about control and maintenance of the airway makes many anesthesiologists uncomfortable with regional techniques when intraoperative airway intervention is awkward. Trigeminal nerve blockade and occipital nerve blockade are used for diagnostic or neurolytic blockade for chronic pain syndromes. Cervical plexus blockade is useful for some surgical procedures on the neck, and topical-regional airway anesthesia is effective in reducing the subjective discomfort and hemodynamic responses to tracheal intubation.

Trigeminal Nerve Blockade

Sensory and motor nerve function of the face is provided by the branches of the fifth cranial (trigeminal) nerve. The roots of this nerve arise from the base of the pons and send sensory branches to the large gasserian (or semilunar) ganglion, which lies on the superior margin of the petrous bone just inside the skull above the foramen ovale. A smaller motor fiber nucleus lies behind it and sends motor branches to one terminal nerve, the mandibular. The three major branches of the trigeminal each have a separate exit from the skull (Fig. 27-3). The uppermost ophthalmic branch passes through the sphenoidal fissure into the orbit. The main terminal fibers of this nerve, the frontal nerve, bifurcate into the supratrochlear and supraorbital nerves. These two branches traverse the orbit along the superior border and exit on the front of the face in the easily palpated supraorbital notch for the former and along the medial border of the orbit for the latter.

Figure 27-3. Lateral view of major branches of the trigeminal nerve. Each major branch exits the skull by a separate foramen. The ophthalmic branch travels in the orbit. The maxillary and mandibular branches emerge from the skull medial to the lateral pterygoid plate, which serves as the landmark for their identification. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

The two major branches of the trigeminal nerve are the middle (maxillary) and lower (mandibular). The maxillary nerve contains only sensory fibers and exits the skull through the foramen rotundum. It passes beneath the skull anteriorly through the sphenomaxillary fossa. At this point, it lies medial to the lateral pterygoid plate on each side. At the anterior end of this channel, it again moves superiorly to re-enter the skull in the infraorbital canal in the floor of the orbit. In the sphenomaxillary fossa, it branches to form the sphenopalatine nerves and to give off the posterior dental branches. The anterior dental nerves arise from the main trunk as it passes through the infraorbital canal. The terminal infraorbital nerve emerges from the foramen of the same name just below the eye and lateral to the nose and gives off the terminal palpebral, nasal, and labial nerves. The mandibular nerve is the third and largest branch of the trigeminal, and the only one to receive motor fibers. It exits the skull posterior to the maxillary nerve through the foramen ovale. At this point, it is just posterior to the lateral pterygoid plate of the sphenoid bone. The motor nerves separate into an anterior branch immediately below the foramen ovale. The main branch continues as the inferior alveolar nerve medial to the ramus of the mandible. This nerve curves anteriorly to follow the mandible and exits as a terminal branch through the mental foramen. The mental nerve provides sensation to the lower lip and jaw.

Gasserian Ganglion Blockade

Ideally, the simplest blockade of the trigeminal nerve is performed in the central ganglion, which includes all three branches, and it is frequently recommended for treatment of disabling trigeminal neuralgia. This blockade is technically the most difficult and has the most undesirable potential for the complications of subarachnoid injection of anesthetic after neurolytic blockade. Residual numbness of the face is sometimes unpleasant, and a neuritis may be as unpleasant as the original condition. Protective corneal sensation may also be lost, and special care of the eye may be needed. Nevertheless, it is a technique useful in severe cases of trigeminal neuralgia that are unresponsive to more peripheral blockade. Alcohol injection has been performed in the past, although radiofrequency ablation by neurosurgeons is now more common. The procedure for blockade follows:

1. Three landmarks are needed to help locate the foramen ovale. First, a skin wheal is raised 3 cm lateral to the corner of the mouth on the involved side. A second mark is made on the skin 1 cm anterior to the midpoint of the zygoma (the midpoint lies just above the deepest part of the sigmoid notch of the mandible). The third landmark is the pupil of the eye on the ipsilateral side.
2. A 12.5-cm needle is introduced through the skin wheal on the cheek. The needle is advanced posteriorly in the sagittal plane formed by an imaginary line between the pupil and the point of insertion. As it moves posteriorly, it is angled superiorly toward the third point (anterior to the midpoint of the zygomatic arch). If advanced properly, the needle will pass through the muscles of the cheek without entering the oral cavity and will contact the base of the skull medial to the mandible and the zygoma. If it has remained in the plane of the pupil, it will be near the foramen ovale.
3. Once bone is contacted, the needle is withdrawn and reinserted to angle slightly more posteriorly until the foramen is entered. At this point, paresthesias of the maxillary branch are sought. The needle should not be advanced more than 1 cm beyond the opening of the foramen. If there is any question about localization,

biplanar fluoroscopy is useful in confirming position.

4. After localization of the nerve, careful aspiration is performed to detect unwanted subarachnoid placement of the needle. Two ml of 1% lidocaine injected slowly usually produces anesthesia of all three sensory branches. If alcohol is used, the anesthesia is preceded by a severe burning sensation; this can be reduced by prior injection of a few drops of local anesthetic.

Superficial Trigeminal Nerve Branch Blockade

Fortunately, most anesthetic applications of trigeminal blockade can be more easily performed by injection of the individual terminal superficial branches. This is relatively simple because the three superficial branches and their associated foramina all lie in the same sagittal plane on each side of the face (Fig. 27-4). Each of these foramina are readily palpable, and these nerves can be easily blocked with superficial injections of small quantities of local anesthetic. Although the bony landmarks are usually sufficient themselves, paresthesias are desirable before alcohol injection. Each of these blocks can be performed with the patient in the supine position. The procedure for blockade follows:

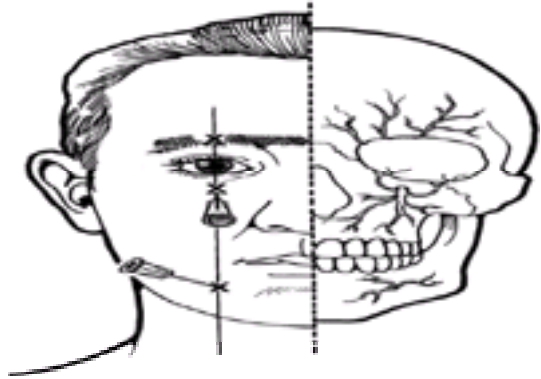

Figure 27-4. Terminal branches of the trigeminal nerve. Each of the three terminal branches (the supraorbital, infraorbital, and mental) exits its respective bony canal in the same sagittal plane, approximately 2.5 cm from the midline. The infraorbital canal is angled slightly cephalad, while the mental canal can be entered if the needle is directed medially and slightly caudad. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

1. The supraorbital notch is easily palpated along the medial superior rim of the orbit, usually 2.5 cm from the midline. Two to three ml of local anesthetic injected immediately in the vicinity of the notch produces anesthesia of the ipsilateral forehead. Anesthesia of the supratrochlear nerve by superficial infiltration of the medial aspect of the orbital rim is needed if the band of anesthesia is to cross the midline.
2. The infraorbital foramen lies below the inferior orbital rim in the same plane at approximately the same distance from the midline as the supraorbital notch (usually 2.5 cm). If the foramen cannot be palpated directly, it can be sought by gently probing with a small-gauge needle. This needle should be introduced through a skin wheal approximately 0.5 cm below the expected opening, because the canal angles cephalad from this point toward the orbital floor. Again, injection of a small quantity of local anesthetic immediately in the vicinity of the foramen produces anesthesia of the middle third of the ipsilateral face.
3. The mental nerve also emerges approximately 2.5 cm from the midline, usually midway between the upper and lower borders of the mandible. The mental canal angles medially and inferiorly so that, in this case, needle insertion should start approximately 0.5 cm above and 0.5 cm lateral to the anticipated location of the orifice if it cannot be palpated directly. In older patients, resorption of the superior margin of the mandibular bone will make the foramen appear to lie more superiorly along the ramus. Again, 2 ml of local anesthesia injected into the canal produces anesthesia of the mandibular area.

Maxillary Nerve Blockade

If anesthesia in superior dental nerves is also required or if superficial infraorbital nerve blockade does not produce adequate anesthesia, proximal block of the maxillary nerve is required. This can be performed by a lateral approach to the sphenopalatine fossa (Fig. 27-5). The procedure for blockade follows:

Figure 27-5. Lateral approach to the maxillary nerve. The needle is introduced through the skin just over the notch of the mandible and directed anteriorly and cephalad to identify the pterygoid plate. As the needle is advanced anteriorly off the plate, the maxillary nerve is encountered before it re-enters the skull in the infraorbital canal in the base of the orbit. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

1. The patient lies supine with a small towel under the occiput and the head turned slightly away from the side to be blocked. The zygomatic arch is marked along its course, and the patient is asked to open and close the mouth slowly so that the curved upper border of the mandible can be identified. The lowest point of the mandibular notch is palpated, and an "X" is marked at this spot, which is usually at the midpoint of the zygoma. A skin wheal is raised at the "X" after the appropriate skin preparations.
2. With the patient's jaw in the open position, a 7.5-cm needle is introduced through the "X" and directed 45 degrees cephalad and slightly anterior. This direction should be toward the imagined posterior border of the globe of the eye.
3. The needle should contact the pterygoid plate. It is then withdrawn and redirected slightly anterior until it succeeds in passing beyond the pterygoid plate. At this point, the nerve should lie approximately 1 cm deeper. A paresthesia in the nose or the upper teeth confirms the nerve localization.
4. Anesthesia can be achieved by injecting 5 ml into the fossa, either on obtaining the paresthesia or blindly by advancing 1 cm beyond the plate.

The major complication of concern is spread of the anesthetic to adjacent structures, especially to the nerves in the orbit.

Mandibular Nerve Blockade

This nerve can also be blocked for inferior dental pain. It is the only branch where anesthesia carries the risk of loss of motor (mastication) function (Fig. 27-6). The procedure for blockade follows:

Figure 27-6. Lateral approach to the mandibular nerve. The needle is introduced in the same manner as for the maxillary nerve block, but directed posteriorly. After contacting the pterygoid plate, it is directed farther posteriorly until it passes behind the plate, where it should encounter the nerve. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

1. Head position and landmarks are the same as those described for the maxillary nerve blockade.
2. A 2-inch needle is introduced through the skin wheal and directed medially but slightly posterior and without the cephalad angulation required for maxillary nerve anesthesia. This leaves the needle approximately perpendicular to the skin in all planes.
3. When the pterygoid plate is contacted, the needle is redirected posteriorly until it passes beyond the plate. It should contact the nerve 0.5–1 cm deep to this point.
4. Paresthesia of the jaw or cheek confirms identification of the nerve. Five to ten ml of solution injected incrementally at this point should produce anesthesia of the terminal branches. If paresthesias are essential, exploration should be carried gently cephalad and caudad from the initial point where the needle passes posterior to the plate. As with maxillary blockade, paresthesias can be painful to the patient, and the use of an assistant to secure the head is occasionally necessary.

Facial nerve anesthesia can occasionally be seen when large volumes are injected to block the mandibular nerve. This is of little consequence unless neurolytic agents are used. A more serious complication is the possibility of intravascular injection in this highly vascularized area. Injection should be performed incrementally with small quantities and constant observation for signs of central toxicity.

Cervical Plexus Blockade

Sensory and motor fibers of the neck and posterior scalp arise from the nerve roots of the second, third, and fourth cervical nerves. This cervical plexus is unique in that the sensory fibers separate from the motor fibers early in their course and can be blocked separately. Classic plexus anesthesia along the tubercles of the vertebral body produces both motor and sensory blockade. The transverse processes of the cervical vertebrae form peculiar elongated troughs for the emergence of their nerve roots. These troughs lie immediately lateral to a medial opening for the cephalad passage of the vertebral artery. The trough at the terminal end of the transverse process divides into an anterior and a posterior tubercle, which can often be easily palpated. These tubercles also serve as the attachments for the anterior and middle scalene muscles, which thus form a compartment for the cervical plexus as well as for the brachial plexus immediately below. The compartment at this level is less developed than the one formed around the brachial plexus. The motor branches (including the phrenic nerve) curl anteriorly around the lateral border of the anterior scalene and proceed caudad and medially toward the muscles of the neck. They give anterior branches to the sternocleidomastoid muscle as they pass behind it. The sensory fibers, as mentioned, also emerge behind the anterior scalene muscle but separate from the motor branches and continue laterally to emerge superficially under the posterior border of the sternocleidomastoid muscle. They provide sensory anesthesia to the anterior and posterior skin of the neck and shoulder.

Anesthesia of either the superficial cervical nerves or the cervical plexus itself can be used for operations on the lateral or anterior neck. Thyroidectomy and carotid endarterectomy fall into this category, although supplemental local infiltration of the thyroid gland may occasionally be necessary because of sensory innervation from cranial nerves. In carotid surgery, local infiltration of the carotid bifurcation may be necessary to block reflex hemodynamic changes associated with glossopharyngeal stimulation. Cervical plexus anesthesia alone is rarely adequate for shoulder surgery. It is preferable to perform interscalene anesthesia of the brachial plexus for these procedures because the likelihood of adequate motor relaxation is greater and the cervical plexus is blocked coincidentally. The procedure for deep cervical plexus blockade follows:

1. The patient is placed supine with a small towel under the head, with the head turned slightly to the side opposite the one to be blocked.
2. The mastoid process is identified and marked. The transverse processes can often be palpated. If not, the most prominent tubercle, that of C6, is marked, and a line is drawn between it and the mastoid process (Fig. 27-7).

Figure 27-7. Superficial landmarks for cervical plexus blockade. A line is drawn from the mastoid process to the prominent tubercle of C6. The transverse processes of C2, C3, and C4 lie 0.5 cm posterior to this line and at 1.5-cm intervals below the mastoid. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

3. The cervical processes should be felt approximately 0.5 cm posterior to the line drawn between the mastoid and the sixth cervical tubercle. The second vertebral process should lie approximately 1.5 cm below the mastoid itself. (There is no process for the first vertebra.)
4. The third and fourth processes lie approximately 1.5 cm below their respective superior neighbors.
5. Skin wheals are raised at the three "X" marks that have been placed over the transverse processes.
6. A 3.75-cm needle is introduced perpendicular to the skin and directed posterior and slightly caudad at each "X" until it rests on the transverse process. It is important to maintain a caudad direction to avoid entry directly into the intervertebral foramina. The needle is walked caudad. It should slip off the bone if it is truly on the process rather than continuing to contact bone if it is on the vertebral body. It is important to contact the transverse process as far laterally as possible to avoid any contact of the needle with the vertebral artery (Fig. 27-8).

Figure 27-8. Anatomy of deep cervical plexus blockade. The transverse processes lie under the lateral border of the sternocleidomastoid muscle, each with a distal trough or sulcus that defines the path of nerve exit. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown,

7. Paresthesias are usually not necessary. A syringe is connected to the needle, and 5 ml of local anesthetic solution is deposited along the transverse process. Anesthesia in the distribution of the nerve should follow within 5 minutes.

The major potential complication of this procedure is intravascular injection into the vertebral artery. Again, injection should be made in small increments, with frequent observation of the patient's mental status and frequent aspiration to detect intravascular placement. If the needle is advanced too far medially into the vertebral foramen, epidural or even subarachnoid anesthesia may be produced. This is more likely in the cervical region because of longer sleeves of dura that accompany these nerve branches. Again, frequent aspiration and careful lateral placement of the needle are important.

Phrenic nerve blockade occurs with deep cervical plexus anesthesia. This blockade is not indicated in any patient who depends on the diaphragm for tidal ventilation, nor is bilateral blockade desirable in most patients. Recurrent laryngeal nerve or vagal blockade can also occur because of diffusion of the local anesthetic. This is a troublesome but not serious complication. It may interfere with the ability to evaluate vocal cord function following thyroid surgery.

Superficial Cervical Plexus Blockade. This is performed in the same position as deep cervical plexus blockade and results in anesthesia only of the sensory fibers of the plexus. The procedure for blockade follows:

1. An "X" is made along the posterior border of the sternocleidomastoid muscle at the level of C4. This usually corresponds with the junction of the external jugular vein as it crosses the posterior border of the muscle ([Fig. 27-9](#)).

Figure 27-9. Superficial cervical plexus blockade. The sensory fibers of the plexus all emerge from behind the lateral border of the sternocleidomastoid muscle. A needle inserted at its midpoint, usually where the external jugular vein crosses the muscle, can be directed superiorly and inferiorly to block all these terminal branches. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

2. A skin wheal is raised at this mark, and superficial local anesthetic infiltration is performed along the posterior border of the sternocleidomastoid muscle 4 cm above and below the level of the "X." Ten to twelve ml of local anesthetic solution usually provides sensory anesthesia of the anterior neck and shoulder.

Occipital Nerve Blockade

The ophthalmic branch of the trigeminal nerve provides sensory innervation of the forehead and anterior scalp, but the remainder of the scalp is innervated by fibers of the greater and lesser occipital nerves, terminal branches of the cervical plexus. These nerves can be blocked by superficial injection at the point on the posterior skull where they emerge from below the muscles of the neck ([Fig. 27-10](#)). Anesthesia is rarely used for surgical procedures; it is more often applied as a diagnostic step in evaluating head and neck pain complaints. The procedure for blockade follows:

Figure 27-10. Occipital nerve blockade. The greater and lesser branches of the occipital nerve emerge from under the muscles at the level of the nuchal ridge on the posterior scalp. They can be easily blocked by a subcutaneous ridge of anesthetic solution. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

1. The block is performed in the sitting position, with the patient leaning the head forward to expose the prominent nuchal ridge of bone at the posterior base of the skull.
2. The external occipital protuberance is identified in the midline, and a mark is placed lateral to this prominence along the nuchal line at the lateral border of the insertion of the erector muscles of the neck, usually 2.5 cm from the midline. The branches of the greater occipital nerve usually pass laterally from behind the muscle to cross the nuchal line at this point.
3. After skin preparation, a small needle is introduced through the mark to the depth of the skull itself. A ridge of 1–4 ml of local anesthetic (1% lidocaine or equivalent) is then deposited across the path of the emerging nerves just above the level of the bone. Paresthesias are occasionally encountered but are not essential for obtaining simple skin anesthesia.
4. If more anterior anesthesia of the scalp is required, the lesser occipital nerve branches are also blocked by advancing the needle subcutaneously from this point in an anterior direction toward the mastoid process. A band of anesthetic solution is deposited along the line between the skin entry and the mastoid. A larger volume (6–8 ml) is required.

Complications of this technique are rare. Care must be taken not to advance the needle anteriorly under the skull, as the foramen magnum might be entered unintentionally with a long needle. Local hematoma may be produced with the superficial injection, but this is only a temporary problem.

Airway Anesthesia

Manipulation of the airway either during laryngoscopy or during tracheal intubation is often associated with laryngospasm, coughing, and undesirable cardiovascular reflexes (see also [Chapter 23](#)). The anesthesiologist can abolish or blunt these reflexes by anesthetizing one or all of the sensory pathways involved. The nasal mucosa is innervated by fibers of the sphenopalatine ganglion, a branch of the middle division of the fifth cranial nerve. These branches lie on the lateral wall of the nasal passages on each side, under the mucosa just posterior to the middle turbinate ([Fig. 27-11](#)). The branches of these fibers continue caudad to provide sensory innervation to the superior portion of the pharynx, uvula, and tonsils. Anesthesia of the maxillary branch of the trigeminal nerve is possible but not a practical solution for airway anesthesia. Transmucosal topical application of local anesthetic is more appropriate. Below the sphenopalatine fiber distribution, sensory innervation of the oral pharynx and supraglottic regions is provided by branches of the glossopharyngeal nerve. These nerves lie laterally on each side of the pharynx submucosally in the region of the posterior tonsillar pillar. Direct submucosal injection can be performed but carries the risk of unintentional intravascular injection into several blood vessels in this area. Topical anesthesia of the terminal branches in the mouth and throat is again an easier approach, but deep injection of the glossopharyngeal nerve may be required to block the gag reflex completely. The larynx itself is innervated by the superior laryngeal branch of the vagus nerve in the area above the vocal

cords. This branch leaves the main vagal trunk in the carotid sheath and passes anteriorly. Its internal branch penetrates the thyrohyoid membrane and divides to provide the sensory fibers to the cords, epiglottis, and arytenoids.

Figure 27-11. Nasal airway anesthesia. Cotton pledgets soaked with anesthetic are inserted along the inferior and middle turbinates to produce anesthesia of the underlying sphenopalatine ganglion by transmembrane diffusion of the solution. Wide pledgets also are needed to provide maximal topical anesthesia and vasoconstriction of the nasal mucosa. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

The recurrent laryngeal nerve provides innervation to the areas below the vocal cords, including motor innervation for all but one of the intrinsic laryngeal muscles. The trachea itself is also innervated by the recurrent laryngeal nerve. Topical anesthesia is again the simplest approach to this nerve.

Airway anesthesia can be performed by anesthetizing one or all of these sensory distributions. Full anesthesia facilitates procedures such as nasal intubation or fiberoptic laryngoscopy. Airway anesthesia below the vocal cords is best avoided if there is concern about potential aspiration, as this may blunt the reflex cough reaction to the presence of foreign bodies in the trachea. Topical postpharyngeal anesthesia may also ablate protective laryngeal reflexes.

In the performance of airway anesthesia, the patient can be anesthetized in the supine position, although many patients find it more comfortable to be semiupright or sitting when topical anesthesia is sprayed into the posterior pharynx. These positions allow them greater ease in swallowing excess solutions and may reduce gagging. In whatever position chosen, there should be a firm support behind the head to reduce involuntary withdrawal motions by the patient, which might dislocate needles being used for injections.

1. For nasal mucosal anesthesia, cotton pledgets soaked with anesthetic solution are introduced through the nares and passed along the turbinates all the way to the posterior end of the nasal passage (see [Fig. 27-11](#)). A second set of pledgets is introduced with a cephalad angulation to follow the middle turbinate back to the mucosa overlying the sphenoid bone. This pledget is the more critical one because anesthesia in this mucosal area is most likely to anesthetize the branches of the sphenopalatine ganglia as they pass along the lateral wall of the airway. Bilateral anesthesia is preferable, even if a nasal tube is to be inserted only on one side; bilateral blockade of the sphenopalatine fibers also produces posterior pharyngeal anesthesia caudad to this level. The pledgets should be allowed to remain in contact with the nasal mucosa for at least 2–3 minutes to allow adequate diffusion of local anesthetic.

Cocaine in a 4% solution has been the traditional topical anesthetic for this application because of its unique vasoconstrictive properties. Cocaine produces shrinkage of the mucosa and reduces the chance of bleeding. Because of the toxicity of cocaine and a significant abuse problem in the United States, alternate solutions have been recommended, primarily a mixture of 3–4% lidocaine and 0.25–0.5% phenylephrine.

2. Topical anesthesia to the posterior pharynx can be performed while the nasal applicators are in place. This can be done with a commercial spray or with an atomizer filled with a 4% solution of lidocaine. (A higher concentration of local anesthetic is required to penetrate mucosal membranes.) For effective anesthesia in the posterior pharyngeal wall, topical application is performed in two stages. First, the tongue itself is sprayed with a local anesthetic, and the patient is encouraged to gargle and swallow the residual liquid in the mouth. The numb tongue is then grasped with a gauze pad with one hand while the spray device is inserted into the mouth with the other. The patient is then encouraged to take rapid deep breaths (“pant like a puppy”) while the spray is applied on inspiration. The inspiratory flow of gases should be enough to draw the lidocaine solution into the posterior pharynx and even to the vocal cords themselves. If superior laryngeal nerve blockade has been performed before this, it is likely that the aerosol will be carried into the trachea itself. Again, a few minutes are needed for adequate onset of topical anesthesia in the pharynx. Topical anesthesia is less effective if there are copious secretions. Premedication with an anticholinergic is frequently beneficial.
3. Superior laryngeal nerve blockade can also be performed while the nasal pledgets are in place ([Fig. 27-12](#)). This nerve is blocked bilaterally by identifying the superior ala of the thyroid cartilage, which usually lies just inferior to the posterior portion of the hyoid bone on each side. A 5-ml syringe with a 1% lidocaine solution with a 23-gauge, 1.75-cm needle is used. The index finger of one hand retracts the skin of the neck caudad down over the thyroid cartilage; the needle is inserted until it rests on the superior margin of the cartilage. The tension on the skin is then released and the needle is withdrawn slightly and allowed to walk superiorly off the cartilage. The needle is then reinserted and passed through the thyrohyoid membrane, which is perceived as a discernible resistance. After careful aspiration, 2.5 ml of solution is injected into the space below the membrane. This procedure is repeated on the opposite side. This blockade can be performed as part of total airway anesthesia or it can be used independently to provide increased acceptance of indwelling endotracheal tubes in the intensive care unit.

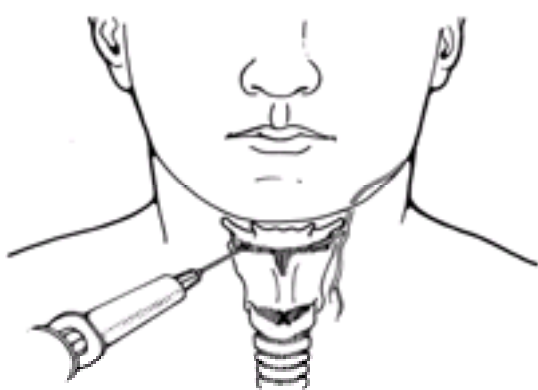

Figure 27-12. Superior laryngeal nerve blockade. The needle is advanced superiorly off the lateral wing of the thyroid cartilage to drop through the thyrohyoid membrane. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

4. The glossopharyngeal nerve can be blocked by a direct injection into the base of the anterior tonsillar pillar if persistent gagging is a problem. The tongue is retracted medially with a gloved finger or a tongue blade to expose the base of the anterior pillar. A long 25-gauge (spinal) needle is inserted 0.5 cm subcutaneously into the base of the pillar 0.5 cm lateral to the base of the tongue. After careful aspiration, 2 ml of 1.5% lidocaine is injected, and the procedure is repeated on the opposite side. This produces anesthesia of the lingual branch (base of the tongue), and may even anesthetize the pharyngeal and tonsillar branches by diffusion. This allows laryngoscopy with less gagging and hemodynamic response.
5. Tracheal anesthesia can be performed by a direct transcricoid (“transtracheal”) injection. This is accomplished by raising a small skin wheal over the cricothyroid membrane. A 20-gauge iv catheter is then inserted gently through this skin wheal and through the membrane. Entry into the trachea can be confirmed by the ability to aspirate air through the catheter. The steel stylet is then removed, and the plastic catheter is left in the trachea. A syringe with 4 ml of 4% lidocaine is attached to the catheter, and the local anesthetic is sprayed into the trachea during inspiration. The flow of air usually carries the local anesthetic distally; the resultant cough continues to spread the anesthetic more proximally up to the underside of the vocal cords and the larynx. Not uncommonly, if the local anesthetic is injected while the patient forcibly exhales, it is possible to obtain adequate anesthesia of the trachea, larynx, and posterior pharynx, without the need for either steps 2 or 3.
6. After each of these steps has been completed, the pledgets can be removed from the nasal passages and nasal intubation performed. If tracheal or laryngeal anesthesia has been omitted because of concern about aspiration, there should be some pharmacologic intervention to reduce the cardiovascular response to the passage of the tube into the trachea. This can be facilitated by pretreatment with iv β -adrenergic blocking drugs, by administration of sedation, or by administration of rapid-acting thiobarbiturates immediately after the airway is secured.

Complications of these techniques are rare. Systemic toxicity from the local anesthetics is a distinct possibility because of the large quantities of drug required to

produce sufficient mucosal anesthesia. If all four stages of airway anesthesia are undertaken, the total milligram doses applied usually exceed the maximal recommended dose for peripheral injection. Fortunately, the mucosal absorption is less than the peripheral absorption, but close attention to the patient's mental status and preparation for treatment of toxicity are necessary. Aspiration of gastric contents is also a possibility when the protective reflexes of the airway are interrupted. Precautions should be taken in the form of the usual prophylaxis to reduce stomach acidity as well as provision for suction and adequate oxygenation if emesis or regurgitation occurs.

Upper Extremity

The innervation of the upper extremity is conveniently derived from five closely approximated nerve roots, extending from C5 to T1 (the brachial plexus). These roots undergo a series of mergers and divisions that produce the terminal nerves of the arm and hand. The plexus branches are close enough to each other to allow reliable anesthesia to be achieved at several points associated with consistent bony or vascular landmarks.

In their proximal course, the nerve roots lie in a well demarcated fascial envelope formed by the anterior fascia of the middle scalene muscle and the posterior fascia of the anterior scalene. These muscles attach to the posterior and anterior tubercles of the transverse processes of the cervical vertebrae from which the nerves emerge. The tubercle can be used as a faithful landmark to guide localization of the nerve, and the fascial planes serve to keep anesthetic solution injected between them close to the nerve bundle. The fascia extends outward for a variable distance from the lateral border of the muscles to enclose the nerves in a "sheath," which can extend into the axilla. This enclosed bundle passes over the first rib just behind the midpoint of the clavicle (and just posterior to the insertion of the anterior scalene on the rib), where it is joined by the subclavian artery, which rises from the mediastinum to cross the rib and pass into the axilla. At the midpoint of the rib, the plexus has consolidated into only three trunks; these rapidly subdivide into the terminal branches. The musculocutaneous nerve is the first major branch to leave the companionship of its partners as it passes into the body of the coracobrachialis muscle high in the axilla. As the individual nerves form, separate compartments in the sheath are formed by developing septa, and reliable blockade of all the nerves with a single injection is not practical distal to the axilla.

Although many techniques of approach to the brachial plexus have been described, there are basically three anatomic locations where anesthetics are placed: (1) the interscalene groove near the transverse processes, (2) the subclavian sheath at the first rib, and (3) surrounding the axillary artery in the axilla. Because of the specific configuration of the nerves at each of these levels, the anesthesia produced is significantly different with each approach and applicable to different situations.¹² Interscalene injection at the level of the sixth cervical transverse process produces extension of the blockade to the lower fibers of the cervical plexus and therefore is ideally suited for shoulder operations and upper arm procedures. It frequently spares the lowest branches of the plexus, the C8 and T1 fibers, which innervate the caudad (ulnar) border of the forearm. Blockade at the level of the first rib is most reliable in producing anesthesia of all four terminal nerves of the forearm and hand. The axillary technique is simpler but carries the risk of missing the musculocutaneous and medial antebrachial cutaneous nerves that depart the sheath high in the axilla, and thus might produce inadequate anesthesia of the forearm. The choice of the appropriate approach depends not only on the patient's anatomy but also on the site of surgery.

The terminal branches can also be anesthetized by local anesthetic injection along their peripheral courses as they cross the joint spaces, or by the injection of a dilute local anesthetic solution intravenously below a pneumatic tourniquet on the upper arm ("intravenous regional", or Bier block).

Brachial Plexus Blockade: Interscalene Approach

This technique was first popularized by Winnie,¹³ who stressed the advantages of the fascial sheath provided by the "envelope" of muscles that surround the origins of the brachial plexus in the neck. Localization of the nerves uses a combination of the muscular and bony landmarks surrounding the nerves.

1. The patient is positioned supine with the head turned to the side opposite that to be blocked. A small towel is placed under the occiput. The arm on the side to be blocked is held at the side, and the patient is asked to hold the shoulder down by pretending to reach for the hip or knee.
2. The lateral border of the sternocleidomastoid muscle is identified and marked, and the patient is then asked to raise the head slightly into a "sniffing" position. This tenses the scalene muscle behind the sternocleidomastoid muscle, and the groove between the anterior and middle scalene is palpated by rolling the fingers posteriorly off the lateral border of the sternocleidomastoid muscle. This groove is marked along its entire extent, as high up as possible. The patient then relaxes the muscles of the neck, and the level of the cricoid cartilage is marked. The index finger then gently palpates in the groove at the level of the cricoid (Fig. 27-13). The prominent transverse process of C6 can often be felt directly.

Figure 27-13. Superficial landmarks for interscalene brachial plexus blockade. The sternocleidomastoid muscle is identified, and the anterior scalene muscle is found by moving the fingertips over the lateral border of the larger muscle while it is slightly tensed. The groove between the anterior and middle scalene muscles can usually be felt easily, along with the tubercle of the 6th cervical vertebra, which lies at the level of the cricoid cartilage. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

3. After aseptic skin preparation, a skin wheal is raised in the groove at the level of the cricoid. A 22-gauge, 3.75-cm needle is introduced through the wheal perpendicular to the skin in all planes so that it is directed medially, caudad, and slightly posteriorly. Resting one hand on the clavicle allows better control of the syringe (Fig. 27-14).

Figure 27-14. Hand position for interscalene blockade. The needle is directed medially and caudad into the interscalene groove while one hand exerts constant control of the depth by resting on the clavicle. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

4. The needle is advanced until the tubercle is contacted or a paresthesia is elicited (or a motor twitch is obtained with a nerve stimulator; Fig. 27-15). If bone is contacted before nerve, the needle is withdrawn and redirected in small steps in an anteroposterior plane until the nerves are identified.

Figure 27-15. Needle direction for interscalene blockade. The needle is always kept in a caudad direction; medial insertion allows the point to pass into the intervertebral foramen and produces epidural, spinal, or intra-arterial injection of anesthetic. Note the relation of the vertebral artery and the nerve roots to the transverse processes. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

5. Once the nerve is located (usually a paresthesia to the thumb or upper arm), the needle is fixed in this position with one hand while 25–30 ml of local anesthetic solution is injected. Careful aspiration is performed first, and the initial injection is performed in small increments to detect intraneural or intra-arterial placement of the needle. A larger volume (30–40 ml) is required if greater spread is desired, such as to the cervical plexus or inferiorly to the C8 to T1 fibers.
6. If arm surgery requiring a tourniquet is planned, a subcutaneous ring of anesthetic across the axilla is usually required to block the superficial intercostobrachial fibers crossing from the chest wall into the axilla.

Complications from this approach are related to the structures located in the vicinity of the tubercle. The cupola of the lung is close and can be contacted if the needle is directed too far inferior. Pneumothorax should be considered if cough or chest pain is produced while exploring for the nerve. If the needle is allowed to pass directly medially, it may enter the intervertebral foramina, and injection of local anesthetic may produce spinal or epidural anesthesia. The vertebral artery passes posteriorly at the level of the sixth vertebra to lie in its canal in the transverse process; direct injection into this vessel can rapidly produce central nervous system toxicity and convulsions. Careful aspiration and incremental injections are helpful in avoiding both of these potential problems.

Even with appropriate injection, the local anesthetic solution spread to contiguous nerves. This produces cervical plexus blockade with high volumes, which may be desirable if shoulder surgery is contemplated. The involvement of the motor fibers of the cervical roots also produces diaphragmatic paralysis,¹⁴ which may be a problem in patients with respiratory insufficiency. A Horner's syndrome is common because of spread to the sympathetic chain on the anterior vertebral body.

Neuropathy of the C6 root is a potential problem because the needle may unintentionally pin the nerve root against the tubercle and predispose to intraneural injection. The needle should be withdrawn slightly if the first injection produces the characteristic "crampy" pain sensation.

Inadequate anesthesia is most likely to occur in the ulnar distribution. As mentioned previously, this can be reduced by the use of higher volumes. Supplemental local anesthesia of the ulnar nerve may also be helpful.

Brachial Plexus Blockade: Supraclavicular Approach

The description of the approach to the brachial plexus at this level is originally attributed to Kulenkampff, but the classic technique is based on the modifications recommended by Moore¹⁵ and Winnie and Collins.¹⁶ Current techniques avoid the originally described medial direction of the needle, which may contact the pleura.

1. The patient lies in the same position as for interscalene blockade, with the ipsilateral arm held at the side and pulled downward to exaggerate the landmarks of the clavicle and the neck muscles.
2. The outline of the clavicle is drawn on the skin, as well as the interscalene groove (as described previously). The midpoint of the clavicle is marked. An "X" is placed posterior to this midpoint in the interscalene groove, usually 1 cm behind the clavicle. The groove ideally extends all the way to the first rib, where the muscles insert, but palpation of the rib is usually difficult. On the thin patient, the pulsation of the subclavian artery can be appreciated in the groove or just anterior to it.
3. After aseptic preparation, a skin wheal is raised at the mark, and a 3.75-cm, 22-gauge needle attached to a 10-ml syringe is introduced in the sagittal plane and advanced caudad until the first rib is contacted (Fig. 27-16, Fig. 27-17 and Fig. 27-18). It is important that the direction of the needle remain perpendicular to the rib, which usually requires that the syringe remain parallel to the axis of the head and neck. If the rib is not contacted, careful exploration should be carried out first laterally to the mark and, last of all, medially. The greatest danger of contacting the pleura occurs when probing medially.

Figure 27-16. Hand position for supraclavicular blockade. The needle is directed caudad behind the midpoint of the clavicle in the interscalene groove. Again, control of depth is maintained by the hand resting on the clavicle. The syringe is kept in the sagittal plane parallel to the patient's head to prevent medial angulation, which would increase the chance of pneumothorax. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

Figure 27-17. Needle direction for supraclavicular blockade (anteroposterior view). The needle is directed downward onto the first rib, where it can be expected to contact the three trunks of the brachial plexus as they cross over the rib. The rib at this point lies along the anteroposterior plane of the body. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

Figure 27-18. Needle direction for supraclavicular blockade (lateral view). The subclavian artery rises from the chest to join the three trunks of the brachial plexus in crossing over the first rib. The nerves usually lie posterior to the artery at this point, although they rapidly encircle it as it becomes the axillary artery. Note that once the needle contacts the rib, it should be withdrawn almost completely to the skin before redirection because short steps along the bone may simply “push” the nerves ahead of the needle. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

4. An alternate approach is to introduce the needle just above the clavicle from the anterior surface of the body, and advance it directly posterior, following a line that would be traversed by a plumb bob toward the floor (assuming the patient is supine).¹⁷ If no paresthesia is encountered, the syringe and needle are withdrawn and rotated in small increments caudad and advanced again. Theoretically, the needle will encounter the nerves before contacting the rib or the pleura.
5. If a paresthesia is produced during the course of exploration, the anesthetic solution is injected while the needle is fixed in position. Twenty-five to 40 ml of 1% lidocaine or 0.25% bupivacaine may produce adequate analgesia; higher concentrations will produce anesthesia and profound motor blockade. Multiple paresthesias are not usually required because there are only three trunks at this level and the sheath that encloses them is well defined.
6. If a paresthesia is not obtained on needle insertion, exploration is continued until the rib is identified. A 5-cm needle may be needed to reach the rib in the heavier patient. Once the rib is contacted, the needle is walked in an anteroposterior plane until a paresthesia is found. Again, the needle is kept in the sagittal plane on the dorsal surface of the rib during exploration. If the needle advances beyond the anterior or posterior border of the rib as it curves medially at these two points, it is simply redirected in the opposite direction until the rib is found again. Medial direction is avoided. While exploring along the direction of the rib, the needle should be withdrawn almost to the skin before redirection for each pass. If it is lifted only a few millimeters from the rib, it may simply push the nerve bundle ahead of it without making contact.
7. If no paresthesia is obtained, the artery can be used as a landmark. Once it is entered with the needle, a series of injections posterior to it can be used to produce a “wall” of 40 ml of anesthetic solution in this area.
8. If a tourniquet is to be used, a ring of subcutaneous anesthesia should be infiltrated along the axilla to block the sensory fibers from the chest wall that cross here to innervate the inner aspect of the upper arm.

Pneumothorax is the most serious complication of this technique. Although it is rare in experienced hands, it does occur more frequently with this approach to the brachial plexus than with any other approach. This may limit the use of this technique, particularly in outpatients, in whom the insertion of a chest tube would then require hospitalization. The other complications of peripheral blockade do not occur with any greater frequency with this blockade than with other methods of blockade.

Axillary Technique

The axillary technique carries the least chance of pneumothorax and thus may be ideal for the outpatient. The nerves are anesthetized around the axillary artery, where they have regrouped into their terminal branches. Because of the observation that the single sheath may be broken up into separate compartments by fascial septa surrounding individual nerves in the axilla, there are several approaches to blockade at this level. Although the septa do not limit diffusion of drug in every case,¹⁸ Thompson and Rorie¹⁹ have identified several patients in whom the development of these divisions has limited the spread of anesthetic to other nerves. This has led to the recommendation that local anesthetic be injected at multiple sites in the axilla in contrast to the single injections possible with the proximal approaches. Another obstacle to the single-injection technique at this level is the early departure of the musculocutaneous branch from the sheath high in the axilla. In light of these controversies, several techniques are described.

1. The patient lies supine with the arm extended 90 degrees from the side and flexed at the elbow. Extension beyond 90 degrees potentially compresses the axillary artery because of the pressure from the head of the humerus and may make identification of the landmarks more difficult. A pillow under the forearm also reduces rotation of the shoulder joint, which can obscure the pulse.
2. The axillary artery is marked as high in its course in the axilla as is practical. It is usually felt in the intramuscular groove between the coracobrachialis and the triceps muscles. It also passes between the insertions of the pectoralis major and the latissimus dorsi muscles on the humerus.
3. After aseptic preparation, a skin wheal is raised over the proximal portion of the artery. The index and middle fingers of the nondominant hand straddle the artery just below this point, both localizing the pulsation and compressing the sheath below the intended site of injection (fig. 27-19).

Figure 27-19. Hand position for axillary blockade. Two fingers of equal length straddle the artery while the needle is introduced along its long axis with a central angulation. The palpating fingers serve not only to identify the vessel but also to compress the perivascular sheath and encourage the spread of anesthetic solution centrally. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

4. Common Approaches

- A. *Eliciting paresthesia.* A three-ring syringe with a 2.5-cm short bevel needle is held in the other hand, and the needle is introduced alongside the artery seeking a paresthesia. Ideally, the nerves serving the area of proposed surgery are sought first. The median and the musculocutaneous nerves lie on the superior aspect of the artery (as viewed by the operator), whereas the ulnar and radial nerves lie below and behind the vessel (Fig. 27-20).

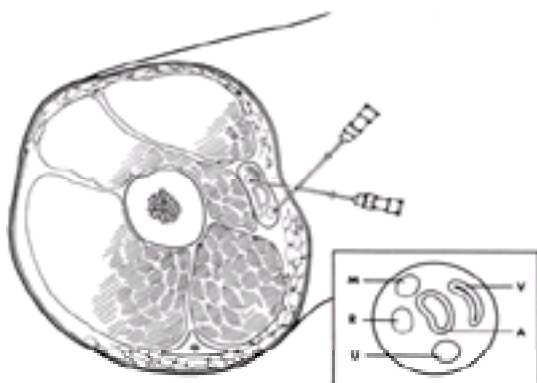

Figure 27-20. Needle position for axillary injection. The median (M) and musculocutaneous nerves lie on the superior side of the artery (A), although the latter may have already departed the axillary sheath at the level of injection. The ulnar nerve (U) lies inferior, and the radial nerve (R) is inferior and posterior. V, vein.

When a paresthesia is obtained, the contents of the syringe are injected, taking precautions to avoid intraneural injection. Firm pressure is maintained on the distal sheath to encourage the solution to move centrally from the point of injection, hopefully to include the point of origin of the musculocutaneous nerve. If a 10-ml syringe is used, the anesthesiologist may elect to fix the needle in position, refill the syringe, and inject a total dose of 25–40 ml of anesthetic solution near this single paresthesia. (A larger bolus may be injected without the need for refilling if a 50-ml syringe is attached to the needle by an iv extension tube.) If multiple injections are planned, and other paresthesias are desired, they should be elicited within 5 minutes of the original injection. Beyond this time, spread of the solution may produce hypesthesia of the other nerves, which prevents their identification. A second paresthesia should be sought on the side of the artery opposite the original one. With this approach, 15–20 ml of solution is injected following elicitation of each paresthesia.

- B. *Perivascular infiltration.* Using the same approach with a shorter, smaller-gauge needle, 5–10 ml of local anesthetic is injected closely on each side of the artery, using multiple passes with a moving needle *not* seeking paresthesias, producing a “wall” of solution that intercepts the paths of each of the branches. After initial infiltration, sensation or motor function is tested in the peripheral nerve distribution within 5 minutes. If anesthesia is not present, reinjection of the area is again performed with multiple passes. This approach may reduce nerve injury.²⁰
 - C. *Transarterial.* Again, preparation and landmarks are the same, but the artery is deliberately entered directly with the needle. The needle is advanced through the vessel until aspiration confirms that it has passed just posterior; at this point, half the anesthetic solution is injected incrementally with careful attention to avoid intravascular placement. The needle is then withdrawn back through the vessel until aspiration confirms that it is just anterior to the artery. The other half of the solution is injected. This technique is simple and effective and should be kept in mind as an alternative if the vessel is unintentionally entered during either of the aforementioned techniques.
 - D. *Nerve stimulator.* The nerve stimulator can be used to identify the nerves in the axilla using the same approach, with injection of anesthetic in the area of one or more responses. If a single injection is made near one of the nerves in the perivascular area at the axillary crease, a separate stimulation of the musculocutaneous nerve may be required. Alternatively, all four major peripheral nerves may be stimulated and anesthetized lower in the arm, at the junction of the upper and middle third of the humerus (midhumeral approach²¹). At this point, the median nerve is stimulated subcutaneously near the artery, the ulnar nerve is deeper and medial to the artery, the musculocutaneous nerve is under the biceps and 2–4 cm away from the artery, and the radial nerve is behind the humerus.
5. If forearm anesthesia is required with higher axillary techniques, supplementary anesthesia of the musculocutaneous nerve may be obtained by injecting an additional 5–10 ml of anesthetic solution into the body of the coracobrachialis muscle. This muscle can be easily grasped between the thumb and forefinger, and the entry into its fascial compartment is readily identified. This step may be required even if 40 ml of solution is used in the perivascular injection because the musculocutaneous nerve may be spared as often as 25% of the time even with this or larger volumes. A supplemental injection of 5 ml subcutaneously inferior to the artery is also required to anesthetize the medial antebrachial cutaneous nerve.

The complications of the axillary approaches to the brachial plexus are minimal compared with those of the more proximal approaches. The problem of neuropathy is the foremost consideration, and the relative risk with various techniques remains controversial. Hematoma can occur if the vessel is punctured, but this is rarely a problem. The use of small-gauge needles may reduce this possibility. The advantages of any one technique in reducing complications remains unclear, and the success rate of the various techniques is variable and appears to depend on personal familiarity.²⁰

Intravenous Regional Anesthesia

The simplest technique of arm anesthesia is the injection of local anesthetic into the venous system below an occluding tourniquet (Bier block).

1. A small-gauge (20 or 22) iv plastic catheter is inserted in the arm to be blocked on the dorsum of the hand. It is taped firmly in place, and a heparin port or small syringe is attached and saline is injected to maintain patency. A pneumatic tourniquet is applied over the upper arm.
2. The arm is elevated to promote venous drainage. An elastic bandage may be applied to produce further exsanguination. After exsanguination, the tourniquet is inflated to 300 mm Hg or 2.5 times the patient's systolic blood pressure and is tested for adequate occlusion of the radial pulse.
3. The arm is returned to the horizontal position, a 50-ml syringe with 0.5% lidocaine is attached to the previously inserted cannula, and the contents are injected. The forearm discolors, and the patient perceives a transient “pins and needles” sensation as anesthesia ensues over the following 5 minutes. Epinephrine should not be added to the local anesthetic solution.
4. For short procedures, the cannula can be removed at this point. If surgery may extend beyond 1 hour, the cannula can be left in place and reinjected after 90 minutes.
5. Beyond 45 minutes of surgery, many patients experience discomfort at the level of the tourniquet. Special “double-cuff” tourniquets are available for this blockade to alleviate this problem. The proximal cuff is inflated first, allowing anesthesia to be induced in the area under the distal cuff. If discomfort ensues, the distal cuff is inflated over the anesthetized area of skin, and the uncomfortable proximal cuff is released. This step is critical because the major risk of this procedure is premature release of solution into the circulation. If a double cuff is used, both cuffs should be tested before starting and the proper sequence for inflation and deflation meticulously followed. The potential for leakage of anesthetic into the circulation is greater with these narrower cuffs used in the double setup. Because the shifting process also increases the potential for unintentional release of anesthetic, the use of a single, wider cuff may be better for short procedures.
6. If surgery is completed in less than 20 minutes, the tourniquet is left inflated for at least that total period of time. If 40 minutes has elapsed, the tourniquet can be deflated as a single maneuver. Between 20 and 40 minutes, the cuff can be deflated, reinflated immediately, and finally deflated after 1 minute to delay the sudden absorption of anesthetic into the systemic circulation, although this may not lower the eventual peak levels achieved.
7. The duration of anesthesia is minimal beyond the time of tourniquet release. Although bupivacaine may produce a slight prolongation of analgesia, the advantage is short. Furthermore, the cardiotoxicity of bupivacaine makes this drug an unwise choice for a Bier block.

The simplicity of this technique is offset by the significant risk of systemic local anesthetic toxicity if the tourniquet fails or is released prematurely. Careful testing of the tourniquet and slow injection of solution into a peripheral (not antecubital) vein will reduce the chance of leakage under the tourniquet.²² Systemic blood levels are time dependent, and careful attention should be paid to the sequence of tourniquet release and to patient monitoring during this period. A separate iv site for injection of resuscitation drugs is needed as well as ready availability of all appropriate resuscitative equipment. With careful attention to these details, this technique is one of the most effective and reliable available to the anesthesiologist.

Distal Upper Extremity Blockade

As in the leg, the nerves to the hand can be blocked at the point where they cross the two major joints, the elbow and the wrist (Fig. 27-21). At these two levels, the overlying muscles are thinned and the bony landmarks are more prominent, allowing easier identification of the nerves. Peripheral blockade is usually not as dense as central blockade but may be useful in anesthetizing one branch that was missed with a central blockade or in providing localized anesthesia on the hand. Because the sensory branches to the forearm from the musculocutaneous nerve and the internal cutaneous nerve have already branched so extensively that adequate anesthesia of the forearm is not easily obtained, blockade at the elbow really produces no greater anesthesia than blockade at the wrist.

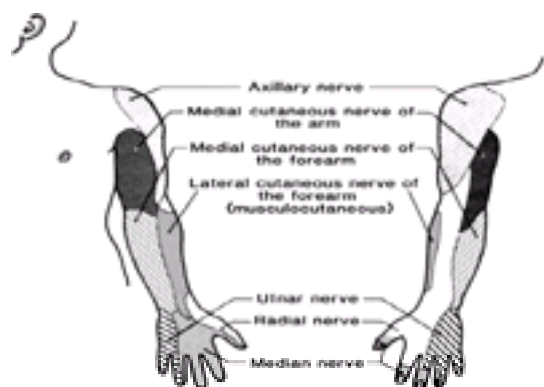

Figure 27-21. Sensory dermatomes of the arm. Sensation is provided by the terminal nerves, as identified. This pattern is different from the classic dermatomal distribution of the nerve roots. Different patterns of anesthesia develop if the blockade is performed at the root level (interscalene blockade) versus the terminal nerve level (axillary blockade). (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

Blockade at the Elbow. Two nerves to the hand cross this joint on the inner aspect, whereas the ulnar travels posteriorly in its well known superficial groove. The procedure for blockade follows:

1. The ulnar nerve is blocked by injection of 1–4 ml of local anesthetic proximal to the groove formed by the medial condyle of the humerus and the olecranon. This is easily done with the joint flexed at approximately 30 degrees. Further flexion may cause the nerve to roll medially and anterior to the condyle. Paresthesias can usually be readily obtained, but direct injection on a paresthesia or directly into the groove under pressure is not advised because of the risk of damage to the nerve. If the injection is made deep to the fascia, anesthesia should commence within 5 minutes.
2. The median nerve crosses the joint in the company of the brachial artery. A line is drawn between the two condyles on the inner aspect of the joint, and a skin wheal is raised at the point where this line crosses the pulsation of the brachial artery, usually 1 cm to the ulnar side of the biceps tendon. A needle is introduced perpendicularly at this point, and paresthesias are sought immediately adjacent to the artery. Five ml of solution is sufficient to produce anesthesia, and, again, intraneural injection is carefully avoided.
3. The radial nerve is identified along the same intracondylar line, approximately 2 cm lateral to the biceps tendon. Another skin wheal is raised here, and, again, a needle is inserted to search for paresthesias in a fan-shaped pattern. If paresthesias are not obtained, a “wall” of anesthetic solution can be deposited here but with less chance of reliable anesthesia.

Blockade at the Wrist. The nerves lie more superficially at this joint and are closely associated with easily identified landmarks (Fig. 27-22). For this reason, blockade at this level is usually preferred to other distal approaches. The procedure for blockade follows:

Figure 27-22. Terminal nerves at the wrist. The median nerve lies just to the radial side of the flexor palmaris longus. The ulnar and radial nerves lie just “outside” their respective arteries. The radial nerve has already begun branching at this level and must be blocked by a wide subcutaneous ridge of anesthetic. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

1. The ulnar nerve lies between the ulnar artery and the flexor carpi ulnaris. A skin wheal is raised at the level of the styloid process on the palmar side of the forearm between these two landmarks. A small-gauge needle is inserted, and 3 ml of solution is injected into the area, with or without paresthesias.
2. At the same level on the forearm, the median nerve lies between the tendons of the palmaris longus and the flexor carpi radialis. If only the palmaris longus can be felt, the nerve is just to the radial side of this tendon. A skin wheal is raised, and a needle is inserted until it pierces the deep fascia. Three milliliters of solution produces anesthesia.
3. The radial nerve requires a broader injection because it has already started to ramify as it crosses the wrist. The anatomic “snuffbox” formed by the tendons of the extensor pollicis longus and extensor pollicis brevis tendons is located, and 3 ml of solution is injected here. A subcutaneous wheal is then raised from this point, extending over the dorsum of the wrist 3–4 cm onto the back of the hand.

Suprascapular Block

The suprascapular nerve is another terminal branch of the brachial plexus that can be anesthetized by a separate injection. Anesthesia of this nerve has become popular for providing postoperative pain relief following shoulder arthroscopy or reconstructive surgery. The nerve arises from the superior trunk of the brachial plexus in the neck, courses through the suprascapular notch, and then passes behind the lateral border of the spine of the scapula to the infraspinatus fossa. It has two terminal branches, a sensory articular branch to the shoulder joint and a motor branch to the supraspinatus muscle. The technique for nerve blockade is as follows:

1. The patient is placed in the upright sitting position, leaning forward so that the scapulae are accentuated. The spine of the scapula is identified and marked along its entire length. The inferior tip of the scapula is then identified, and the original line of the spine is bisected at a point immediately superior to this inferior tip.
2. A skin wheal is raised approximately 1 cm superior and 1 cm lateral from this midpoint of the scapular spine, and a 1.5 inch needle is advanced through the skin until contact is made with the superior surface of the scapula. The needle is then withdrawn and redirected cephalad and medially towards the midline until the edge of the suprascapular notch is encountered. At this point, the patient may perceive a paresthesia into the shoulder joint, or the nerve stimulator may produce an internal rotation of the arm itself.
3. Once the nerve is localized, 10 ml of local anesthetic is injected. Even in the absence of nerve localization, this volume of solution injected into the notch should produce adequate anesthesia of the shoulder joint.

Trunk

Anesthesia of the abdomen and chest is most simply obtained with spinal and epidural injections of local anesthetics, as discussed in [Chapter 26](#). In some situations, a narrower band of intercostal or paravertebral anesthesia is preferable, or epidural injection may be hazardous because of infection or coagulopathy. In many clinical situations, it may also be desirable to separate the anesthesia of the somatic and sympathetic fibers that occurs in combination when axial blockades are performed. The sympathetic nerves separate from their somatic counterparts early in their course, which makes independent somatic and sympathetic blockade a practical consideration. Sympathetic blockade is most commonly performed at the major ganglia, particularly the stellate, celiac, and lumbar plexus. These blockades often require multiple injections and are technically more difficult than axial anesthesia, but they do offer advantages in certain clinical situations.

The somatic nerves of the chest emerge from their respective intervertebral foramina and pass through the narrow, triangular-shaped paravertebral space. In this triangle, they give off the sympathetic branch and also a small dorsal branch, which provides sensation to the midline of the back. The main trunks then pass into the intercostal groove along the ventral caudad surface of each rib. An artery and vein travel along with each of these nerves in the groove under the protection of the overhanging external edge of the rib. The fasciae of the internal and external intercostal muscles provide interior and external borders of this intercostal groove. As the nerves travel beyond the midaxillary line, they give off a lateral sensory branch while the main trunk continues on to the anterior abdominal wall to provide sensory and motor innervation for the trunk and abdomen down to the level of the pubis. The intercostal groove becomes much less well defined anterior to the midaxillary line, and the nerve begins to move away from its protected position. The lowermost intercostal nerve (the 12th) is much less closely applied to its accompanying rib and is not as easy to identify and anesthetize using a classic intercostal blockade technique. The upper lumbar roots form the ilioinguinal nerves, which pass laterally within the muscles of the abdominal wall at the level of the iliac crest and eventually move anteriorly to provide innervation of the groin region as the ilioinguinal nerves.

The anatomic basis for separate sympathetic anesthesia is the early separation of sympathetic fibers from their somatic roots in the form of the white rami communicantes, which separate from the somatic nerves shortly after their emergence from the intervertebral foramina and join the sympathetic ganglia, which lie anteriorly on each side of the vertebral bodies. These preganglionic fibers of the sympathetic system usually arise only from the first thoracic through the second lumbar segments. The spinal ganglia formed by these fibers constitute the sympathetic trunks, which extend upward into the neck and caudad along the lumbar spine. They give terminal sympathetic branches to all the areas of the body. The sympathetic innervation of the head and the lower extremities is derived from fibers that originate from the spinal cord, join sympathetic trunks, and then pass cephalad or caudad along the chain of ganglia before reaching their target organs. Segmental sympathetic innervation of the body from the cervical to the sacral roots is provided by postganglionic nerves departing from the chains (the gray rami communicantes), which rejoin the somatic nerves early in their course. In the head (where motor and sensory innervation is by cranial nerves), the sympathetic fibers reach their end organs by traveling with the arterial vascular supply. The sympathetic ganglia in the neck lie along the lateral border of the relatively flat vertebral bodies. In the chest, the vertebral bodies become more rounded, and the chain of ganglia lies more posteriorly on the lateral side of the vertebral body near the head of each rib. In the abdomen and pelvis, the sympathetic chains begin to move anteriorly and lie on the ventral surface of the vertebral bodies, and thus are more widely separated from their respective somatic nerves.

Intercostal Nerve Blockade

Anesthesia of the intercostal nerves provides both motor and sensory anesthesia of the entire abdominal wall from the xiphoid to the pubis. The 6th to 11th ribs are usually easily identified, and their accompanying nerves are reliably blocked by injections along the easily palpated sharp posterior angulation of the ribs, which occurs

between 5 and 7 cm from the midline in the back. Ribs above the fifth are difficult to palpate because of the overlying scapula and paraspinal muscles and are therefore most easily blocked using the paravertebral technique. Establishing five or six levels of intercostal nerve blockade is a useful anesthetic procedure for providing analgesia and motor relaxation for upper abdominal procedures such as cholecystectomy and gastric surgery. This form of anesthesia usually requires supplementation with light general anesthesia or an additional sympathetic blockade because much of the intraperitoneal and subdiaphragmatic sensation is carried by other nerve trunks. This form of anesthesia for upper abdominal surgery offers the advantages of muscle relaxation without the necessity of an accompanying sympathetic blockade (unless celiac plexus blockade is chosen as an optional supplement). Intercostal blockade with long-acting amide local anesthetics also provides postoperative analgesia for 8–12 hours, which may greatly facilitate patient satisfaction and immediate recovery.²³ Unilateral blockade of these nerves is a useful treatment for the pain of rib fracture and also serves to reduce postoperative analgesia requirements in patients with subcostal incisions. Several segments must be blocked in each of these applications because of the overlap of the intercostal nerves. This technique is also useful in reducing the pain associated with the insertion of chest tubes or percutaneous biliary drainage procedures. The procedure for blockade follows:

1. For the performance of intercostal blockade, the patient may be in the lateral, sitting, or prone position. For operative anesthesia, the prone position is most practical. A pillow is placed under the abdomen to provide slight flexion of the thoracic spine. The arms are draped over the edge of the stretcher or operating table so that the scapula falls away laterally from the midline. The anesthesiologist stands at the patient's side. Most anesthesiologists prefer to stand on the side that allows their dominant hand to hold the syringe at the caudad end of the patient.
2. The spinous processes in the midline from T6 through T12 are marked (Fig. 27-23). The ribs are then identified along the line of their most extreme posterior angulation. For the 12th rib, this is usually 7 cm from the midline. At the level of the sixth rib, this posterior angulation is best appreciated somewhat more medially, usually 5 cm from the midline. These two ribs are marked first at their inferior borders, and a line is drawn between these two points. The rest of the ribs between them are identified, and a mark is placed on the inferior border of each rib along the angled parasagittal plane identified by the first line between the 6th and 12th ribs.

Figure 27-23. Landmarks for intercostal blockade. The inferior borders of the ribs are identified at their most prominent points on the back. The marks then usually lie along a line that angles slightly medially from the 12th to the 6th rib. The triangle drawn between the 12th ribs and their spinous processes is used for the celiac plexus blockade. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

3. After aseptic preparation, sedation and analgesia are provided for the patient, and a skin wheal is raised at each mark.
4. The ribs are usually blocked starting with the lowermost and moving upward. The 12th rib is not closely associated with its intercostal nerve, and a reliable blockade is not usually possible. For upper abdominal procedures, blockade of this nerve can be omitted without jeopardizing the anesthesia.
5. Starting with the lowest rib on the side closest to the anesthesiologist, the index finger of the cephalad hand is placed on the skin above the identifying mark; this finger should lie immediately over the midpoint of the rib. The skin is then retracted in a cephalad direction, so that the previous mark now lies over the rib itself, somewhat toward the inferior side. The anesthesiologist's other hand inserts a 22-gauge, 3.75-cm needle directly onto the rib. This needle is attached to a 10-ml syringe filled with local anesthetic. The syringe and needle are held in such a way that they maintain a constant 10-degree cephalad angulation.
6. Once the needle is safely "parked" on the dorsal surface of the rib, the cephalad hand releases the tension on the skin and takes control of the needle and syringe (Fig. 27-24). This is done by placing the ulnar border of the hand firmly against the skin and grasping the hub of the needle firmly between the thumb and index finger. The middle finger of this hand rests along the shaft of the needle to provide guidance. Once the syringe is firmly gripped by the cephalad hand, the fingers of the caudad hand are placed in an "injection" position, either in the rings of a three-ring syringe or on the plunger of a straight syringe.

Figure 27-24. Hand and needle positions for intercostal blockade. The depth of the needle is controlled by the hand resting on the back. The other hand injects solution when the needle is under the rib, but that is the only function performed while the needle is near the pleura. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

7. The needle and syringe are then raised slightly off the bone and walked in a caudad direction until they pass below the inferior border of the rib. The entire needle and syringe unit is kept at a 10-degree cephalad angle to the rib at all times. As it passes the inferior border, the needle is advanced 4–6 mm under the rib, with the needle actually pointing slightly cephalad into the intercostal groove.
8. Once in the groove, aspiration is performed, and 3–5 ml of local anesthetic solution is injected. Generally, 0.25% bupivacaine produces good sensory anesthesia, whereas 0.5% bupivacaine is required for prolonged anesthesia with motor blockade. Ropivacaine 0.5% also provide motor blockade, but for a shorter duration. Aspiration is not reliable in preventing intravascular injection of the anesthetic; a slight jiggling motion of the needle during the injection will reduce this chance by ensuring that the needle is in a vessel only transiently if it does occur.
9. As soon as the injection is complete, the needle is withdrawn from the groove and moved cephalad and "parked" again on the safe dorsal surface of the rib. The fingers of the caudad hand are then removed from the injection position and assume control of the syringe again. The cephalad hand now relinquishes control and is moved up to the next rib to repeat this cyclic process.
10. The six or seven designated ribs on each side are blocked in this process by progressively moving up the back, with control of the syringe alternating between the cephalad and caudad hands at the time of injection. The ribs on the opposite side are blocked in a similar manner. This can be done with the anesthesiologist standing on the same side and reaching across the back, or by moving to the opposite side of the patient. If the contralateral blockades are performed from the opposite side of the bed, an attempt should be made to switch hands, so that the functions of the cephalad and caudad hands remain the same even though the right and left hands have changed roles. It is sometimes more difficult for operators to control the syringe with their nondominant hand, but attempting to hold the syringe in the cephalad hand often makes maintenance of the proper cephalad angulation difficult. The syringe often ends up being rotated along its long axis as it is moved to the caudad edge of the rib, with the result that the needle is pointed in a caudad rather than a cephalad direction.
11. If the intercostal nerve blockades are to be supplemented by a number of somatic paravertebral nerve blockades or sympathetic blockade of the celiac plexus, these are performed at the completion of intercostal anesthesia. Care should be taken to adjust the total dose of drug in such combinations of techniques so that the maximal recommended amounts are not exceeded.

Despite frequent concern about the incidence of pneumothorax with intercostal blockade, this complication is rare in experienced hands. This depends primarily on maintaining strict safety features of the described technique. Emphasis should be placed on absolute control of the syringe and needle at all times, particularly during the injection. The cephalad hand, which is securely resting on the back, is the one that controls the depth of needle insertion. The needle rests on the safe dorsal side surface of the rib at all other times except for the brief moment of injection.

A common complication is related to the sedation required to perform this blockade in the prone position. The 12–14 needle insertions are uncomfortable, and patients usually require opioid and amnestic sedation. Overdose can lead to airway obstruction and respiratory depression in the prone position. Attention must also be paid to the patient's mental status because this blockade produces the highest blood levels of local anesthetics when compared with any other regional anesthetic technique. Because this blockade is frequently supplemented by a light general anesthetic for surgery, signs of systemic toxicity are rarely seen. When the blockade is performed

for postoperative pain relief, the dose should be reduced to 0.25% bupivacaine or ropivacaine to minimize the chance for toxicity.

It is possible to produce partial spinal or epidural anesthesia if the injection is made close to the midline and the anesthetic tracks along a dural sleeve to the epidural or subarachnoid space. This appears to be more likely if intrathoracic injection is performed intraoperatively by a surgeon. Hypotension may result in this situation. Hypotension has also been observed rarely when this blockade is used for postoperative pain relief in a patient who has received generous doses of opioids. Once the local anesthetic succeeds in relieving the pain, the patient's intrinsic sympathetic response is reduced, and the respiratory depressant effect of previously injected opioids is unmasked. Patients should be observed for at least 20–30 minutes after performance of intercostal blockade. Respiratory insufficiency can also be seen if the intercostal muscles are blocked in a patient who depends on them for ventilation. Patients with chronic obstructive disease with ineffective diaphragm motion are not good candidates for this technique.

Paravertebral Blockade

The upper five ribs are more difficult to palpate laterally, and blockade of their associated intercostal nerves is best performed with a paravertebral injection. This approach is technically more difficult and has slightly greater potential for complications because of the proximity of the lung and of the intervertebral foramina. Anatomically, the injection is made into the triangle formed by the intervertebral body, the pleura, and the plane of the transverse processes (Fig. 27-25). The intervertebral foramina at each level lie between the transverse processes and approximately 2 cm anterior to the plane formed by the transverse processes in their associated fasciae. At this point, the sympathetic ganglia lie close to the somatic nerves, and coincidental sympathetic blockade is usually attained. This is also related to the injection of larger volumes of local anesthetic, which is required because location of the nerve is less reliable with this technique. Nevertheless, it is a useful technique for segmental anesthesia, particularly of the upper thoracic segments. It is also useful if a more proximal blockade is needed, such as to relieve the pain of herpes zoster or of a proximal rib fracture. Paravertebral nerve blockade has been used successfully for outpatient surgery. In the upper chest, it is effective for providing intraoperative anesthesia and postoperative analgesia for breast surgery.²⁴ It has also been used successfully for outpatient hernia operations, providing significant postoperative analgesia.

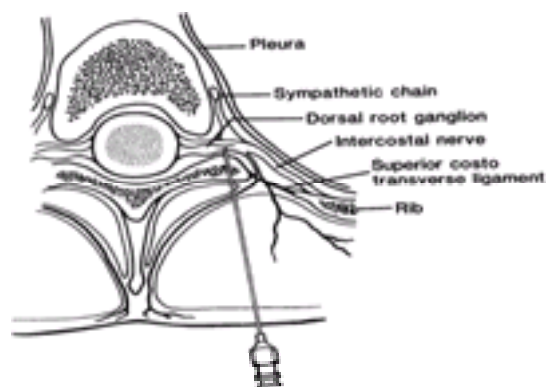

Figure 27-25. Paravertebral blockade. As it exits the intervertebral foramen, the thoracic somatic nerve enters a small triangular space formed by the vertebral body, the plane of the transverse process, and the pleura. Medial direction of the needle is obviously important in reducing the chance of a pneumothorax.

The paravertebral approach varies somewhat, depending on the spinal level. In the upper thoracic spine, the transverse process is located lateral to the spinous process of the vertebral body above it. In the lower thoracic spine, the spinous processes are less steeply angled, so that the 11th and 12th spinous processes lie between the associated transverse processes. In the lumbar region, the spinous processes are straight, and the transverse processes lie opposite their own respective spinous process. Thus, paravertebral blockade in the upper thoracic region is performed at each level by identifying the spinous process of the vertebra above the level to be blocked; in the lumbar region, the spinous process of the level to be blocked is used to locate the transverse process.

1. This blockade is also performed in the prone position, with a pillow under the patient's abdomen to produce flexion of the thoracic and lumbar spine. The spinous processes in the region to be blocked are marked. These can be identified by counting upward from the fourth lumbar process (which usually lies just at or above the line joining the two iliac crests) or by counting down from the seventh cervical process (which is the most prominent in the cervical region).
2. Transverse lines are drawn across the cephalad border of the spinous processes and extended laterally to overlie the transverse process (~1–4 cm). In the lumbar region, the lines overlie the transverse process of the associated vertebra. In the thoracic region, they indicate the transverse process of the vertebral body immediately below the associated spinous process. Finally, a vertical line is drawn parallel to the spine 3–4 cm lateral to it joining the transverse lines from the spinous processes. For a diagnostic blockade, a single nerve may need to be anesthetized. For pain control, several levels must be identified. The injection of at least three segments (as in intercostal blockade) is required to produce reliable segmental blockade because of sensory overlap.
3. After aseptic skin preparation, skin wheals are raised at the intersections of the vertical and transverse lines.
4. A 22-gauge needle is introduced through the skin wheal in the sagittal plane and directed slightly cephalad to contact the transverse process. A 7.5-cm needle is usually required in the average patient, and the transverse process lies between 3 and 5 cm from the skin. Gentle cephalad or caudad exploration may be required to identify the bone. The depth of the transverse process is carefully noted on the needle shaft.
5. The needle is now withdrawn from the transverse process and walked inferiorly to pass below its caudad edge. This usually requires more perpendicular direction relative to the skin. The needle is advanced 2 cm below the transverse process and angled slightly medial to attempt to contact the vertebral body. Paresthesias are not sought unless a neurolytic injection is planned. When the needle has entered the paravertebral space, 5–10 ml of local anesthetic solution is injected after careful aspiration.

The complication of pneumothorax is more likely in the thoracic region with a paravertebral technique than with intercostal blockade.²⁵ The needle should be directed medially as it passes below the transverse process and never more than 2 cm beyond the transverse process (see Fig. 27-25). If cough or chest pain occurs, a chest radiograph should be performed to rule out pneumothorax. Subarachnoid injection is also more likely in the thoracic area because of the extension of the dural sleeves to the level of the intervertebral foramina. Careful aspiration is important but may not prevent the unintentional injection of local anesthetic into a subdural pocket. Total spinal anesthesia can result with a 5–10-ml injection. Systemic toxicity is also a possibility because of the need for relatively large volumes of local anesthetic. Attention must be paid to the total milligram dose injected. The volume required for each level obviously limits the concentrations that can be used and the total number of levels that can be blocked. If lumbar paravertebral injections are combined with intercostals, the concentration and total volume for both blockades may have to be reduced.

Intrapleural Anesthesia

Upper abdominal analgesia can also be obtained by inserting an epidural catheter into the intrapleural space for injection or infusion of local anesthetic. The anesthetic appears to diffuse through the parietal pleura onto the intercostal nerves and produce anesthesia similar to that provided by injection of multiple intercostal nerve blocks. It may also act upon the sympathetic nerves by diffusion to the ganglia lying along the anterior vertebral borders.

1. As with intercostal block, the technique can be performed with the patient in the prone, lateral, or sitting position.
2. The seventh or eighth intercostal space is identified 8–10 cm from the midline and marked at the upper border of the lower rib.
3. A skin wheal is made at this site, and a blunt-tipped epidural needle (e.g., Touhy) is inserted with the bevel directed cephalad and advanced over the inferior rib in a slightly medial and cephalad angle through the intercostal muscles. Once in the intercostal layers, the stylet is removed, and an air-filled 5-ml glass syringe is attached.
4. The needle is advanced farther until the parietal pleura is punctured, signaled by a negative pressure that moves the plunger of the syringe forward. The syringe is removed, and a standard epidural catheter is threaded 5–6 cm beyond the tip. Aspiration is performed to exclude perforation of the lung or a blood vessel.
5. Twenty ml of 0.5% bupivacaine with epinephrine is injected into the pleural space, and the catheter is carefully taped to the skin. Reinjection is required every 3–6 hours, or a constant infusion of 0.25% bupivacaine ($0.125 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) can be initiated.

There have been several enthusiastic reports of success with this technique,²⁶ but limitations have been described. Pain relief is usually reliable, and respiratory depression is not a problem. However, the duration is short enough that large quantities of local anesthetic are required to maintain analgesia, and systemic toxicity has been reported in 1.3% of patients.²⁷ The incidence of pneumothorax (averaging 2%) is not inconsequential, especially with first attempts. Puncture of the lung also occurs, apparently with a higher incidence if a loss-of-resistance technique is used rather than the passive identification process described earlier. A major limitation is the unilateral analgesia, which limits this technique to procedures such as cholecystectomy and nephrectomy, rib fracture, and treatment of herpetic pain. Loss of local anesthetic solution to thoracostomy drainage makes this technique less reliable for thoracotomy pain.

Ilioinguinal Blockade

The L1 nerve root (occasionally joined by a branch of the T12 root) provides sensory innervation to the lowermost portion of the abdominal wall and the groin by means of its superior iliohypogastric branch and its inferior ilioinguinal branch. These nerves travel in a path similar to that of the intercostal nerves, but without the convenient bony landmark of a rib to identify them. Nevertheless, they can be anesthetized relatively easily in the groin because of their relationship to the anterosuperior iliac spine. Anesthesia of these two nerves is useful in providing lower abdominal wall anesthesia to supplement intercostal blockade. It is more commonly used to produce field anesthesia for hernia repair surgery. Anesthesia of these nerves alone is not sufficient for hernia repair, and subcutaneous infiltration is also necessary. The procedure for blockade follows:

1. The patient lies in a supine position, and the anterosuperior iliac spine is identified. An "X" is placed on the skin 2.5 cm medial to the spine and slightly cephalad.
2. After aseptic preparation, a skin wheal is raised at the "X."
3. A 2.5-cm, 22-gauge needle is introduced through the "X" and directed perpendicular to the skin until it reaches the fascia of the external oblique muscle. A "wall" of local anesthetic solution is then laid down between this point and the iliac spine and also opposite the mark on an imaginary line extending toward the umbilicus. Injections are made at and below the level of the external oblique, with some solution injected at the level of the internal oblique. A total of 10–15 ml of anesthetic is usually required. A solution of 1% lidocaine, 0.25% bupivacaine, or an equivalent is adequate.
4. If field anesthesia for inguinal hernia repair is required, further subcutaneous infiltration of anesthetic is performed along the skin crease of the groin and along the imaginary line extending to the umbilicus. This produces a triangular-shaped area of skin anesthesia. For hernia operations, further anesthesia of the spermatic cord is required. This is usually performed by local injections in the area of the cord and the internal ring. Although epinephrine is useful in the subcutaneous and ilioinguinal blockade, it should be avoided in solutions used to anesthetize the base of the penis or the spermatic cord. Further anesthesia of the groin area and below can be obtained by blockade of the femoral and lateral femoral cutaneous nerves (see [Penile Blockade](#)), but this may result in unwanted weakness of the leg musculature, which may prevent ambulation.

Complications of this procedure are extremely rare. Hematoma formation and unwanted motor blockade of the femoral nerve are possible, but rare. More commonly, anesthesia produced by this technique is inadequate for hernia repair because the patient is still able to perceive the discomfort of peritoneal traction. Administration of local anesthesia by the surgeon or systemic opioids may be required.

Penile Blockade

If surgery is confined to the penis (*e.g.*, circumcision, urethral procedures), the organ should be blocked with simple local infiltration. Two skin wheals are raised at the dorsal base of the penis, one on each side just below and medial to the pubic spine. A 22-gauge, 3.75-cm needle is introduced on each side, and 5 ml of anesthetic is deposited superficially and deep along the lower border of the pubic ramus to anesthetize the dorsal nerve. An additional 5 ml is infiltrated in the subcutaneous tissue around the underside of the shaft to produce a complete ring of anesthetic. A larger needle or a second injection site may be needed to complete the ring. Twenty to 25 ml of 0.75% lidocaine or 0.25% bupivacaine usually suffices. Epinephrine is strictly avoided.

Sympathetic Blockade

Stellate Ganglion

Separate blockade of the sympathetic fibers of the upper extremity and head can be achieved by a single injection of a local anesthetic on the stellate ganglion. The ganglion is the large fusion of the first thoracic sympathetic ganglion with the lower cervical ganglion on each side, and it lies on the generally flat lateral border of the vertebral body of C7. All the fibers to the middle and superior cervical ganglia pass through this lowermost collection and thus can be anesthetized with a single injection. Although technically simple, the location of this ganglion near the carotid artery, the vertebral artery, and the pleura makes this a challenging blockade. It is useful in providing pain relief for sympathetic dystrophies of the upper arm. Stellate ganglion blockade may relieve the pain of acute herpes zoster infection of the head or neck region. It has also been advocated as a means of reducing post-thoracotomy pain by blocking the sympathetic sensory fibers to the pleural cavity. The procedure for blockade follows:

1. The patient is placed in a supine position with a small towel or pillow under the neck, and the arms are held at the side.
2. The medial border of the sternocleidomastoid muscle on the involved side is marked with a pen, as is the level of the cricoid cartilage. Gentle palpation approximately 2 cm lateral to the cartilage often reveals the anterior tubercle of the transverse process of the sixth cervical vertebra (Chassaignac's tubercle). A circle is marked over this tubercle, and an "X" is placed 1.5–2 cm caudad to this mark at the same distance from the midline. This "X" should overlie the tubercle of the seventh cervical vertebra and should fall at the medial border of the sternocleidomastoid muscle body and approximately two fingerbreadths above the clavicle itself.
3. A skin wheal is made at the "X" after aseptic skin preparation.
4. With the index and middle finger of one hand, the sternocleidomastoid muscle and the carotid sheath are retracted laterally ([Fig. 27-26](#)). A 22- or 25-gauge, 3.75-cm needle is introduced through the "X" and passed directly posterior until it rests on bone. Paresthesia of the brachial plexus implies that the needle is too far laterally and has passed beyond the transverse process. It may have to be readjusted slightly more medially and perhaps more cephalad or caudad.

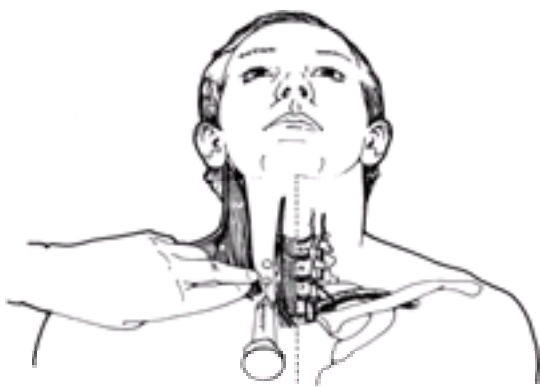

Figure 27-26. Stellate ganglion blockade. The sternocleidomastoid muscle and the carotid sheath are retracted laterally with one hand while the needle is introduced directly onto the lateral border of the seventh vertebral body, just medial to the transverse process. The vertebral artery passes posteriorly at this level to enter its canal in the transverse process, but here it lies near the level of intended injection. After contacting bone, the needle is withdrawn slightly and careful aspiration is performed before incremental injection. (Reproduced with permission from Mulroy M: *Handbook of Regional Anesthesia*. Boston, Little, Brown, 1996.)

5. Once bone is contacted, the needle is withdrawn a few millimeters, and very careful aspiration is performed to rule out contact with the vertebral artery. A 2-ml test dose is injected to evaluate further an unrecognized intravascular position. The patient's mental status must be closely observed.
6. If no change occurs, a total of 10 ml of local anesthetic can be injected incrementally with frequent aspiration. One percent lidocaine or 0.25% bupivacaine or their equivalents are more than adequate to produce anesthesia of the sympathetic nerves.
7. Onset of sympathectomy is usually, but not reliably, indicated by the appearance of a Horner's syndrome on the ipsilateral side. Ptosis, miosis, and anhydrosis usually develop within 10 minutes, as well as vasodilatation in the arm. Nasal congestion is another common sign usually associated with Horner's syndrome.

As implied, there are several potential complications of stellate ganglion blockade related to the surrounding anatomy. The pleura can be punctured, with resulting pneumothorax. Intravascular injection is the most serious complication because of the proximity of the vertebral artery to the site of injection. Careful aspiration and incremental injections are essential. Only a few milligrams of local anesthetic is required to produce cerebral symptoms when injected directly into the vertebral circulation. Cardiovascular changes are possible with the loss of the cardiac accelerator fibers from the cervical sympathetic ganglia. This is particularly a problem if bilateral blockade is performed, a procedure rarely indicated. Hoarseness from recurrent laryngeal nerve paralysis is a minor but troublesome side effect. Somatic anesthesia of the brachial plexus nerves can be produced by injection behind the level of the tubercle, and phrenic nerve paralysis has also been reported. Subarachnoid injection is also a possibility if the needle is misplaced. The close association of so many vital structures has discouraged the use of neurolytic agents in the region of the stellate ganglion.

Celiac Plexus

The thoracic sympathetic ganglia send branches anteriorly that merge as greater and lesser splanchnic nerves to pass below the diaphragm and around the aorta to

coalesce in a diffuse periaortic supplementary sympathetic ganglion known as the celiac plexus. This extensive network is usually located at the level of the first lumbar vertebra in the retroperitoneal space, along the aorta at the level of the origin of the celiac artery. Fibers from this ganglion send postganglionic innervation to all the intra-abdominal organs and appear to carry pain sensation from many of the intraperitoneal organs such as the pancreas and liver. Injection into this retroperitoneal space allows anesthetic solution to diffuse around the ganglia and the splanchnic nerves to provide blockade of these fibers. This blockade produces supplementary intra-abdominal anesthesia when used in conjunction with intercostal blockade or general anesthesia. It is more commonly applied as a neurolytic sympathetic blockade for the relief of pain from malignancy of the pancreas, liver, or other upper abdominal organs.²⁸ The procedure for blockade follows:

1. As with intercostal blockade, the patient is placed in the prone position with the thoracic spine flexed by the use of a pillow under the abdomen.
2. The spinous processes of the 12th thoracic and the 1st lumbar vertebral bodies are identified and marked along their entire extent. The 12th rib is likewise identified and marked 7 cm from the midline. A line is drawn between the 12th ribs on each side, usually crossing the midline at the level of the spinous process of the L1 vertebra. Lines are also drawn from the spinous process of the 12th thoracic vertebra to the points on these ribs on both sides. The net result is a shallow triangle, with the spinous process of the 12th vertebra at its apex (see [Fig. 27-23](#)).
3. Skin wheals are raised bilaterally at the marks along the ribs after aseptic skin preparation. Deeper infiltration of local anesthetic with a 22-gauge needle is often helpful in improving patient tolerance of this procedure.
4. On each side, a 12.5-cm, 22- or 20-gauge needle is introduced through the skin wheals and advanced anteriorly and medially and cephalad along the two lines of the triangle that was previously drawn ([Fig. 27-27](#)). The needle should be passed at approximately a 45-degree angle anteriorly so that it will contact the lateral border of the vertebral body of L1 at a depth of approximately 5 cm from the skin. (The 12th spinous process partially overlies the L1 vertebral body.)

Figure 27-27. Celiac plexus blockade. The surface landmarks are described in [Figure 27-23](#). The needles are advanced medially and superiorly to contact the lateral aspect of the vertebral body. They are then advanced more anteriorly to pass beyond the vertebra to the prevertebral space, where the greater and lesser splanchnic nerves and their subsequent celiac plexus lie. No attempt is made to advance the needles to the anterior aspect of the vessels. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

5. When contact with a vertebral body is made, the needle is withdrawn several centimeters, and the angle of insertion is steepened so that it advances more anteriorly with subsequent passage, in the hope that it will walk off the anterior border of the vertebral body. The periosteum may be encountered several times during this attempt and should always be palpated gently because of the associated discomfort. Intravenous sedation may be required for tolerance of this blockade, although it must be kept to a minimum if evaluation of a diagnostic pain blockade is desired.
6. Once the anterior border of the vertebral body is reached, the needle is advanced 2–3 cm beyond this, and careful aspiration is performed. On the left side, advancement should be halted whenever aortic pulsation is appreciated. If the artery is unintentionally punctured, the needle should be withdrawn slightly and cleared immediately of blood. On the right side, the needle can often be advanced 1–2 cm further than the needle on the left side.
7. If radiologic confirmation is desired, it is obtained at this point, before injection of the anesthetic. The bony landmarks themselves are usually sufficient to identify the retroperitoneal space anterior to the first lumbar vertebral body. If neurolytic agents are to be used or if the anatomy is difficult, radiographic confirmation may be desirable. Although simple flat-plate radiographs are usually sufficient, fluoroscopy may be indicated in difficult cases. The use of a computed tomographic scan is not economically justified except in the most difficult of anatomic localizations.
8. Careful aspiration is performed, and a test dose is injected on each side to rule out subarachnoid or intravascular injection.
9. A large volume of local anesthetic solution is required. Twenty to 25 ml of 0.75% lidocaine or 0.25% bupivacaine is usually adequate, but a large volume is needed to diffuse in the retroperitoneal space to reach the ganglia.
10. The most reliable sign of successful anesthesia is the disappearance of pain in patients or the appearance of hypotension in normal patients. Patients with pain must remain supine for several hours and should have appropriate iv fluid supplementation to avoid orthostatic hypotension. Gradual ambulation is mandatory.

Hypotension is the most common complication of celiac plexus blockade. As mentioned previously, it can be reduced by the administration of 1 liter of balanced salt solution before performing the blockade. The most serious complication is the development of paralysis from unrecognized subarachnoid injection of a neurolytic drug. Radiographic confirmation of needle location is advisable before injection of any neurolytic drug. Even with correct placement of neurolytic drugs, back pain is common and patients may require iv opioids. This pain can be reduced by diluting the alcohol solution with an equal volume of local anesthetic such that a total volume of 50 ml is injected, consisting of 25 ml of alcohol and 25 ml of anesthetic. Even with this approach, diaphragmatic irritation (manifested as shoulder pain) is not uncommon. The duration of pain relief in the patient with chronic pain is unpredictable but is often 2–6 months. The blockade can be repeated as often as necessary, although a trial diagnostic blockade with a local anesthetic agent is indicated before each use of neurolytic drugs. One minor side effect of celiac plexus blockade is the increased peristalsis of the gut that is produced by the shift in the balance of the parasympathetic and sympathetic innervations. This may produce diarrhea within the first 12 hours after the blockade and may be a source of relief to patients on chronic opioid therapy for cancer pain.

Lumbar

Lumbar sympathetic blockade combines some of the anatomic considerations for stellate ganglion blockade and paravertebral anesthesia. As with the sympathetic innervation of the head and arm, the sympathetic nerves to the lower extremities all exit the cord above L2 and all pass through a common “gateway” ganglion in the sympathetic chain at the L2 level. Thus, as in the neck, sympathetic blockade of the lower extremity can be achieved by a single injection of one ganglion. The approach to this ganglion is similar to paravertebral anesthesia, as discussed previously, except that in the lumbar region, the sympathetic chain lies much more anterior from the somatic nerves, and thus a clean separation of sympathetic blockade from somatic blockade can be attained more easily.

As in the upper extremity, lumbar sympathectomy can be used in the treatment of sympathetic dystrophies or herpes zoster in an early stage. It is also occasionally used in patients with severe vascular disease in the lower extremities to give some indication of whether the patient would profit from permanent chemical or surgical sympathectomy. The procedure for blockade follows:

1. The patient position is similar to that for celiac plexus blockade. The patient lies prone with a pillow under the lumbar spine.
2. The spinous processes of L2 and L3 are identified and marked over their entire course. A horizontal line is drawn through the midpoint of the L2 spinous process and extended 5 cm to either side of the midline. An “X” is placed at this point, which should overlie the space between the transverse process of the second and third vertebrae or the caudad edge of the second transverse process.
3. A skin wheal is raised after aseptic skin preparation at each “X.”
4. A 10-cm needle is introduced on each side through the “X,” angled 30–45 degrees cephalad, and advanced until it contacts the transverse process ([Fig. 27-28](#)).

Figure 27-28. Lumbar sympathetic blockade. The needle is first placed on the transverse process of L2 and then advanced below it to pass 5 cm deeper. The needle can be angled slightly medially to contact the body of the vertebra; the sympathetic chain lies along the anterior margin of these bodies. (Reproduced with

permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

5. The depth of the needle insertion is marked, and the needle is then withdrawn slightly, angled caudad, and walked inferiorly off the transverse process (usually in a direction perpendicular to the skin). A slight medial angulation is used in the hope of contacting the vertebral body below the transverse process. The needle is advanced 5 cm below the depth of the transverse process. If it encounters a vertebral body, it is angled slightly more anteriorly to walk off that body at the desired depth.
6. Once the needle is in position, careful aspiration is performed, and a test dose is injected on both sides. Ten ml of local anesthetic solution injected on each side should produce sympathetic blockade. Again, 1% lidocaine, 0.25% bupivacaine, or an equivalent concentration is more than sufficient to produce sympathetic nerve blockade. If a neurolytic drug such as phenol is used, confirmation of needle position by radiography should be obtained. A slightly more caudad site of injection may be more effective for neurolytic blockade;²⁹ injection of smaller quantities at several levels may be more appropriate for neurolytic drugs.
7. Care is taken not to inject anesthetic solution as the needle is withdrawn, because this may produce a somatic nerve blockade as the needle passes the course of the L2 nerve root.
8. Vasodilatation and increase in skin temperature should be noted within the leg in 5–10 minutes. This can be quantitated objectively if a skin temperature probe is placed on the foot before the start of the blockade.

Complications with this technique are unusual, but, again, intravascular or subarachnoid injection can be a potential problem. The most troublesome and frequent complication is simultaneous blockade of the L2 somatic nerve root. This produces a band of anesthesia across the lateral and anterior thigh, which may confuse the evaluation of a diagnostic sympathetic blockade.

Hypogastric Plexus

At the terminal end of the prevertebral sympathetic chain is the superior hypogastric plexus, which extends from the lower one third of the fifth lumbar vertebral body to the upper third of the first sacral vertebral body. Fibers passing through this ganglion provide visceral sensation to the pelvic organs. Malignancies in the pelvis often produce chronic pain syndromes that involve transmission of nociception through this ganglion plexus, and significant relief can be obtained by the performance of neurolytic blocks in this area.³⁰

1. The patient is placed in the prone position with a pillow under the pelvis to reduce the lumbar lordosis.
2. The L4–5 intervertebral space is identified and marked, and a line drawn at the midline of this space. An “X” is then placed on the skin 5–7 cm lateral to this interspace on both sides.
3. Aseptic skin preparation is performed, and a skin wheal raised at the “X” marks at each side.
4. Fifteen cm, 22-gauge needles are then introduced through the skin wheals and direct medially. Both needles are advanced at approximately a 45-degree angle with a 30-degree caudad deflection to approach the anterolateral body of the L5–S1 space. If the L5 vertebral body is encountered, the needle is redirected more anteriorly. The use of fluoroscopy and contrast dye can document the correct placement of the needles just anterior to the L5–S1 intervertebral space.
5. After careful aspiration to exclude intravascular placement, anesthesia can be obtained with 8 ml of 0.25% bupivacaine for a diagnostic block. For neurolytic procedures, an equal volume of 10% phenol can be used on each side.

The major risk of this block is intravascular placement of the drug. The side effects and complications of neurolytic agents apply here if they are used.

Lower Extremity

The nerves to the lower extremity are most easily blocked by the spinal, caudal, or epidural techniques described in [Chapter 26](#). There are occasions when anesthesia by these routes is contraindicated because of systemic sepsis or coagulopathy, or when selective anesthesia of one leg or foot is needed. Peripheral nerve blockade is possible because the motor and sensory fibers to the lower extremities are somewhat similar to those of the upper extremities in that they form a series of intertwined branching roots and divisions that are enclosed in a fascial sheath before they emerge as the terminal nerves to the extremity. They can also be successfully blocked by a single injection in one plane, although the anatomic landmarks identifying this fascial sheath are not as clearly defined as those in the upper extremity. Because of this, the majority of lower extremity blockades are performed more distally, where the nerves have already separated into terminal branches. Thus, in addition to the fascial compartment approach (psoas blockade), there are peripheral approaches described at the hip, knee, and ankle.

The nerves to the legs emerge from the roots of L2 through the third sacral spinal segments ([Fig. 27-29](#)). The upper nerve roots from L2 to L4 form the lumbar plexus, which then ramifies eventually to form the lateral femoral cutaneous, femoral, and obturator nerves. These primarily provide sensorimotor innervation of the upper leg, although a branch of the femoral nerve commonly extends along the medial side of the knee as far down as the big toe. A branch of this lumbar plexus, the lumbosacral trunk of L4 and L5, joins the sacral fibers to form the major trunks of the large nerve of the posterior thigh and lower leg, the sciatic. The sciatic nerve is made up of two main trunks, the tibial and the common peroneal, which divide just above the knee. As in the brachial plexus, the upper nerve roots emerge from their foramina into a compartment lined by the fasciae of muscles anterior and posterior to it. In this case, the quadratus lumborum is posterior, whereas the posterior fascia of the psoas muscle provides the anterior border of the compartment. The sacral roots have a similar envelope except that the posterior border is the bone of the ilium, which prevents approach with a needle.

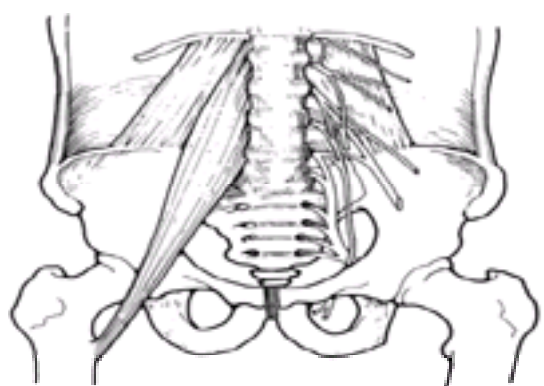

Figure 27-29. Psoas compartment anatomy. The roots of the lumbar plexus emerge from their foramina into a fascial plane between the quadratus lumborum muscle posteriorly and the psoas muscle anteriorly. The origin of the lumbosacral plexus is broader than the corresponding brachial plexus in the neck, and the lower sacral roots cannot be easily reached by a single injection. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

The lumbar plexus branches form their three terminal nerves early. Each of these passes anteriorly and laterally to circle around the pelvis and emerge anteriorly in the groin. The femoral nerve is the only one to continue in the fascial compartment formed by the psoas fascia as it passes into the groove between the psoas and the iliac muscles. The femoral nerve becomes associated with the femoral artery in the area of the groin and passes under the inguinal ligament just lateral to the artery. The lateral femoral cutaneous nerve migrates laterally early and passes under the inguinal ligament near the anterosuperior iliac spine. The third branch of the lumbar plexus, the obturator, remains somewhat medial and posterior in the pelvis and emerges under the superior ramus of the pubis through the obturator foramen to supply motor and sensory fibers to the medial thigh and medial border of the knee.

The branches of the sacral plexus also travel laterally within the pelvis before exiting posteriorly through the sciatic notch as the sciatic nerve. This largest nerve of the body is actually the conjunction of two trunks. The lateral trunk forms from the roots of L4 through S2 and eventually emerges as the common peroneal nerve. Other branches of L4 through S3 form the medial trunk, eventually becoming the tibial nerve. These combined nerves exit through the sciatic notch and pass anteriorly to the piriformis muscle between the ischial tuberosity and the greater trochanter of the femur. They curve caudad and descend the posterior thigh immediately behind the femur. After their bifurcation high in the popliteal fossa, the peroneal nerve provides the motor and sensory fibers to the anterior calf and dorsum of the foot, whereas the tibial nerve remains posterior and provides sensation to the calf and sole of the foot. Thus, there are three major branches that cross the knee: the femoral, tibial, and peroneal. By the time these nerves reach the ankle, there are five branches that cross this joint to provide innervation for the skin and muscles of the foot.

Psoas Compartment Blockade

As described previously, the roots of the lumbar plexus lie in an envelope similar to the interscalene fascial compartment in the neck (see [Fig. 27-29](#)). Unfortunately,

this fascial compartment is more difficult to identify in the lower than in the upper extremity and lies much deeper beneath the skin than its equivalent in the neck. Nevertheless, psoas compartment blockade is useful if single-injection anesthesia of the leg is desired.³¹ The procedure for blockade follows:

1. The patient is placed in the prone or the lateral position. The spinous processes of the lumbar vertebrae are identified, and an "X" is placed on the skin 5 cm lateral to the spinous process of L3. This is similar to the technique described for lumbar paravertebral blockade.
2. After aseptic preparation, a skin wheal is raised at the "X." A 10-cm needle is advanced perpendicular to the skin in all planes and passed through the muscles of the back. The nerve roots should lie at a depth of between 7 and 10 cm. Although in some patients the well demarcated fascial planes can identify the entry into the perineural sheath, anesthesia is much more reliable if paresthesias are obtained. If they are not obtained at a 10-cm depth, probing with the needle in a fan-like manner should be performed in a cephalad-caudad plane (which is perpendicular to the known paths of the emerging nerves).
3. When a paresthesia is obtained, the needle is fixed in position and careful aspiration and administration of a test dose are used to rule out intravascular or subarachnoid placement. Forty ml of local anesthetic solution is usually required to fill the sheath. Lidocaine 1.5% or bupivacaine 0.5% is adequate to provide sensory and motor anesthesia. Lower concentrations provide adequate sensory anesthesia with less profound motor blockade. Fifteen to 20 minutes may be required for spread of the anesthetic to all the roots of the lumbosacral plexus. It may take longer to produce anesthesia of the caudad branches (the lower sacral fibers that form the tibial nerve), or they may not be anesthetized at all.³²

Complications of this technique are rare, although hematoma in the muscle sheath and neuropathy of the nerves are possible. Inadequate anesthesia of some of the branches may occur more frequently than these rare complications.

Anesthesia at the Level of the Hip

Many anesthesiologists feel more confident when administering regional anesthesia in the hip region when paresthesias are sought for each of the major nerves. This technique is cumbersome and usually requires the patient to assume at least two separate positions for the injections. The anesthesia is more reliable but also requires a larger volume of anesthetic drug. Each of the four nerves may be blocked selectively on an individual basis. Anesthesia of the lateral femoral cutaneous nerve is occasionally used to provide sensory anesthesia for obtaining a skin graft from the lateral thigh. It can also be blocked as a diagnostic tool to identify cases of meralgia paresthetica. A sciatic nerve blockade alone provides adequate anesthesia for the sole of the foot and lower leg. Procedures on the knee require anesthesia of the femoral and the obturator nerves. Anesthesia of the lateral femoral cutaneous is also required if a tourniquet is to be placed on the thigh during foot surgery. Femoral nerve block provides significant postoperative analgesia for the first 18 hours after total knee arthroplasty,³³ and the use of a continuous technique can facilitate rehabilitation.¹

Sciatic Nerve Blockade, Classic Posterior Approach

1. The patient lies with the side to be blocked uppermost and rolls slightly anterior, flexing the knee so that the ankle of the involved side rests on top of the knee of the opposite side (Fig. 27-30). This position rotates the femur so that the trochanter is more easily palpated and the muscles overlying the sciatic nerve become stretched.

Figure 27-30. Sciatic nerve blockade, classic posterior approach. With the patient in the lateral position and the hip and knee flexed, the muscles overlying the sciatic nerve are stretched to allow easier identification. The nerve lies beneath a point 5 cm caudad along the perpendicular line that bisects the line joining the posterosuperior iliac spine and the greater trochanter of the femur. This is also usually the intersection of that perpendicular line with another line joining the greater trochanter and the sacral hiatus. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

2. The superior aspect of the greater trochanter of the hip is marked with a circle. A similar circle is placed on the posterosuperior iliac spine, and a line is drawn between these two points.
3. A perpendicular line is drawn from the midpoint of this original line and extended 5 cm in the caudad direction. An "X" is marked at this point. A third line drawn between the greater trochanter and the sacral hiatus should intersect this "X." In the taller patient, the original perpendicular may need to be extended caudad to intersect with the third line, and the nerve may lie closer to the intersection of the second and third lines than to the original "X."
4. A skin wheal is raised at the "X" after aseptic skin preparation.
5. A 10-cm needle is introduced perpendicular to the skin in all planes, and paresthesias or motor responses of the lower leg and foot are sought. If they are not obtained at the full depth of the needle, the needle is withdrawn to the skin and reintroduced in a fanwise fashion in a path perpendicular to the imagined course of the nerve in the hip. This path can usually be visualized by following the muscular groove on the back of the thigh up and into the imagined position of the sciatic notch. The bony edges of the sciatic notch itself may be encountered. These should be noted, and the search continued. The nerve should lie at approximately this depth as it emerges from inside the pelvis. Nerve localization is critical because blind infiltration of a large quantity of local anesthetic rarely produces adequate anesthesia. If localization cannot be obtained in the first 10 minutes, the landmarks should be reassessed.
6. When a paresthesia or motor response in the foot is obtained, the needle is held immobile, and 25 ml of local anesthetic is injected. Again, 1.5% lidocaine, 0.5% bupivacaine, or the equivalent is adequate. A lower concentration may be needed if several nerves are to be blocked, which requires a large total volume of anesthetic in several locations.

Sciatic Nerve Blockade, Supine Approach (Lithotomy). If a patient is uncomfortable in the lateral position or cannot be turned to the side because of a fracture or pain, the nerve can be blocked with the patient in the supine position. An assistant is required to elevate the leg into a lithotomy-type position so that the posterior aspect can be reached. The procedure for blockade follows:

1. With the patient supine, the hip is flexed by an assistant so that the upper leg is at a 90-degree angle to the torso.
2. The greater trochanter is identified as well as the ischial tuberosity, and a line is drawn between these two. An "X" is marked on the midpoint of this line.
3. A skin wheal is raised at the "X" after aseptic skin preparation. A 10-cm needle is introduced, and paresthesias are sought in a direction along the length of this line (which is perpendicular to the course of the nerve).
4. When a paresthesia or motor response in the foot is obtained, 25 ml of local anesthetic is injected.

Lateral Femoral Cutaneous Nerve Blockade. The other three nerves of the leg can be blocked at the level of the hip with the patient in the supine position. If no paresthesias are sought, the patient can be sedated more heavily than was used for the sciatic nerve blockade.

1. In the supine position, the anterosuperior iliac spine is identified and marked. An "X" is placed on the skin 2.5 cm below and 2.5 cm medial to the spine.
2. A skin wheal is raised at the "X" after aseptic preparation.
3. A 3.75-cm, 22-gauge needle is introduced through the wheal and directed laterally until a "pop" is felt as it pierces the fascia lata. Three to 5 ml of local anesthetic solution is injected as the needle is withdrawn slowly. The needle is then reinserted slightly medially, and the procedure is repeated until a "wall" of anesthesia has been spread over a 5-cm area above and below the fascia lata extending medially from the level of the anterosuperior spine. A total of 15–20 ml of local anesthetic may be required. No paresthesias are sought.

Femoral Nerve Blockade. This blockade can be performed blindly, or paresthesias or nerve stimulation can be sought for a "three-in-one" blockade [see [Lumbar Plexus \("Three-in-One"\) Blockade](#)]. The procedure for blockade follows:

1. In the supine position, a line is drawn from the anterosuperior iliac spine to the pubic tubercle. The femoral artery is identified as it passes below this line, and an "X" is marked on the skin lateral to the artery 2.5 cm below the line.
2. After aseptic preparation, a skin wheal is raised at the mark.
3. A 5-cm, 22-gauge needle is introduced through the "X" and passed perpendicular to the skin until it lies next to the artery and slightly deep to it (Fig. 27-31). Entry

into the vessel is not sought, but the needle should be easily perceived to be moving with pulsation of the vessel if it is in sufficient proximity.

Figure 27-31. Blockade of the anterior lumbosacral branches in the groin. The lateral femoral cutaneous nerve emerges approximately 2.5 cm medial to the anterosuperior iliac spine and is best blocked 2.5 cm caudad to this point. The femoral nerve emerges alongside and slightly posterior to the femoral artery and is again easily approached approximately 2.5 cm below the inguinal ligament. On that same line, the obturator nerve emerges from the obturator canal but is deeper and less reliably located. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

4. Five ml of local anesthetic is injected slowly as the needle is withdrawn. The needle is then reinserted slightly more laterally, and the process is repeated again until another "wall" of anesthesia has been laid down lateral to and slightly deep to the femoral artery.
5. Anesthesia of the medial thigh should ensue within 5–10 minutes.

Obturator Nerve Blockade. This nerve is more difficult to locate because of its depth, but anesthesia is essential for operations in the area of the knee. The procedure for blockade follows:

1. In the supine position, the pubic tubercle is identified and an "X" is placed 1.5 cm below and 1.5 cm lateral to this structure. This should lie medial to the femoral artery, and a line drawn between the three "X's" used for these three nerve blockades should be parallel to the line between the superior spine and the pubic tubercle.
2. After aseptic skin preparation, a skin wheal is raised at the "X," and a 7.5-cm, 22-gauge needle is introduced through the "X" perpendicular to the skin.
3. The needle is advanced until it contacts bone, which should be the inferior ramus of the pubis. The needle is withdrawn slightly and redirected laterally and slightly caudad to enter the obturator foramen. It is advanced another 2-3 cm, and 5 ml of anesthetic is injected as the needle is withdrawn through the presumed depth of the obturator foramen.
4. The needle is then reinserted slightly more laterally, and the process is repeated again until 20 ml of anesthetic solution has been injected to form another "wall" along the presumed path of the obturator nerve (see [Fig. 27-31](#)).

Lumbar Plexus ("Three-in-One") Blockade. Winnie *et al*³⁴ have popularized the concept of a single-injection blockade for the lumbar plexus, utilizing the fascial plane that the femoral nerve travels in as it crosses the pelvis. The object of this blockade is to inject a large quantity of local anesthetic solution in this plane so that it will spread upward into the pelvis and anesthetize the obturator and lateral femoral cutaneous nerves at the point where they still travel in conjunction with the femoral nerve. Unfortunately, the obturator is frequently missed with this technique.³² Because it is essential to have the needle exactly in the plane of the nerve, eliciting paresthesias or use of nerve stimulation is critical for this approach. The procedure for blockade follows:

1. Preparation for femoral nerve blockade is made as described previously.
2. The needle is inserted in a cephalad manner rather than in a perpendicular angle recommended previously. It is advanced alongside the artery angled at about 45 degrees so that it passes under the inguinal ligament. A paresthesia is sought, recognizing that the nerve lies slightly posterior to and occasionally partially under the femoral artery. When the paresthesia is obtained, the needle is fixed and the fingers of an assistant are used to compress the femoral artery and the neural sheath below the inguinal ligament while the operator injects 40 ml of anesthetic solution. The injection is performed incrementally after careful aspiration.

Complications of these techniques are rare. Hematomas can occur in any of the areas of injection and are annoying but rarely serious. The problem of systemic toxicity is a major one because of the large volumes of anesthetic solution required. As mentioned previously, careful attention must be paid to the total-milligram dose involved when multiple injections are used. Neuropathy is a possibility. Intraneural injection must be avoided by watching for signs of any discomfort at the time of actual injection. If the technique is used for analgesia following outpatient surgery, quadriceps weakness may limit ambulation, and crutches may be needed to enable patient discharge home.

Popliteal Fossa Blockade

The nerves of the lower leg can also be anesthetized by injections at the level of the knee.³⁵ The success of this technique depends on locating the sciatic nerve near its bifurcation into the tibial and peroneal branches high in the popliteal fossa ([Fig. 27-32](#)). Supplemental anesthesia of the femoral nerve is needed to block its terminal saphenous branch, which serves the medial anterior calf and the dorsum of the foot. The procedure for blockade follows:

Figure 27-32. Popliteal fossa blockade. The two major trunks of the sciatic bifurcate in the popliteal fossa 7–10 cm above the knee. A triangle is drawn using the heads of the biceps femoris and the semitendinosus muscles and the skin crease of the knee; a long needle is inserted 1 cm lateral to a point 5 cm cephalad on the line from the skin crease that bisects this triangle. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

Classical Approach

1. The patient is placed in a prone position. The triangular borders of the popliteal fossa are outlined by drawing the borders of the biceps femoris and the semitendinosus muscles. The base of the triangle is the skin crease behind the knee. The patient can help identify the muscles by slightly flexing the lower leg.
2. After the triangle is drawn, a perpendicular line is drawn from the midpoint of the base to the apex of the triangle. Six centimeters from the base, an "X" is drawn 1 cm lateral to this bisecting line.
3. After aseptic skin preparation, a skin wheal is raised at the "X."
4. A 7.5- or 10-cm needle is introduced through the "X" and directed 45 degrees cephalad along the middle of the triangle ([Fig. 27-33](#)). The nerves should be passing down the back of the leg parallel to the bisecting line of the triangle. A fanwise search is conducted perpendicular to this line until the nerve is contacted. If the femur is contacted by the needle, the depth is noted. The nerve should lie midway between the skin and the femur.

Figure 27-33. Popliteal fossa blockade, needle direction. The needle is inserted at the point described in [Figure 27-32](#) and angled 45 degrees cephalad. The nerves usually are contacted halfway between the skin and the femur. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

5. Once a paresthesia or response to a stimulator is obtained, the needle is fixed in position and 30–40 ml of local anesthetic solution is injected.
6. The femoral branches can be injected in the same position by raising a subcutaneous wheal of 5–10 ml of local anesthetic along the medial tibial head just below the knee.

Lateral Approach. An alternative approach to the block of the popliteal fossa is from the lateral side while the patient is lying supine.³⁶

1. On the lateral side of the knee, the groove between the biceps femoris tendon and the vastus lateralis muscle is identified and marked. An “X” is placed 7 cm cephalad to the lateral femoral epicondyle.
2. A 22 gauge, 10-cm needle is inserted at this mark at a horizontal plane. The shaft of the femur is usually contacted within about 5 cm. The needle is then redirected 30 degrees posteriorly to search for the sciatic nerve or its divisions at approximately the same depth of the femur. A paresthesia or motor response to nerve stimulation in the foot identify the nerve, usually the common peroneal nerve which lies laterally. A second stimulation or paresthesia of the tibial nerve may be sought. 10–15 ml of anesthesia injected around each nerve provides adequate anesthesia.

Ankle Blockade

All the nerves of the foot can be blocked at the level of the ankle.³⁷ Although this approach is ideal in producing the least amount of immobility of the lower extremity, it is technically more difficult because at least five nerves must be anesthetized ([Fig. 27-34](#)). Several of these nerves can be blocked by simple infiltration of a “wall” of anesthesia, but increased reliability can be produced by seeking paresthesias of the major branches. If paresthesias are not sought, this blockade may actually be less time consuming than other techniques, even though five separate injections are required. The procedure for blockade follows:

Figure 27-34. Ankle blockade. Injections are made at five separate nerve locations. The superficial peroneal nerve, sural nerve, and saphenous nerve are usually blocked simply by subcutaneous infiltration because they may have already generated many superficial branches as they cross the ankle joint. Paresthesias can be sought in the posterior tibial or the deep peroneal nerve, but the bony landmarks usually suffice to provide adequate localization for the deeper injections. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Boston, Little, Brown, 1996.)

1. Posterior tibial nerve. The posterior tibial nerve is the major nerve to the sole of the foot. It can be approached with the patient either in the prone position or with the hip and knee flexed so that the foot rests on the bed. The medial malleolus is identified, along with the pulsation of the posterior tibial artery behind it. A needle is introduced through the skin just behind the posterior tibial artery and directed 45 degrees anteriorly, seeking a paresthesia in the sole of the foot. Five ml of a local anesthetic produce anesthesia if a paresthesia is identified. If not, a fan-shaped injection of 10 ml can be performed in the triangle formed by the artery, the Achilles tendon, and the tibia itself.
2. Sural nerve. With the foot in the same position, the other posterior nerve of the ankle can be blocked by injection on the lateral side. The subcutaneous injection of a ridge of anesthesia behind the lateral malleolus, filling the groove between it and the calcaneus, produces anesthesia of the sural nerve. This will require another 5 ml of local anesthetic.
3. Saphenous nerve. The last three branches of the ankle lie anteriorly. The patient is either turned supine, or the leg can now be extended so that the anesthesiologist's attention is turned to the anterior surface. The saphenous nerve is anesthetized by infiltrating 5 ml of local anesthetic around the saphenous vein at the level where this vein passes anterior to the medial malleolus. A wall of anesthesia between the skin and the bone itself suffices to block the nerve.
4. Deep peroneal nerve. This is the major nerve to the dorsum of the foot and lies in the deep plane of the anterior tibial artery. Pulsation of the artery is sought at the level of the skin crease on the anterior midline surface of the ankle. If it can be felt, 5 ml of local anesthetic is injected just lateral to this. If the artery is not palpable, the tendon of the extensor hallucis longus can be identified by asking the patient to extend the big toe. Injection can be made into the deep planes below the fascia using either one of these landmarks.
5. Superficial peroneal branches. Finally, a subcutaneous ridge of anesthetic solution is laid along the skin crease between the anterior tibial artery and the lateral malleolus. This subcutaneous ridge will overlies the previous subfascial injection for the deep peroneal nerve. Another 5–10 ml of local anesthetic may be required to cover this area.

Anesthesia of the foot should ensue within 10 minutes after performance of these five injections. Complications of this blockade are rare, although neuropathy can be produced. Care should be taken not to pin any of the deep nerves against the bone at the time of injection, and intraneural injection should be avoided as usual.

NEUROPHYSIOLOGY AND NEUROANESTHESIA

To understand how anesthetics act on the nervous system and how these actions may affect the practice of neuroanesthesia, one first needs to understand the basic principles of neurophysiology. The following description of cellular neurophysiology provides background information only; greater detail may be sought elsewhere.^{1,2,3,4} and ⁵

Membrane Potentials

Neurons have an electrical potential across their cell membrane owing to different intra- and extracellular ion concentrations. These concentration differences lead to an opposing voltage called the *equilibrium potential*. The Nernst equation calculates the equilibrium potential for a single ion. The Nernst or equilibrium potential for potassium (E_K) at 37°C can be calculated using the following equation:

$$E_K = -61 \log(K_i / K_o)$$

where k_i is the potassium concentration inside the cell and k_o is its concentration outside the cell.⁴ This value is approximately -90 mV, yet the membrane potential for most neurons at rest is closer to -70 mV. This is because both sodium and potassium ions contribute to the resting membrane potential. An ion's contribution to the membrane potential of a neuron is determined by its conductance, which is proportional to the membrane's permeability for that ion. Because the conductance to potassium (g_K) is much higher than the sodium conductance (g_{Na}) in an unexcited neuron, the resting membrane potential is nearer to the potassium equilibrium potential than the sodium equilibrium potential ($E_{Na} = +45$ mV). The following equation can be used to calculate a cell's membrane potential:

$$E_m = [g_K(E_K) + g_{Na}(E_{Na}) + g_X(E_X)] / (g_K + g_{Na} + g_X)$$

where X refers to any other ion.⁴

The conductance of ions across the cell membrane is through channels, which are proteins that span the membrane and have a hydrophilic pore. Many channels are predominantly permeable to one ion type. The sodium channel (Fig. 28-1) is highly selective for sodium and lets very little potassium pass through it; the potassium channel is likewise selective for potassium. These channels are controlled by gates that open and close. During rest, most of the sodium channels have their gates closed, and more of the potassium channels' gates are in the open position. The opening and closing of the ion channel's gates controls the conductance of the cell membrane for that ion.

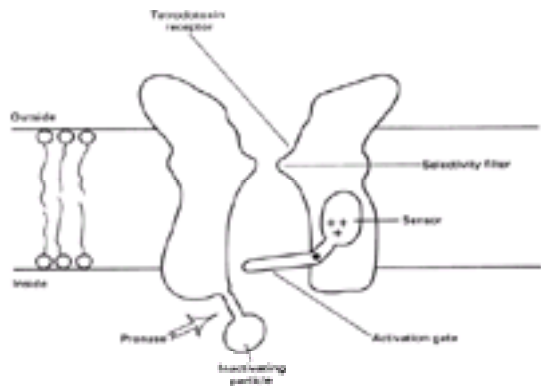

Figure 28-1. Sodium channel. The selectivity filter allows sodium but not potassium to pass through. The channel is open and allows sodium through when both the activation gate and the inactivation gate, which is also called the inactivating particle, are in the open position. Closing either gate will block the passage of ions. (Reprinted with permission from Aidley DJ: *The Physiology of Excitable Cells*. New York, Cambridge University Press, 1989.)

Neurons signal over long distances by propagating action potentials, which are rapid depolarizations of the membrane, along their axons. The action potential is caused by a fast increase in the sodium conductance (because of the opening of the sodium activation gate) and a slower increase in the potassium conductance. These conductance changes are triggered by a depolarization of the cell membrane, and therefore the channels that open in response to the depolarization are described as voltage-sensitive channels. When the neuron depolarizes past a threshold voltage level, an action potential is generated. The peak voltage of the action potential is approximately +20 mV; this level is attained because, at the peak, the sodium conductance is much greater than the potassium conductance. The voltage during the action potential returns rapidly to resting levels (repolarizes) because of the following:

1. The sodium conductance shuts itself off by closing a second gate (inactivation gate) in the channel (see [Fig. 28-1](#)).
2. The potassium conductance increases due to the opening of potassium channels.

A detailed description of membrane potentials, ion channels, gating, and action potentials can be found in Aidley,¹ Hille,² and Kandel and Schwartz.⁴

Synaptic Transmission

Neurons communicate using chemical synapses. The chemical, called a transmitter, is released from the presynaptic neuron, diffuses across the synaptic cleft, and combines with a receptor molecule on the postsynaptic neuron. The release of the neurotransmitter is initiated by an action potential traveling down the axon of the presynaptic neuron, causing the depolarization of the presynaptic terminal. This depolarization leads to the opening of voltage-dependent calcium channels and the entry of calcium from the extracellular fluid into the terminal. Vesicles containing the neurotransmitter then fuse with the terminal membrane, releasing the neurotransmitter into the synaptic cleft. The combination of the neurotransmitter with its receptor located on the postsynaptic cell alters ion channels associated with the receptor. These channels are described as ligand-gated channels. The opening of these ion channels leads to a change in the membrane potential of the postsynaptic neuron. If the transmitter is excitatory, this postsynaptic neuron is depolarized and therefore is more likely to generate an action potential. If the transmitter is inhibitory, the neuron is hyperpolarized and is less likely to generate an action potential.

In addition to opening ion channels, neurotransmitters work through intracellular second messengers. One example of a second messenger is cyclic AMP, which activates protein kinases to phosphorylate proteins and change their activity. Ion channels may be phosphorylated, which may change their conductance. A group of proteins that bind guanosine triphosphate, called G proteins, are activated when a transmitter binds a specific receptor molecule. In some cases these G proteins activate ion channels directly, but in other cases they can either stimulate (G_s) or inhibit (G_i) adenylate cyclase, the enzyme that converts adenosine triphosphate (ATP) into cyclic AMP¹ ([Fig. 28-2](#)). G proteins can also activate the phosphatidylinositol second-messenger system; in this case, a transmitter binds to a receptor, which causes another G protein (G_p) to activate phospholipase C ([Fig. 28-3](#)). This membrane-bound enzyme breaks down a membrane phospholipid into diacylglycerol and inositol trisphosphate, both of which are second messengers. Diacylglycerol activates protein kinase C, which will then phosphorylate other proteins, whereas inositol trisphosphate increases cytosolic calcium by releasing it from intracellular stores (endoplasmic reticulum).⁶

Figure 28-2. G proteins and adenylate cyclase. Different transmitters bind to either a stimulatory receptor (R_s) or an inhibitory receptor (R_i). Both are coupled to GTP-binding proteins (G proteins). G_s stimulates adenylate cyclase to increase cAMP levels; G_i inhibits adenylate cyclase and decreases cAMP levels. (Reprinted with permission from Aidley DJ: *The Physiology of Excitable Cells*. New York, Cambridge University Press, 1989.)

Figure 28-3. G proteins and phosphodiesterase. A transmitter binds to a receptor activating a G protein (G_p), which activates the membrane-bound enzyme phosphodiesterase. This enzyme converts phosphatidylinositol-4,5-bisphosphate (PIP_2) into inositol 1,4,5-trisphosphate (IP_3), which is water-soluble and causes the release of calcium from endoplasmic reticulum, and diacylglycerol, which is lipid-soluble and remains in the membrane to activate protein kinase C. Protein kinase C will in turn phosphorylate certain other proteins, altering their activity. (Reprinted with permission from Aidley DJ: *The Physiology of Excitable Cells*. New York, Cambridge University Press, 1989.)

There are many neurotransmitters in the brain. In this chapter two common neurotransmitters and their receptors will be examined.

γ -Aminobutyric acid (GABA) is a major inhibitory amino acid transmitter that is active throughout the brain and reduces the excitability of neurons by hyperpolarizing them. There are two major GABA receptors. Activation of the $GABA_A$ receptor opens chloride channels²; this activity is enhanced by benzodiazepines and barbiturates.

The GABA_B receptor acts via a second messenger either to open potassium channels or to close calcium channels, but does not affect chloride channels.⁸ The response to GABA_B receptor activation has a slower onset and a more prolonged activation than the response to the GABA_A receptor. Both receptors may be present on the same neuron, providing a mechanism for rapid and prolonged inhibition.

Glutamate is the major excitatory transmitter in the brain. Its activation depolarizes neurons, making it more likely that they will fire action potentials. There are three main ionotropic glutamate receptors, which have been named for their preferential pharmacologic agonists. The AMPA and kainate receptors allow sodium and potassium but not calcium through their channels.^{9,10} These channels are responsible for the normal excitatory responses seen with glutamate. The third glutamate receptor, the *N*-methyl-D-aspartate receptor (NMDA), is activated when neurons are depolarized; the channels associated with this receptor are not opened by glutamate at normal resting membrane potentials. These channels allow passage of calcium as well as sodium and potassium. NMDA receptor activation is important in changing a neuron's excitability over a period of hours and days (long-term potentiation); this has been correlated with learning in animals.¹⁰ Glutamate receptors have also been associated with neuronal injury after anoxia.¹¹ In addition to ionotropic effects, glutamate activates metabotropic receptors, which act via a second messenger. Inositol trisphosphate, one second messenger, releases calcium from intracellular stores (see Fig. 28-3); this can affect the excitability of the neuron.⁶

The above is a simple description of how synapses operate to convey information from one neuron to another. This process is finely controlled; there are neurotransmitters that act on presynaptic terminals to regulate the amount of transmitter the terminal releases.³ Indeed, some neurons have receptors on their presynaptic terminals, called *autoreceptors*, that reduce the amount of transmitter that terminal releases in response to the buildup of that same transmitter in the synapse. This is a way of controlling the concentration of transmitter in the synaptic cleft. There are compounds called *neuromodulators* that, when applied to a neuron alone, have no observable effect on the excitability of that neuron but alter the effect of other excitatory or inhibitory inputs to that neuron. These neuromodulators are released in the same manner as neurotransmitters; indeed, it is possible for the same substance to be a neuromodulator at one synapse and a neurotransmitter at another. Furthermore, some synapses have been shown to release two neuroactive compounds from the same presynaptic terminal; these cotransmitters can have synergistic actions on the postsynaptic terminal. Many of the peptide neurotransmitters, such as enkephalin and substance P, are released as cotransmitters with a nonpeptide transmitter (*e.g.*, norepinephrine and serotonin).

Brain Metabolism

The main substance used for energy production in the brain is glucose.¹² When oxygen levels are sufficient, glucose is metabolized to pyruvate in the glycolytic pathway (Fig. 28-4). This biochemical process generates ATP from adenosine diphosphate and inorganic phosphate and produces NADH from nicotinamide adenine dinucleotide (NAD). Pyruvate from this reaction then enters the citric acid cycle, which, with regard to energy production, primarily generates NADH from NAD. The mitochondria use oxygen to couple the conversion of NADH back to NAD with the production of ATP from ADP and inorganic phosphate. This process, called *oxidative phosphorylation*, forms three ATP molecules for each NADH converted. The process of aerobic metabolism yields 38 ATP molecules for each glucose molecule metabolized.¹³

Figure 28-4. Energy metabolism in the brain. Dotted lines indicate reactions that occur during ischemia. The dotted line across the oxidative phosphorylation reaction indicates that this reaction is blocked during ischemia.

This pathway requires oxygen; if oxygen is not present, the mitochondria can neither make ATP nor regenerate NAD from NADH. The metabolism of glucose requires NAD as a cofactor and is blocked in its absence. Thus, in the absence of oxygen, glycolysis proceeds by a modified pathway termed *anaerobic glycolysis*; this modification involves the conversion of pyruvate to lactate, regenerating NAD. There is a net hydrogen ion production, which lowers the intracellular pH. A major problem with anaerobic glycolysis, in addition to lowering pH, is that only two molecules of ATP are formed for each molecule of glucose metabolized.¹³ This level of ATP production is insufficient to meet the brain's energy needs.

When the oxygen supply to a neuron is reduced, mechanisms that reduce and/or slow the fall in ATP levels include: (1) the utilization of phosphocreatine stores (a high-energy phosphate that can donate its energy to maintain ATP levels), (2) the production of ATP at low levels by anaerobic glycolysis, and (3) a rapid cessation of spontaneous electrophysiologic activity.

Pumping ions across the cell membrane is the largest energy requirement in the brain (Table 28-1). The sodium, potassium, and calcium concentrations of a neuron are maintained against large electrochemical differences with respect to the outside of the cell. When a neuron is not excited (firing action potentials), there is a slow leak of potassium out of the cells and of sodium into the cells. Neuronal activity markedly increases the flow of potassium, sodium, and calcium; this increases the rate of ion pumping required to maintain the neuron's ion concentration. Because ion pumping uses ATP as an energy source, the ATP requirement of active neurons is greater than that for resting neurons. If energy production does not meet the demand of energy use in the brain, the neurons first become unexcitable and then are irreversibly damaged.^{14,15}

Pumping ions across membranes

Metabolism of proteins, lipids, carbohydrates, and other molecules

Transporting of molecules within cells

Table 28-1. CELLULAR PROCESSES THAT REQUIRE ENERGY

Neurons require energy to maintain their structure and internal function. The cell's membranes, internal organelles, and cytoplasm are made of carbohydrates, lipids, and proteins, which require energy for their synthesis. Ion channels, enzymes, and cell structural components are important protein molecules that are continuously formed, modified, and broken down in the cell. If ATP is not available, protein synthesis cannot continue and the neuron will die. Carbohydrates and lipids are also continuously synthesized and degraded in normally functioning neurons; their metabolism also requires energy. Most cellular synthesis takes place in the cell body; thus, energy is required for the transport of components down the axon to the nerve terminal. The importance of this transport is illustrated by the death of the distal end of an axon when it is severed from its cell body. Thus, energy is required to maintain the integrity of neurons even in the absence of electrophysiologic activity.

The overall metabolic rate for the brain of a young adult man (mean age, 21 years) is $3.5 \text{ ml O}_2 \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ brain tissue or $5.5 \text{ mg glucose} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$.¹² This rate is virtually the same in elderly men (mean age, 71 years). Children (mean age, 6 years) have a markedly higher metabolic rate of $5.2 \text{ ml O}_2 \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ brain

tissue. Although the reasons for this high metabolic rate are unknown, it may reflect extra energy requirements for the growth and development of the nervous system.¹²

Cerebral Blood Flow

The brain receives approximately 15% of cardiac output, yet makes up only 2% of total body weight.¹² The disproportionately large blood flow is due to the high metabolic rate of the brain. Global blood flow and metabolic rate remain fairly stable. Regional blood flow and metabolic rate of the brain can change dramatically; when metabolic rate goes up in a region of the brain, the blood flow to that region also increases. The mechanism of this coupling of blood flow and metabolism is not known; however, an increase in either potassium or hydrogen ion concentrations in the extracellular fluid surrounding arterioles may lead to dilatation and increased flow. Other agents that may mediate the coupling are calcium, adenosine, nitric oxide and the eicosanoids (e.g., prostaglandins).¹⁴ None of these mechanisms need be exclusive, and more than one or all of them may contribute to this exquisite coupling of flow and metabolism.

Increasing carbon dioxide level causes vasodilatation and increased blood flow (Fig. 28-5). Increasing the carbon dioxide tension from 40 to 80 mm Hg doubles the flow; reducing the carbon dioxide from 40 to 20 mm Hg halves the flow.^{16,17} These changes are transient, and blood flow returns to normal in 6–8 hours, even if the altered carbon dioxide levels are maintained. These effects may be related to hydrogen ion concentration. High carbon dioxide levels increase the extracellular hydrogen ion concentration and blood flow, whereas low carbon dioxide levels decrease the extracellular hydrogen ion concentration and reduce blood flow. The bicarbonate concentration in the extracellular fluid of the brain adjusts, bringing the pH back to normal, even though the carbon dioxide levels remain altered.¹⁸ This has important clinical implications in patients hyperventilated for prolonged periods. If normocarbica is rapidly re-established, brain interstitial fluid pH will decrease and cerebral blood flow (CBF) will increase dramatically, perhaps increasing intracranial pressure (ICP).

Figure 28-5. The effect of perfusion pressure (PP), arterial carbon dioxide pressure (PaCO_2), and arterial oxygen pressure (PaO_2) on cerebral blood flow. Each parameter on the abscissa is varied independently while the other parameters are held at their normal levels. (Reprinted with permission from Michenfelder JD: *Anesthesia and the Brain*, pp 6, 94–113. New York, Churchill Livingstone, 1988.)

If a patient is hypoventilated, carbon dioxide increases, pH decreases, and blood flow increases throughout the brain. The arterioles could become maximally dilated throughout the brain, impeding the ability to direct flow to areas of high metabolic demand. Thus, this luxury flow caused by high carbon dioxide levels throughout the brain could “steal” blood flow from areas that require extra oxygen and produce metabolites. This is particularly important during focal ischemia with the blockage of an intracerebral artery. The vessels supplying collateral flow to the area of the blocked artery would already be maximally dilated due to the metabolic demands of the ischemic tissue, and high PaCO_2 would cause blood flow to be shunted away to areas of less demand.¹⁹ The blood flow to the brain can be manipulated to advantage during focal ischemia. Reducing carbon dioxide with hyperventilation or reducing metabolism with agents such as thiopental would reduce blood flow to most areas of the brain, and the vessels in the ischemic area would be maximally dilated because of low pH. These manipulations, which are sometimes called *inverse steal* or the *Robin Hood effect* (rob from the rich, give to the poor), could have the effect of maximizing blood flow to compromised areas.¹⁹ The clinical relevance of flow redistribution due to hypocarbica has been questioned.²⁰

The CBF autoregulates with respect to pressure changes. In normotensive individuals, mean arterial pressure (MAP) can vary from 50 to 150 mm Hg and CBF will be maintained constant because of an adjustment of the cerebral vascular resistance (see Fig. 28-5). This phenomenon is a myogenic response of the arterioles due to their ability to constrict in response to an increased distending pressure. This response takes a few minutes to develop; therefore, after a rapid increase in MAP, there is a short period (about 1–3 min) of increased blood flow.^{21,22} If mean blood pressure falls below 50 mm Hg, CBF is reduced; at a pressure of 40 mm Hg, mild symptoms of cerebral ischemia occur.^{22,23} Patients who are hypertensive demonstrate a shift of autoregulation to a higher blood pressure.²⁴ Their lower limit of autoregulation could be well above 50 mm Hg; their upper limit of autoregulation is also increased. This shift, due to hypertrophy of the vessel wall, takes 1 or 2 months to become established.²³ Autoregulation can be abolished by trauma, hypoxia, and certain anesthetic and adjuvant anesthetic drugs. When blood pressure exceeds the autoregulated range, it can cause a disruption of the blood–brain barrier and cerebral edema.

The cerebral vasculature is also regulated by neurogenic factors that seem to have their greatest influence on the larger cerebral vessels. They control flow to large areas of the brain and play less of a role in the regulation of local CBF.²² The innervation includes cholinergic, adrenergic, and serotonergic systems. Sympathetic activation leads to increased MAP and shifts the autoregulatory curve to the right, increasing the pressure at which the breakthrough of autoregulation occurs.²³

Cerebrospinal Fluid

The neurons in the brain are exquisitely sensitive to changes in their environment. Small alterations in extracellular ion levels can profoundly alter neuronal activity. Substances that circulate in the blood, such as catecholamines, if not sequestered from direct contact with the brain, might also disrupt brain function. Thus the composition of the fluid surrounding the brain is tightly regulated and distinct from extracellular fluid in the rest of the body (Table 28-2).²⁵ There are two barriers, the blood–brain barrier and the blood–cerebrospinal fluid barrier, that maintain the difference between blood and cerebrospinal fluid (CSF) composition.

| | CSF | Serum |
|--|------|-------|
| Sodium ($\text{mEq}\cdot\text{l}^{-1}$) | 141 | 140 |
| Potassium ($\text{mEq}\cdot\text{l}^{-1}$) | 2.9 | 4.6 |
| Calcium ($\text{mEq}\cdot\text{l}^{-1}$) | 2.5 | 5.0 |
| Magnesium ($\text{mEq}\cdot\text{l}^{-1}$) | 2.4 | 1.7 |
| Chloride ($\text{mEq}\cdot\text{l}^{-1}$) | 124 | 101 |
| Bicarbonate ($\text{mEq}\cdot\text{l}^{-1}$) | 21 | 23 |
| Glucose ($\text{mg}\cdot 100\text{ ml}^{-1}$) | 61 | 92 |
| Protein ($\text{mg}\cdot 100\text{ ml}^{-1}$) | 28 | 7000 |
| pH | 7.31 | 7.41 |
| Osmolality ($\text{mOsm}\cdot\text{kg}^{-1}\text{ H}_2\text{O}$) | 289 | 289 |

Table 28-2. PREANESTHETIC ASSESSMENT OF THE HEAD-INJURED PATIENT

Brain capillary endothelial cells (the blood–brain barrier) have tight junctions that prevent extracellular passage of substances between the endothelial cells. They also have a low level of pinocytotic activity, which reduces the transport of large molecules across the cells. Processes of astrocyte glial cells are interposed between the neurons of the brain and the capillaries. The functional importance of the astrocytes to the blood–brain barrier is currently unknown; however, they are located wherever the blood–brain barrier is present and appear to be necessary for the development and perhaps the maintenance of the barrier. The blood–brain barrier impedes the flow of ions such as potassium, calcium, magnesium, and sodium; polar molecules such as glucose, amino acids, and mannitol; and macromolecules such as proteins.²⁵ Lipid-soluble compounds, water, and gases such as carbon dioxide, oxygen, and volatile anesthetics pass rapidly through the blood–brain barrier. Many substances that do not cross the blood–brain barrier are required for brain function; these substances are transported across the capillary endothelial cell by

carrier-mediated processes. These processes consist of either active transport, which requires the expenditure of energy, or passive transport, which does not. Passive transport, also referred to as *facilitated diffusion*, can move molecules into the brain only if their concentration in the blood is higher than their concentration in the brain. Glucose is an example of a molecule that enters the brain by passive transport. All of these transport processes have a limited capacity. The blood–brain barrier can become disrupted by acute hypertension, osmotic shock, disease, tumor, trauma, irradiation, and ischemia.

Cerebrospinal fluid is primarily formed in the choroid plexus of the cerebral ventricles. The capillaries of the choroid plexus have fenestrations and intercellular gaps that allow free movement of molecules across the endothelial cells; however, they are surrounded by choroid plexus epithelial cells, which have tight junctions and form the basis of the blood–CSF barrier. It is these cells that secrete the CSF. The CSF volume in the brain is between 100 and 150 ml; it is formed and reabsorbed at a rate of 0.3–0.4 ml · min⁻¹. This allows a complete replacement of the CSF volume three or four times a day. The blood–CSF barrier is similar to the blood–brain barrier in that it allows the free movement of water, gases, and lipid-soluble compounds but requires carrier-mediated active or passive transport processes for glucose, amino acids, and ions. Proteins are largely excluded from the CSF. The CSF is primarily formed by the transport of sodium, chloride, and bicarbonate with the osmotic movement of water. Two clinically used substances that reduce CSF formation are furosemide, which inhibits the combined transport of sodium and chloride, and acetazolamide, which reduces bicarbonate transport by inhibiting carbonic anhydrase.²⁶ The CSF flows from the lateral ventricles to the third and fourth ventricles and then to the cisterna magna. It then flows around the brain and spinal cord in the cerebral and spinal subarachnoid space. The fluid in the subarachnoid space provides cushioning for the brain, reducing the effect of head trauma. The CSF is absorbed into the venous system of the brain by the villi in the arachnoid membrane. These arachnoid villi allow one-way flow of CSF from the subarachnoid space into the venous sinuses when CSF pressure is greater than the pressure in these sinuses. Owing to the high rate of CSF formation and its absorption into the venous system, proteins and other matter released into the brain extracellular fluid are removed. If the foramina connecting the ventricles or the arachnoid villi are blocked, pressure builds and hydrocephalus develops.

Intracranial Pressure

The brain is enclosed in the cranium, which has a fixed volume; therefore, if any of the components located in the cranial vault increase in volume, the ICP will increase (Table 28-3). An increase in volume of one of these components can increase ICP and result in two major deleterious effects on the organism. The first is to reduce blood flow to the brain. The cerebral perfusion pressure (CPP) is determined by the MAP minus the ICP. If ICP increases to a greater extent than MAP, CPP is reduced. If ICP rises sufficiently, the brain can become ischemic. The second important effect of increased ICP is its ability to induce brain herniation. This herniation could be across the meninges, down the spinal canal, or through an opening in the skull. Herniation can rapidly lead to neurologic degeneration and death.

trauma. The CSF is absorbed into the venous system of the brain by the villi in the arachnoid membrane. These arachnoid villi allow one-way flow of CSF from the subarachnoid space into the venous sinuses when CSF pressure is greater than the pressure in these sinuses. Owing to the high rate of CSF formation and its absorption into the venous system, proteins and other matter released into the brain extracellular fluid are removed. If the foramina connecting the ventricles or the arachnoid villi are blocked, pressure builds and hydrocephalus develops.

Table 28-3. THE THREE MAJOR COMPONENTS THAT OCCUPY SPACE IN THE SKULL

The ICP in humans is normally less than 10 mm Hg.²⁷ Under normal circumstances, a small increase in intracranial volume will not greatly increase ICP because of the elastance of the components located in the cranium (Fig. 28-6). After a certain point, however, the capacity of the system to adjust to increased volume is exceeded and even a small increase in volume will increase ICP.²⁸ Increases in ICP can be caused by the following: (1) increased CSF volume due to blockage of the circulation or absorption of the CSF, as described above; (2) increased blood volume from vasodilatation or hematoma; and (3) increased brain tissue volume caused by a tumor or edema.

Figure 28-6. The effect of increasing volume on intracranial pressure. At first, as volume is increased, pressure does not increase, owing to the elastance of intracranial structures. This elastance is exceeded and then a small increase in volume can cause a large increase in intracranial pressure. (Modified from Miller JD, Garibi J, Pickard JD: The effects of induced changes of cerebrospinal fluid volume during continuous monitoring of ventricular pressure. Arch Neurol 28:265, 1973.)

Brain edema is typically classified as cytotoxic or vasogenic.²⁹ The former is due to neuronal damage, which leads to increased sodium and water in the brain cells, and therefore an increase in intracellular volume. Vasogenic edema is caused by a breakdown of the blood–brain barrier and the movement of protein from the blood into the brain's extracellular space. Water moves osmotically with the protein, increasing the extracellular fluid volume in the brain.

Pathophysiology

The brain is the organ most sensitive to ischemia; therefore, when the blood supply to the brain is limited, ischemic damage to neurons can occur.¹⁴ To understand the rationale for treatments used to protect the brain against ischemic damage, one needs an appreciation of the pathophysiologic mechanisms that may lead to this damage. The central event precipitating damage is reduced energy production due to blockage of oxidative phosphorylation. This causes ATP production per molecule of glucose to be reduced by 95%. At this rate of production, ATP levels fall, leading to the loss of energy-dependent homeostatic mechanisms. (Complete ischemia would block all ATP production.) The activity of ATP-dependent ion pumps is reduced and the intracellular levels of sodium and calcium increase, while intracellular potassium levels decrease (Fig. 28-7). These ion changes cause the neurons to depolarize and release excitatory amino acids such as glutamate. High levels of glutamate further depolarize the neurons and allow more calcium to enter through the NMDA receptor channel. The high intracellular calcium level is thought to trigger a number of events that could lead to the anoxic or ischemic damage. These include increasing the activity of proteases and phospholipases.³⁰ The latter would increase the levels of free fatty acids and free radicals. Free radicals are known to damage proteins and lipids, whereas free fatty acids interfere with membrane function. In addition, there is a buildup of lactate and hydrogen ions. All of these processes, coupled with the reduced ability to synthesize proteins and lipids due to the reduced ATP levels, may lead to irreversible damage with ischemia. In addition, phospholipase activation leads to the production of excess arachidonic acid, which, on reoxygenation, can form eicosanoids, including thromboxane, prostaglandins, and leukotrienes. Thromboxane can cause intense vasoconstriction and reduced blood flow in the postischemic period, while leukotrienes can increase edema. Thus, procedures that may protect against ischemia should interfere with these damaging mechanisms (Table 28-4). Specific agents that might accomplish these objectives will be detailed in the section on brain protection later in the chapter.

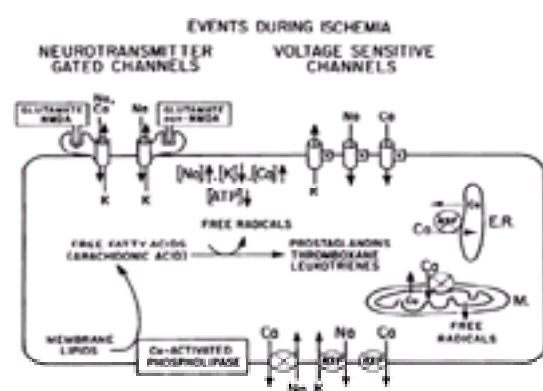

Figure 28-7. The effect of ischemia on ion and metabolite levels in neurons. For clarity, ion channels are shown on the top membrane and ion pumps on the bottom membrane; their actual location can be on any membrane surface. Circles indicate energy-driven pumps, and a crossed-through circle indicates that this pump is blocked or has reduced activity during ischemia. V indicates a voltage-dependent channel.

Maintaining ATP levels by reducing the metabolic rate
 Blocking sodium or calcium influx
 Scavenging free radicals

 Maintaining blood flow

Table 28-4. PROCEDURES THAT MAY PROTECT AGAINST ISCHEMIC DAMAGE

Ischemia can be either global or focal in nature; an example of the former would be cardiac arrest; of the latter, a localized stroke. The mechanisms leading to neuronal damage are probably similar for both, but there are important distinctions between the two. In focal ischemia there are three regions. The first receives no blood flow and responds the same as globally ischemic tissue; the second, called the *penumbra*, receives collateral flow and is partially ischemic; the third is normally perfused. If the insult is maintained for a prolonged period, the neurons in the penumbra will die. More neurons in the penumbra will survive if collateral blood flow is increased. Mechanisms such as inverse steal (described under Cerebral Blood Flow) will enhance collateral blood flow, and hence neuron survival, in focal but not global ischemia.

Epileptic activity is sudden, excessive, and synchronous discharges of large numbers of neurons. Aside from those patients with established epilepsy, this massive increase in activity is seen in patients with ionic and electrolyte imbalances, disorders of brain metabolism, infection, brain tumor, brain trauma, or elevated body temperature.³¹ The electroencephalogram (EEG) shows spikes, which are rapid changes in voltage corresponding to excess activity in many neurons. During the epileptiform activity, sodium and calcium ions enter the cells and potassium leaves. Thus the cells use more energy (ATP) for ion pumping. High extracellular potassium may be responsible for the large and progressive depolarization of the neurons that is commonly found. The mechanisms that lead to permanent neuronal damage with epilepsy may be similar to those that damage cells during ischemia. Intracellular calcium levels rise, which may precipitate the damage. It is clear that during epileptiform activity the energy demand, and hence the cerebral metabolic rate (CMR) and blood flow, increases greatly. Thus, in conditions in which blood flow to the brain may be compromised, it is imperative to avoid excess brain activity. Anticonvulsant medications increase neuronal inhibition or reduce excitatory processes in the brain. Epileptic activity may be accompanied by systemic lactic acidosis, reduced arterial oxygenation, and increased carbon dioxide; therefore, it is important to maintain ventilation, oxygenation, and blood pressure. Prolonged or recurring epileptic activity can lead to profound brain damage.

Brain trauma can directly lead to permanent physical neuronal damage. Primary damage can also be caused by brain herniation or severing of blood vessels in the brain, resulting in direct ischemia. Reversal of the primary damage is not possible; however, much of the brain injury in trauma patients is secondary and occurs following the initial insult.³² Calcium influx resulting from the trauma has been implicated as a trigger for the damage.³³ It is important to prevent the secondary ischemia that frequently follows brain trauma and is possibly due to the release of vasoconstrictive substances during reperfusion.³⁴ In addition, hemorrhage may increase intracranial blood volume and ICP, reducing CPP. The intracranial blood can be damaging by directly promoting free-radical formation using the iron in hemoglobin. Secondary damage may be reduced with proper monitoring and treatment. Treatment includes reducing ICP, maintaining blood flow, reducing vasospasm, removing blood from the subarachnoid space, and perhaps using pharmacologic agents that interfere with the cascade of events that lead to neuron damage.

Brain tumors are expanding, space-occupying lesions that may significantly increase ICP and lead to reduced CPP or brain herniation. Frequently, the blood vessels supplying the tumor have a leaky blood-brain barrier which may contribute to vasogenic brain edema and elevated ICP.

Thus, for several pathophysiologic events in the brain, ionic imbalance (particularly high intracellular calcium levels) has been implicated as a possible cause of brain damage. A common mechanism of neuronal cell death for various pathophysiologic events may exist.

NEUROANESTHESIA

Effects of Anesthetics and Other Adjunctive Drugs on Brain Physiology

Volatile Anesthetics

Halothane, enflurane, sevoflurane, desflurane, and isoflurane have direct vasodilatory effects that increase CBF (Table 28-5). Halothane with nitrous oxide (1.5 MAC) has been shown to increase blood flow almost 65%, whereas enflurane and isoflurane have a lesser effect at equal anesthetic potency.³⁵ Enflurane increased blood flow approximately 35%; isoflurane caused an even smaller increase. The increase in CBF returns to baseline levels approximately 3 hours after the initial exposure to 1.3 MAC of anesthetic.³⁶ Sevoflurane and desflurane appear similar to isoflurane with respect to CBF.^{37,38} and ³⁹ The importance of increased CBF is its influence on ICP. Increasing blood flow would tend to increase the amount of blood in the head, which could lead to increases in ICP under conditions of abnormal intracranial elastance. The volatile anesthetics reduce the CMR; isoflurane reduces the metabolic rate to a greater extent than halothane.⁴⁰ Sevoflurane and desflurane are similar to isoflurane. It is thought that isoflurane's metabolic effect, which reduces CBF, competes with its direct vasodilatory action to limit the net increase in CBF with this agent. Enflurane has been shown to induce seizure-type discharges; this effect is potentiated by hypocapnia. Seizures induced with 1.5 MAC enflurane, hypocapnia, and an auditory stimulus increased CMR and blood flow by 50%.⁴¹ The main advantage of desflurane over isoflurane is a faster onset and recovery from anesthesia. Studies have indicated that it can cause greater ICP increases than isoflurane in patients with altered intracranial elastance.⁴² Therefore, it is not recommended for patients with space-occupying lesions. Desflurane has also been shown to cause sympathetic hyperactivity in healthy volunteers.⁴³ Sevoflurane has the potential for toxicity, since it can be converted to toxic agents; however, the concentration of these agents is normally below the toxic threshold.⁴⁴ Sevoflurane has been shown to be a useful alternative to halothane for pediatric induction if given with nitrous oxide.⁴⁵ Sevoflurane demonstrated cerebral protection during incomplete ischemia in rats when compared to fentanyl with nitrous oxide.⁴⁶ These considerations make sevoflurane and isoflurane the volatile anesthetics of choice for neuroanesthesia. However, both of these agents are vasodilators and have the potential to increase ICP under certain circumstances.^{47,48}

| | CBF | CMRO ₂ | Direct Cerebral Vasodilation |
|--|-----|-------------------|------------------------------|
| Halothane | ↑↑↑ | ↓ | Yes |
| Enflurane | ↑↑ | ↓ | Yes |
| Isobarane | ↑↑ | ↓ | Yes |
| Desflurane | ↑↑ | ↓ | Yes |
| Sevoflurane | ↑↑ | ↓ | Yes |
| N ₂ O alone | ↑↑ | ↓ | — |
| N ₂ O with volatile anesthetic | ↑↑ | ↓ | — |
| N ₂ O with intravenous anesthetic | 0 | 0 | — |
| Thiopental | ↓↓↓ | ↓↓↓ | No |
| Etomidate | ↓↓↓ | ↓↓↓ | No |
| Propofol | ↓↓↓ | ↓↓↓ | No |
| Midazolam | ↓↓↓ | ↓↓↓ | No |
| Ketamine | ↑↑ | ↑↑ | Yes |
| Fentanyl | ↓/0 | ↓/0 | No |

Table 28-5. EFFECTS OF ANESTHETICS ON CBF/CMRO₂

Nitrous oxide can increase CBF and ICP.^{49,50} Barbiturates and hypocapnia in combination may prevent these increases. There are indications that, even when given independently, barbiturates, benzodiazepines, and morphine are effective in blunting nitrous oxide's effect on CBF and ICP.^{51,52} In contrast, a volatile anesthetic may add to the increases in CBF obtained with nitrous oxide.⁵³ Although the data on nitrous oxide's effect on brain metabolism are far from unequivocal, the evidence seems to indicate that there can be a substantial increase in CMR if nitrous oxide is administered alone.⁴⁹ Although nitrous oxide is commonly used in neuroanesthesia, its use should be carefully considered given its potential effects on CBF, CMR, and ICP.⁵⁴

Intravenous Anesthetics

Barbiturates decrease the CMR and CBF.^{55,56} A major problem with barbiturates is that they can substantially reduce MAP, which, if not controlled, can reduce CPP. At high doses (10–55 mg · kg⁻¹), thiopental can produce an isoelectric EEG and decrease the CMR by 50%.⁵⁶ This direct metabolic effect of thiopental leads to constriction of the cerebral vasculature and thereby reduces CBF. Barbiturates are also effective in reducing elevated ICP and controlling epileptiform activity.⁵⁷ Methohexital is an exception with regard to epileptiform activity; it can activate some seizure foci in patients with temporal lobe epilepsy.⁵⁸

Etomidate, like the barbiturates, reduces CMR and CBF.^{59,60} and ⁶¹ In addition to the indirect effect of reduced cerebral metabolism on blood flow, etomidate is also a direct vasoconstrictor even before metabolism is suppressed.⁶⁰ Its advantage over the barbiturates is that it does not produce clinically significant cardiovascular depression. Prolonged use of etomidate may suppress the adrenocortical response to stress.⁶²

Propofol is a rapidly acting intravenous anesthetic that, like etomidate and the barbiturates, reduces the CMR and CBF.^{63,64} and ⁶⁵ It is able to reduce ICP; however, because it also reduces MAP, its effect on CPP must be carefully monitored.⁶⁶ Propofol demonstrated longer-lasting ventilatory depression when compared with barbiturates.⁶⁷

Benzodiazepines have been shown to reduce CMR and CBF;^{68,69} however, this effect is not as pronounced as that with the barbiturates. As with the barbiturates, the blood flow reduction by benzodiazepines is thought to be secondary to a reduction in CMR. Benzodiazepines may reduce ICP owing to their effect on CBF. Flumazenil is a benzodiazepine antagonist that has been shown to reverse the CMR, CBF, and ICP lowering effects of the benzodiazepine midazolam.⁷⁰ Thus, flumazenil should be used cautiously, if at all, in patients with high ICP or abnormal intracranial elastance.

The opioid anesthetics, morphine and fentanyl, cause either a minor reduction or no effect on CBF and CMR when compared with conditions in the unstimulated brain;^{71,72} however, if the patient is aroused or in pain, they can cause a modest reduction in these parameters.⁷³ There is controversy concerning the effects of sufentanil: some studies demonstrate a reduction in CBF and metabolism,^{74,75} whereas others report an increase in blood flow and ICP.^{76,77} The latter study found no increase in ICP with fentanyl.⁷⁷ The duration of the increased blood flow and ICP effects of sufentanil in the above studies was short and could be overcome by hypocapnia. In animal studies, alfentanil decreased CBF and metabolism after 35 minutes and had no significant effect on ICP.⁷⁸ In patients with brain tumors, alfentanil increased CSF pressure.⁷⁹ Its effect on CSF pressure was less than that found with sufentanil but greater than that found with fentanyl. Alfentanil had the greatest effect on MAP and CPP.⁷⁷ Remifentanyl, a rapidly metabolized opioid, had similar effects to fentanyl on CBF; both agents maintained CO₂ reactivity.⁸⁰ Remifentanyl's main advantage is that it allows a more rapid neurologic assessment of the patient.

Ketamine, a dissociative anesthetic, activates certain areas in the brain and can increase CBF and CMR.^{81,82} and ⁸³ It is therefore not commonly used in neuroanesthesia.

Barbiturates, propofol, and benzodiazepines are intravenous agents recommended for neuroanesthesia; opioids, particularly fentanyl and remifentanyl, have also proved useful.

BRAIN PROTECTION

Morbidity and mortality rates for elective neurosurgery are so low that detecting a decrease in mortality is virtually out of the question and daunting sample sizes would be required to detect even a 30% improvement in major morbidity. Accordingly, we are limited to drawing inferences from the laboratory, from clinical trials of therapies that are instituted subsequent to ischemic injury—primarily in stroke and head trauma patients—and from a small number of trials that test for prophylactic neuroprotection.

Mild Hypothermia

Laboratory results have demonstrated since 1956⁸⁴ that the beneficial attributes of mild hypothermia are likely to outweigh its real but manageable untoward effects when neurosurgical procedures are high risk and/or protracted. Berntman *et al* found that one degree of hypothermia (to 36°C) maintains ATP at normoxic levels during a hypoxic insult that depletes ATP by half at normothermia (37°C), and three degrees of hypothermia (to 34°C) more than doubled preservation of phosphocreatine.⁸⁵ These results suggest that the initial decline of cerebral metabolic rate (CMR) during hypothermia is greater than has been previously assumed.^{86,87}

The protection afforded by intra-ischemic mild hypothermia has been attributed to reduction of calcium entry, reduction of glutamate release, reduction of glycine and dopamine release, recovery of ubiquitin synthesis, inhibition of protein kinase C, and reduction of free-radical-triggered lipid peroxidation. However, the protection afforded by intra-ischemic mild hypothermia is likely to be attributable to diminution of all the deleterious consequences of ischemia and the consequent relative preservation or restoration of favorable conditions, because the reduction in CMR that occurs during mild hypothermia retards and diminishes the primary synergists of the ischemic cascade.^{86,87}

A survey conducted in 1993–1994 indicates that more than 40% of neuroanesthesiologists already use mild (33–35°C) to moderate (28–32°C) intraoperative hypothermia, 26% use hypothermia in every patient, and 14% think it is unethical to continue to use normothermia.⁸⁸ A multi-institutional clinical trial of intraoperative mild hypothermia for elective neurosurgical cases is underway, with encouraging preliminary data.⁸⁹ Until those results are available, mild hypothermia remains a neurosurgical option rather than a standard of care. In contrast, the data are available on mild hyperthermia. A few bouts of postoperative hyperthermia can undo all of the advantages of intraoperative hypothermia, and/or degrade the condition of normothermic patients.^{90,91,92,93} and ⁹⁴

Our guess is that the future of intraoperative mild hypothermia is quite promising. Likewise, for head injury patients, moderate hypothermia in the ambulance may be within the window of opportunity for neuroprotection.

Anesthetic and Adjuvant Drugs

Clinically verified pharmacologic brain protection is even more elusive than the benefits of mild hypothermia. Nevertheless, as with hypothermia, reducing CMR is the mainstay of cerebral protection.

Barbiturates

Some of the proximate mechanisms by which barbiturates lower CMR include reduction of calcium influx, sodium channel blockade, inhibition of free-radical formation, potentiation of GABAergic activity, and inhibition of glucose transfer across the blood–brain barrier. All of these mechanisms are consistent with Goodman and coauthors' report that pentobarbital coma markedly reduces lactate, glutamate, and aspartate in the extracellular space of head-injured patients with severely increased ICP.⁹⁵ An *in vitro* investigation suggests that thiopental also delays the loss of transmembrane electrical gradients caused by application of NMDA and AMPA. This stands in marked contrast to the effect of propofol, which can aggravate glutamate excitotoxicity and increase neuronal damage.⁹⁶ Unfortunately, the only clinical trial providing evidence of barbiturate protection remains that of Nussmeier and coauthors.⁹⁷

Calcium Channel Blockers

Several clinical trials and two meta-analyses suggest that calcium channel blockers—nimodipine, nicardipine, and AT877—reduce the frequency of vasospasm subsequent to subarachnoid hemorrhage and/or improve outcome.^{98,99} The most favorable finding of the most recent meta-analysis suggests that nimodipine improves outcome, on average, by preventing one poor outcome in 1 of every 13 patients treated.⁹⁹ Whether the reduction in blood pressure that accompanies these Ca blockers improves outcome relative to hypertensive, hypervolemic hemodilution remains controversial. Neither meta-analysis was able to detect a statistically significant reduction in mortality.

Magnesium loading for cerebral protection is receiving renewed enthusiasm,¹⁰⁰ and more than 600 patients have been randomized in an ongoing study designed to test efficacy in 2700 patients.¹⁰¹ Magnesium blocks both ligand- and voltage-dependent Ca entry and has shown considerable promise in *in vivo* experiments.^{102,103} The fact that magnesium is also powerfully protective *in vitro* suggests that it may critically reduce calcium influx, as distinct from primarily improving CBF subsequent to cerebrovascular dilation, as may be the case with nimodipine.¹⁰⁴ Nelson and Grether's retrospective finding that *in utero* exposure to MgSO₄ was more frequent in very low–birth-weight children without cerebral palsy than in low–birth-weight children with cerebral palsy also implies a potential for broad spectrum efficacy.¹⁰⁵

Steroids

Clinical application of the 21-amino steroid tirilazad has also shown tentative promise.¹⁰⁶ Unfortunately, recent results from a North American trial of tirilazad subsequent to subarachnoid hemorrhage failed to reach statistical significance.¹⁰⁷ This discrepancy may be due to the preponderant use of phenytoin in the NA trial (80% of patients), as phenytoin has been shown to increase clearance of tirilazad by 50% in healthy volunteers.¹⁰⁸ Tirilazad did not compare favorably with methylprednisolone in a recent clinical trial for acute spinal cord injury.¹⁰⁹

Additional Clinical Trials

Remacemide reduces glutamate release, and hence excitotoxicity, by blocking NMDA channels. Evidence for a prophylactic beneficial effect of this NMDA blocker was gleaned by combining scores from nine neuropsychological tests in coronary artery bypass patients. Those data allow the inference ($p < 0.03$) that in exchange for a higher risk of dizziness during nine days of drug administration, patients in the treatment group retained more of their ability to learn.¹¹⁰

Piracetam,¹¹¹ a nootropic agent that may increase compromised cerebral blood flow; ebselen,¹¹² an antioxidant that may reduce exotoxicity; and cerebrolysin,¹¹³ a porcine brain tissue hydrolysate containing a mixture of 85% free amino acids and 15% small peptides, have all shown encouraging results in preliminary clinical stroke trials. Similarly promising results have been obtained with neurotrophic insulin-like growth factor (IGF-I) in a subset of head injury patients.¹¹⁴

Sodium Channel Blockers—From the Laboratory

Sodium channel blockers have shown particular promise in laboratory investigations.¹¹⁵ Like barbiturates, riluzole reduces Na influx and also reduces glutamate release during ischemia.¹¹⁶ Riluzole has shown protective effects in gerbils after global ischemia and in rats after focal ischemia when administered subsequent to initiation of the cerebral insult.^{117,118} Most recently, riluzole has demonstrated neuroprotective effects in a rabbit model of experimental spinal cord ischemia.¹¹⁹ Riluzole also appears to be efficacious in the treatment of amyotrophic lateral sclerosis in humans.¹²⁰

Lamotrigine, an anticonvulsant that blocks voltage-gated sodium channels, has also shown cerebroprotective properties after experimental middle cerebral artery occlusion¹²¹ and after transient global ischemia.¹²² An even more promising usedependent sodium channel blocker, BW619C89, has demonstrated efficacy against experimental focal ischemia, global ischemia, subdural hematoma, middle cerebral artery occlusion, and traumatic brain injury. A single oral dose of BW619C89 given prior to permanent middle cerebral artery occlusion provided substantial long-term protection in rats.¹²³

What to Avoid

The evidence against some current practices and anesthetics is stronger than the evidence in their favor.

Post-Injury Hypothermia

Overenthusiasm and extension of hypothermia beyond where laboratory evidence indicates a window of opportunity is a real concern. Although hypothermia may be the most potent technique at our disposal for prophylactic cerebral protection, Dietrich and coauthors' experimental results,¹²⁴ and more recently those of Yubo *et al*,¹²⁵ indicate that hypothermia administered after an ischemic event only delays neuronal death. Recent clinical trials of moderate hypothermia after head injury are encouraging, but none of them has shown a statistically significant improvement in outcome,^{126,127,128} and 129 and reported trends are of a magnitude that could be expected from the elimination of bouts of hyperthermia in the hypothermic groups in combination with comparatively lax temperature control in “normothermic” groups.

The authors of the largest published study of moderate hypothermia interpreted their findings to “suggest an improved outcome 12 months after the injury” in a subgroup of patients with initial Glasgow Coma Scale scores (GCS) of 5–7.¹²⁹ Unfortunately, that inference ignored the authors' own logistic regression analysis, which shows that this result may have been an artifact of initial differences in the computed tomographic classes of patients assigned to the hypothermic vs. normothermic groups.¹³⁰ Another recent report draws an encouraging inference about mild postischemic hypothermia; even though there was no normothermic control group, 10 out of 25 patients contracted pneumonia, and 9 patients died.¹³¹ Results from a recent multicenter trial of moderate hypothermia in head-injured patients are yet to be published, but the trial was terminated after enrollment of 392 patients because morbidity and mortality were higher in the hypothermic group and suggestive improvements in outcome within subgroups of patients were not sufficient to meet pre-established continuation criteria.¹³²

Despite this lack of empirical support, a 1998 survey indicates that 34% of today's neurosurgeons advocate the use of moderate hypothermia for 24 hours in the ICU after head trauma.¹³³ One worries that the desire to help head-injured patients is interfering with the objective analysis of data.¹³⁴

Etomidate

EEG burst suppression with etomidate prior to temporary vessel occlusion gained prominence 11 years ago on the basis of a clinical trial for which there was no control group, no alternative drug tested, and no historical standard for comparison.¹³⁵ Despite the absence of supportive clinical evidence and the presence of troubling laboratory results,¹³⁶ etomidate remains the standard regimen for cerebral protection at several institutions.¹³⁷ We now have clinical evidence that the standard propylene glycol formulation of etomidate¹³⁸ induces more cerebral tissue hypoxia, tissue acidosis, and neurologic deficits than does an EEG-equivalent dose of desflurane.¹³⁹

Nitrous Oxide and Ketamine

In 1938, C. D. Courville published “The pathogenesis of necrosis of the cerebral gray matter following nitrous oxide anesthesia”—an article that presented photographs of vacuolated cortical neurons from patients who died subsequent to administration of nitrous oxide (N₂O).¹⁴⁰ Sixty years later, JevtovicTodorovic and coauthors published compelling evidence that N₂O causes vacuolation of both the endoplasmic reticulum and mitochondria of neurons in the posterior cingulate and retrosplenial cortices of rats.¹⁴¹ Are we on our way to where we might have been if Courville's work had received more sustained attention?

Nitrous oxide's mechanism of action appears to be NMDA receptor antagonism, and like other NMDA antagonists, N₂O has been shown to reduce damage from excessive glutamate release. Also like other NMDA antagonists, including “angel dust” and MK-801, N₂O can cause neural damage in and of itself.^{141,142} In patients with folic acid deficiency, a single exposure to N₂O has caused spinal cord degeneration.¹⁴³ Less direct, but also less rare, brief exposure to N₂O causes a substantial increase in plasma homocysteine,¹⁴⁴ which can increase coagulation¹⁴⁵ and decrease flow-mediated vasodilation¹⁴⁶—either of which could complicate recovery in a neurosurgical ICU patient. Prolonged hyperhomocysteinemia is an independent risk factor for cerebrovascular disease.¹⁴⁷

In comparison to the highly variable degree of cerebral protection probably provided by all anesthetics whose primary mechanism of action is activation of GABA receptors, N₂O is likely to be deleterious. This has been shown experimentally in reference to isoflurane^{148,149} and methohexital,¹⁵⁰ but in defense of clinical N₂O use, it has been argued that “co-administration of agents that are known to activate or potentiate the GABA receptor appears to block the neurotoxic effects of NMDA antagonists.”¹⁵¹ Accordingly, Jevtovic-Todorovic *et al* found that pretreatment with pentobarbital nearly eliminated the toxic effect of N₂O in rats—but that was not under the condition of cerebral ischemia.¹⁴¹

While neuroanesthesiologists are familiar with the ability of barbiturates to reduce ischemic damage, the question is whether N₂O diminishes the protective effect of primary anesthetics in the event of cerebral ischemia. That question has been inadvertently addressed by investigations of barbiturate neuroprotection. For example, in 1966 Goldstein *et al* found substantial prophylactic barbiturate protection using a well controlled and highly regarded experimental model¹⁵²; but when Steen *et al* tried to replicate that finding in 1979, they changed the experimental protocol to include administration of N₂O and failed to find cerebral protection.¹⁵³

In a 1984 report that also used N₂O and failed to find cerebroprotection in a primate model, Gisvold *et al* did not proffer an explanation for the Goldstein–Steen discrepancy, but did comment that: “Although N₂O may not be as indifferent as hitherto believed, it is most unlikely that it should offset a beneficial effect of the barbiturate.”¹⁵⁴ This prevailing assumption prompted examination of 32 published investigations of barbiturate protection. Twenty-one of 24 papers that used little or no N₂O found protection while 6 of 8 papers that co-administered substantial N₂O failed to find protection ($p < 0.01$).¹⁵⁵

The question of N₂O's effect on the neuroprotective effect of primary anesthetics has been addressed more directly by several investigations. Following Arnfred and Secher's demonstration that thiopental more than doubles survival time in mice subjected to hypoxia¹⁵⁶ while N₂O used alone reduces survival,¹⁵⁷ we found that co-administration of N₂O virtually eliminates the protective effect of thiopental in the same model.^{155,158,159} Two years later, Baughman and coauthors found that 0.5 MAC N₂O added to either 1 MAC or 0.5 MAC isoflurane cut the protective effect of isoflurane in half relative to the effect of 0.5 MAC N₂O alone during moderate forebrain ischemia.¹⁴⁹ More recently, Sugaya and Kitani reported that N₂O attenuates the protective effect of isoflurane on preservation of a critically important neuronal cytoskeletal protein during forebrain ischemia in the rat.¹⁶⁰ Most recently, Jevtovic-Todorovic and coauthors found that the adverse effects of ketamine are multiplied 5-fold in the presence of what would otherwise be an ineffective dose of N₂O in their rat model.¹⁶¹

Evidence that the above clinical and *in vivo* laboratory findings resulted in part from a direct neurotoxic effect of N₂O is provided by findings in the hippocampal slice model, where nitrous oxide markedly reduced electrophysiologic recovery from severe hypoxia without affecting fundamental biochemical parameters like ATP concentration, Ca influx, K efflux, and Na influx.¹⁶²

Direct neurotoxicity aside, N₂O has been repeatedly shown to increase cerebral metabolic rate (CMR), cerebral blood flow (CBF), and intracranial pressure (ICP) when used alone; but these effects are variable when N₂O is used as an adjunct anesthetic, with or without hypocapnia and with or without EEG burst suppression. The CBF/CMR issue presented by N₂O has been articulated in reference to barbiturates and midazolam: “If N₂O elevates cerebral metabolism without causing a concomitant increase in CBF during barbiturate anesthesia, as it has been shown to do during midazolam anesthesia, the resulting mismatch between CBF and CMRO₂ could be critical during O₂ deprivation.”¹⁶³

Prospects

Until evidence is sufficient to warrant a standard-of-care recommendation for prophylactic cerebral protection, each clinician must proceed on a best-guess basis. Our guess is that mild hypothermia is useful, that magnesium loading is promising, and that etomidate, nitrous oxide, ketamine, and post-injury hypothermia should be avoided.

MONITORING

Electroencephalogram

The EEG can be used to monitor cerebral function during general anesthesia. The primary use of intraoperative EEG monitoring is the detection of cerebral ischemia during carotid endarterectomy, cerebral aneurysmectomy with temporary clip application, cardiopulmonary bypass, and extracranial–intracranial bypass procedures. EEG monitoring is also used for intraoperative or perioperative assessment of pharmacologic interventions, such as barbiturate-induced burst suppression, during deliberate hypotension, and for the assessment of coma or brain death. Another important intraoperative application of EEG is in the diagnosis and management of intractable epilepsy.

The EEG waves recorded on the surface of the scalp are spontaneous electrical potentials generated by the pyramidal cells of the granular cortex. The EEG signal consists of graded summations of inhibitory and excitatory postsynaptic potentials that create dipole fields in the dendrites of the pyramidal cells.¹⁶⁴ When a number of dipoles develop at once, the summation creates electrical potentials large enough to produce detectable voltage on the scalp.

The EEG waveforms are interpreted by pattern recognition and quantification. Specific complexes are described in terms of morphology, spatial and temporal distribution, and reactivity of the waveforms. Quantification involves measuring frequency and amplitude. Frequency is measured in Hertz (Hz) and is defined as the number of times per second the wave crosses the zero voltage line. Amplitude, which is measured in microvolts (mV), is the electrical height of the wave. The frequency bands are divided into delta (0–3 Hz), theta (4–7 Hz), alpha (8–13 Hz), and beta (>13 Hz) rhythms (Table 28-6).

| | |
|------------------------|---|
| Delta rhythm (0–3 Hz) | Deep sleep, deep anesthesia, or pathologic states (e.g., brain tumors, hypoxia, metabolic encephalopathy) |
| Theta rhythm (4–7 Hz) | Sleep and anesthesia in adults, hyperventilation in awake children and young adults |
| Alpha rhythm (8–13 Hz) | Resting, awake adult with eyes closed; predominantly seen in occipital leads |
| Beta rhythm (>13 Hz) | Mental activity, light anesthesia |

Table 28-6. EEG FREQUENCY RANGES

The traditional EEG is a plot of voltage against time. Sixteen channels are usually recorded, allowing analysis of activity of different regions of the brain. EEG waveform changes associated with anesthetic drugs, PaO₂, PaCO₂, and temperature are described in Table 28-7.

| | |
|--|---|
| Increased Frequency Barbiturates (low dose) Benzodiazepines (low dose) Etomidate (low dose) Propofol (low dose) Ketamine N ₂ O (30–70%) Inhalation agents (<1 MAC) Hypoxia (initially) Hypercarbia (mild) Seizures Decreased Frequency/Increased Amplitude Barbiturates (moderate dose) Etomidate (moderate dose) Propofol (moderate dose) Opioids Inhalation agents (>1 MAC) Hypoxia (mild) Hypercarbia (moderate to extreme) Hypothermia | Decreased Frequency/Decreased Amplitude Barbiturates (high dose) Hypoxia (mild) Hypercarbia (severe) Hypothermia (<35°C) Electrical Silence Barbiturates (coma dose) Etomidate (high dose) Propofol (high dose) Desflurane (2 MAC) Isoflurane (2 MAC) Sevoflurane (2 MAC) Hypoxia (severe) Hypothermia (<15–20°C) Brain death |
|--|---|

Table 28-7. EEG CHANGES ASSOCIATED WITH ANESTHETIC DRUGS, PaO₂, PaCO₂, AND TEMPERATURE

The EEG response to anesthetic agents can vary from cortical excitation through depression to isoelectricity. Usually, anesthetic induction produces a decrease in alpha and an increase in beta activity. As the depth of anesthesia increases, EEG frequency decreases until theta and delta activity predominate. By further increasing the dose of anesthesia, the EEG changes to a burst suppression pattern, which coincides with near-maximal depression of cerebral metabolic activity. Complete electrical silence or isoelectricity follows an additional increase in anesthesia. Anesthesia-induced burst suppression is used to provide cerebral protection by metabolic suppression. EEG monitoring verifies burst suppression and electrical silence, and is valuable when determining the dose of drug required to induce and maintain the coma.

Efforts to use the EEG as a monitor of depth of anesthesia have been problematic because of the variety of agents used during an anesthetic and because some anesthetic agents do not follow the general pattern described above (Fig. 28-8).^{41,165} Current techniques using processed EEG in combination with facial muscle activity show promise for the assessment of anesthetic depth and detection of conditions that may reduce intraoperative awareness.¹⁶⁶

Figure 28-8. EEG changes with increasing doses of fentanyl and alfentanil. Awake: mixed alpha (8–13 Hz) and beta (>13 Hz) activity; Stage 1: slowing with alpha spindles; Stage 2: more slowing, theta activity present (4–7 Hz); Stage 3: maximal slowing, delta waves present (<4 Hz) with high amplitude. (Reprinted with permission from Scott JC, Ponaganis KV, Stanski DR: EEG quantification of narcotic effect: The comparative pharmacodynamics of fentanyl and alfentanil. *Anesthesiology* 62:234, 1985.)

Intraoperative EEG monitoring allows early detection of cerebral hypoxia and ischemia. Inadequate PaO₂ or insufficient CBF is reflected within seconds in the EEG.^{167,168} Hypoxia may initially produce EEG activation, which is followed by slowing and eventually electrical silence.¹⁶⁸

Other physiologic parameters that affect EEG waveforms are PaCO₂, temperature, and sensory stimulation. Hypocarbica causes EEG slowing. Mild hypercarbia causes increased frequency, and severe hypercarbia produces a decrease in frequency and amplitude. When body temperature falls below 35°C, hypothermia causes a progressive slowing of activity. Complete electrical silence occurs at 15–20°C. Sensory stimulation is associated with EEG activation.

When monitoring an EEG during anesthesia, the changes resulting from hypoxia or ischemia must be distinguished from the drug and physiologic effects that also may influence the EEG. Because of this, the EEG must always be interpreted within the clinical context in which it is observed.

A specific intraoperative application of the EEG, called *electrocorticography* (EcoG), is the localization of epileptic foci during surgery for intractable epilepsy. For these procedures, recording electrodes are applied on or in the brain. The craniotomy can be performed under local anesthesia with conscious sedation (typically using propofol or fentanyl and droperidol) or under a light general anesthetic. The anesthetic administered must avoid pharmacologic cortical depression, which would prevent provocative seizure activity. Provocative techniques and agents, such as hyperventilation, low-dose barbiturates (methohexital 10–50 mg, thiopental 25–50 mg), propofol 10–20 mg, or etomidate 2–4 mg, have been used to activate the foci.¹⁶⁹ If the patient is under general anesthesia, alfentanil 20–50 mg · kg⁻¹ and enflurane can be used.

Computerized EEG Processing

The development of the computer-processed EEG has facilitated intraoperative EEG monitoring. The most widely used and best validated technique is *power-spectrum analysis*, which uses a computer to perform a Fourier transformation. A given epoch of EEG (usually 2–8 seconds) is converted from a plot of voltage against time to a plot of power (amplitude squared) against frequency. With this technique, data are displayed in one of three formats: the compressed spectral array, the density spectral array, and the band spectral array or power bands. For example, to generate the compressed spectral array format, the Fourier transformation converts the irregular EEG waves to equivalent sine waves of known frequency and power (Fig. 28-9).¹⁶⁷ This display shows time and power as one axis (vertical) and frequencies on the horizontal axis. The Fourier spectral data from successive segments are stacked one on top of the other, creating a pseudo three-dimensional display; that is, the plot is shifted vertically with time and compressed. A major advantage of power-spectrum analysis is that it retains almost all the information in the original EEG. Power-spectrum analysis has documented value as a monitor of cerebral ischemia and possible value in the determination of anesthetic depth.^{166,170,171} The main disadvantages of this analysis technique are lack of detection of spike activity, inclusion of artifact within frequency bands, and limited review of raw EEG data to determine reliability of the ongoing input.

Figure 28-9. Schematic diagram of technique used to generate compressed spectral array. Below the diagram is an example of compressed spectra of the alpha rhythm from a normal subject. (Reprinted with permission from Stockard JJ, Bickford RG: The neurophysiology of anesthesia. In Gordon E [ed]: *A Basis and Practice of Neuroanesthesia*, 2nd ed, pp 3–49. Amsterdam, Elsevier, 1981.)

An early method used for processing the EEG was the zero-cross analysis. The zero-cross frequency, or mean frequency, of the EEG is estimated by counting the number of times the EEG waveform crosses the zero-voltage axis.¹⁶⁶ Aperiodic analysis is a variant of the zero-cross method. With this technique, each waveform is analyzed in relation to its frequency, amplitude, and time of occurrence. Aperiodic analysis does not rely on averaging many waveforms over a given epoch. The signal is broken into the four component frequencies, with the amplitudes at each frequency in each hemisphere displayed. Aperiodic analysis of the EEG can be used quite effectively to detect the presence of intraoperative cerebral ischemia (Fig. 28-10).¹⁷²

Figure 28-10. EEG as displayed by a Lifescan™ monitor using aperiodic analysis. This photograph was obtained approximately 3 minutes after occlusion (marked “XC”) of the left carotid artery. Frequency is displayed on the x axis. The amplitude of each mapped EEG wave is a vertical “pole.” Time is displayed on the diagonal axis, with the most recent time at the bottom front of the box. This display shows attenuation of activity on the left with occlusion that is more apparent in the higher frequency range. The regional cerebral blood flow with occlusion was $9 \text{ ml} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$. (Reprinted with permission from Spackman TN, Faust RJ, Cucchiara RF et al: A comparison of aperiodic analysis of the EEG with standard EEG and cerebral blood flow for detection of ischemia. *Anesthesiology* 66:229, 1987.)

Several technical matters must be considered to effectively implement intraoperative electrophysiologic monitoring. Awake controls should be obtained before induction of general anesthesia. Monitoring should be continuous throughout anesthesia and continue until the patient is awake. Bilateral data must be obtained, especially during cerebrovascular procedures. For example, during a carotid endarterectomy, bilateral changes may indicate anesthetic or systemic effects, whereas ipsilateral changes on the operated side are more likely consistent with surgical trauma or ischemia. Marked changes in anesthetic depth, systemic blood pressure, PaCO_2 , and brain temperature must be avoided in order to distinguish between anesthetic and physiologic effects on the EEG and those due to hypoxia or ischemia.

Evoked Potentials

Evoked potentials are used intraoperatively to monitor the integrity of specific sensory and motor pathways. Sensory evoked potentials (SEPs) evaluate the functional integrity of ascending sensory pathways, whereas motor evoked potentials (MEPs) test the functional integrity of descending motor pathways.

There are major differences between evoked potentials and the EEG. The EEG is a recording of spontaneous, random electrical activity that has a nonspecific function and generates a relatively large signal, e.g., 50 mV or more. Evoked potentials are comparatively small-amplitude responses (0.1–20 mV) to a specific stimulus that are pathway-specific.

Sensory Evoked Potentials

The application of a sensory stimulus—a click, a flash, a shock—results in an afferent nerve impulse that can be detected by appropriately placed surface electrodes as transient potential differences. The amplitude of these evoked potentials is very small and obscured by normal background bioelectric activity from the EEG, electrocardiogram (ECG), muscle activity, and other extraneous electrical activity. Signal averaging is required to extract the evoked responses from this background noise. The background noise is random and is eliminated by the averaging process.

Three SEP modalities are employed clinically: *somatosensory* (SSEP), *auditory* (BAEP), and *visual* (VEP). The waves of the evoked potential are thought to represent potentials from specific neural generators. The individual peaks in the waveform are described in terms of polarity (negative, positive), post-stimulus latency (msec), and peak-to-peak amplitude (mV or nV). They are also described by the distance separating the neural generators and recording electrodes (near-field, far-field).

Anesthetic Considerations for Sensory Evoked Potential Recording. Compromise or injury of a neurologic pathway is manifested as an increase in the latency and/or a decrease in the amplitude of evoked potential waveforms. For SSEPs, a 50% reduction in amplitude from baseline in response to a specific surgical maneuver is considered to be a significant change warranting action to avert potential damage. For BAEPs, an increase in latency of more than 1 millisecond is considered clinically significant. Accordingly, anesthetic, physiologic, and environmental factors capable of producing this pattern of alteration must be controlled when recording evoked potentials. All anesthetics that have been studied influence evoked potentials to some extent. Table 28-8 summarizes the known effects of intravenous and inhaled agents.^{173,174,175,176,177,178,179,180,181,182,183,184,185,186,187,188,189,190,191,192,193,194,195,196} and ¹⁹⁷ The sensitivity of evoked potentials to drug effects varies with the sensory modality being monitored. Evoked potentials of cortical origin (i.e., the cortical component of the somatosensory evoked potentials [SSEP] and visual evoked potentials [VEP]) are more vulnerable to anesthetic influences than brain stem potentials (e.g., brain stem auditory evoked potentials [BAEP] and the subcortical components of SSEP). In general, to obtain satisfactory intraoperative SEP recordings, it is important to maintain constant anesthetic drug levels. Specifically, bolus administration of intravenous agents and step changes in inspired inhalation agent concentration must be avoided, especially at times when neurologic injury might occur. When recording cortical evoked potentials (SSEPs or VEPs), one should employ intravenous techniques. High concentrations of volatile agents essentially eliminate cortical evoked potentials. However, end-tidal concentrations of 0.5 MAC of a volatile agent are compatible with satisfactory recordings in patients who are neurologically normal.

| Agent | SSEP | | BAEP | | VEP | |
|---------------------------|------|------|------|------|-----|------|

Table 28-8. EFFECTS OF INTRAVENOUS AND INHALED AGENTS ON SENSORY EVOKED POTENTIALS

In general, volatile agents cause a dose-dependent increase in latency and a decrease in amplitude of the cortical SSEP or VEP.^{173,174,175,176} and ¹⁷⁷ As exemplified in a study by Peterson et al (Fig. 28-11), reductions in SSEP amplitude greater than 50% were observed with 1 MAC halothane, 0.5 MAC enflurane, and 0.5 MAC isoflurane, all administered with 60% nitrous oxide in oxygen.¹⁷³ The authors concluded that halothane disrupted the SSEP the least, and enflurane disrupted the most. The effects of inhalation agents on VEPs are similar to the effects on cortical SSEPs.^{175,176} and ¹⁷⁷ Nitrous oxide alone has been shown to produce significant decreases in amplitude with minimal latency changes in the cortical SSEP, but it decreases amplitude and increases latency in the VEP.^{178,179} and ¹⁸⁰ When nitrous oxide is administered in combination with a volatile anesthetic, it produces a profound depressant effect on SSEPs or VEPs.

Figure 28-11. The responses of cortical somatosensory evoked potentials to various minimal alveolar concentrations (MACs) of halothane, enflurane, and isoflurane. A marked alteration of evoked potentials occurs at 1 MAC and higher levels of inhaled agents, and a modest improvement of the response occurs when N₂O is withdrawn. (Reprinted with permission from Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on multilevel somatosensory evoked potentials. *Anesthesiology* 65:35, 1986.)

Brain stem responses are considerably more resistant to anesthetic influences than are cortical responses. For example, clinically used concentrations of the inhaled agents tend to increase the latencies of early or subcortical peaks of the BAEP with minimal amplitude effects.^{181,182 and 183} Most anesthetic regimens are compatible with recording of brain stem responses. However, as with the other evoked potential modalities, large step changes (greater than 0.5 MAC) in inspired inhalation agent concentration should be avoided during critical periods.

Studies on the effects of intravenous agents demonstrate that induction doses of thiopental, etomidate, and fentanyl preserve SSEP recordings.¹⁸⁴ Increasing doses of thiopental result in dose-dependent increases in latency and decreases in amplitude in cortical SSEPs and progressive increases in latency in BAEPs.¹⁸⁵ Very high doses of thiopental, exceeding that which produce an isoelectric EEG, alter SSEPs and BAEPs predictably, but waveforms are preserved.¹⁸⁶ VEPs are more sensitive than the other sensory modalities to the effects of barbiturates with only the early potentials persisting at low doses and increasing in latency at higher doses.¹⁸⁶ Either bolus administration or intravenous infusion of etomidate causes increases in latency and increases in amplitude of cortical SSEPs and slight decreases in amplitude of cervical potentials.¹⁸⁷ Etomidate produces minimal changes in the early or subcortical peaks of the BAEP, but causes a dose-dependent attenuation and prolongation of the middle latency cortical peaks.¹⁸⁸ Etomidate alone does not change VEP amplitudes (P100 or N70), but increases latency (P60, N70, and P100).¹⁸⁹ During fentanyl–nitrous oxide anesthesia, etomidate causes decreases in amplitude and increases in latency of VEPs. The benzodiazepines produce minimal SSEP and VEP changes and no changes in BAEPs.^{187,190,191 and 192} Propofol increases the latency and decreases the amplitude of cortical SSEPs.¹⁹³ Propofol (2 mg · kg⁻¹ iv followed by an infusion) increases the BAEP latency of I, III, and V waves without changing the amplitudes.¹⁹⁴ Propofol completely suppresses middlelatency auditory potentials.

The opioids produce minimal changes in SEP waveforms. For example, fentanyl and morphine cause minimal latency prolongation and amplitude depression of the SSEP waveforms,^{184,195} and high-dose opioid administration has been shown to be compatible with reproducible recordings of SSEPs.¹⁹⁶ Opioids also produce minimal to no effect on BAEP recordings.¹⁹⁷ Furthermore, low-dose continuous infusions of opioids tend to depress SEPs less than intermittent bolus injections.¹⁹⁵

Because opioids preserve SEP recordings even in relatively high doses, they are recommended for use as infusions during intraoperative monitoring. As with all intravenous agents used, bolus administration should be avoided during critical times when neurologic injury might occur.

Physiologic factors such as temperature, systemic blood pressure, PaO₂, and PaCO₂ can alter SEPs and must be controlled during intraoperative recordings. Both hypothermia and hyperthermia alter all SEPs.^{198,199 and 200} In addition, fluids used to irrigate the brain or spinal cord can cause marked changes in recordings despite normal core temperature measurement. Therefore, body-temperature irrigating fluids should be used. Systemic hypotension below levels of cerebral autoregulation produces progressive decreases in amplitude of cortical SSEPs until the waveform is lost.^{198,201,202} During scoliosis surgery, SSEP changes have been observed that resolved with increases in systemic blood pressure, suggesting that spinal cord manipulation during “safe” levels of hypotension may cause significant ischemia.²⁰³ Changes in PaO₂ and PaCO₂ also alter SEPs, probably reflecting changes in blood flow or oxygen delivery to neural structures.^{198,202,204}

Motor Evoked Potentials

A motor evoked potential (MEP) can be produced by direct (epidural) or indirect (transosseous) stimulation of the brain or spinal cord. Following transcranial stimulation, the signal descends through both the dorsolateral and ventral spinal cord. It is primarily localized in the pyramidal tracts, and can be recorded from spinal cord (epidural space), peripheral nerve, and muscle using conventional electromyographic and evoked potentials averaging techniques. Stimulation of the motor cortex elicits contralateral peripheral nerve signals, electromyographic signals, or limb movements.

Transosseous activation of motor neurons is accomplished by either electrical or magnetic stimulation. Transcranial electrical stimulation of the motor cortex is a reliable method of eliciting intraoperative MEPs. It is achieved by delivering brief high-voltage pulses through scalp electrodes. Percutaneous electrical stimulation can be uncomfortable, however, producing hypertension and tachycardia in awake and anesthetized patients.²⁰⁵ These cardiovascular responses may be minimized by reducing the rate and duration of stimulation.

Transcranial magnetic stimulation is produced by placing a magnetic coil over the motor cortex.²⁰⁶ This technique is painless, noninvasive, and does not require direct contact with the scalp. Because high-resistance tissues such as bone and skin are transparent to magnetic fields, smaller voltages can be used to stimulate neural elements below the surface. Despite these advantages, it is more difficult to perform in the operating room because the stimulating coils are cumbersome and tend to overheat with repeated stimulation. There also is the problem of movement of ferromagnetic objects that lie within the magnetic field.

With either electrical or magnetic stimulation, there is concern that repetitive cortical stimulation can induce epileptic activity, neural damage, and cognitive or memory dysfunction. Guidelines for transcranial MEP stimulation recommend intermittent rather than continuous stimulation over several hours and cautious use in patients with a history of seizures, possible skull fractures, or implanted metallic devices.²⁰⁷ Disruptions of the calvarium—*i.e.*, a skull fracture—could focus the current toward certain regions of the brain and potentially cause neural damage. Other situations of concern are patients with cardiac pacemakers and central venous or pulmonary artery catheterization. Transcranial MEP stimulation should probably be avoided in these patients.

There are several indications for intraoperative monitoring of MEPs. They are especially useful in preserving motor function during procedures in which surgically induced damage may be specific to the motor system. For example, surgical removal of intramedullary tumors can result in selective damage to corticospinal tracts, and MEPs are used to guide surgical resection. During scoliosis surgery, a direct monitor of motor pathway function obviates the need for the intraoperative wake-up test and provides continuous information about motor function throughout the surgical procedure. During cerebrovascular procedures and resection of cerebral tumors involving the motor cortex or subcortical motor pathways, the ability to guide the surgical resection by monitoring motor function may prevent postoperative motor deficits. Paralysis is an unpredictable complication that can occur after aortic aneurysm surgery. Although SSEPs have been used to identify intraoperative spinal cord dysfunction during aortic cross-clamping, a monitor of motor function would provide more specific information. In all of these procedures, MEPs should be monitored in conjunction with SSEPs to fully evaluate the functional integrity of both motor and sensory pathways.

Motor evoked potentials are extremely sensitive to depression by anesthetics. [Table 28-9](#) summarizes the known effects of intravenous and inhaled agents.^{208,209,210,211,212,213,214 and 215} Increasing N₂O concentration gradually attenuates and abolishes MEPs at concentrations between 60 and 70%.^{208,209} However, N₂O concentration of 50% is reported to cause a minimal response alteration and appears to be compatible with monitoring.²⁰⁸ The volatile agents are powerful depressants of myogenic MEPs.²¹⁰ During nitrous oxide–opioid anesthesia, even low concentrations of isoflurane are reported to abolish MEP responses.²¹¹ Benzodiazepines, barbiturates, and propofol also produce marked depression of the myogenic MEP.^{209,212} Fentanyl, etomidate, and ketamine have little or no effect on myogenic MEP and are compatible with intraoperative recording.^{212,213 and 214} Muscle relaxants affect the recorded electromyographic response by depressing myoneural transmission. By adjusting a continuous infusion of muscle relaxant to maintain one or two twitches in a train of four, reliable MEP responses have been recorded.²¹⁵ Although it appears that MEPs are more sensitive to the effects of anesthetic agents, reliable responses can be recorded with a nitrous oxide–narcotic technique and with agents such as ketamine or etomidate. It appears that agents with central nervous system (CNS) inhibitory action (*e.g.*, thiopental and midazolam) produce profound changes in MEP responses and should be avoided. As with SEPs, hypothermia, hypoxia, and hypotension will alter MEPs under anesthesia.

| | Latency | Amplitude |
|---------------------------|---------|-----------|

| Nitrous oxide | ↑ | ↓ |

↑ = increased; ↓ = decreased; 0 = no change.
* Latency delay in doses = 20–40 mg·kg⁻¹; amplitude depression in doses = 15–20 mg·kg⁻¹.

Table 28-9. EFFECTS OF INTRAVENOUS AND INHALED AGENTS ON MOTOR EVOKED POTENTIALS

Cranial Nerve Monitoring

Potential injury to the cranial nerves can occur during posterior fossa and lower brain stem procedures. The integrity of these cranial nerves can be preserved by monitoring the electromyographic (EMG) potential of cranial nerves with motor components (V, VII, IX, X, XI, XII).²¹⁶ Both spontaneous and triggered muscle activity can be recorded. Recordings can be obtained by placing two wire electrodes within the muscle or using surface electrodes. Simultaneous spontaneous EMG and compound muscle action potential (CMAP) recordings can be obtained by using intramuscular wire and surface electrodes. Intramuscular wire electrodes increase the sensitivity for detecting spontaneous EMG activity, while surface electrodes allow for more reliable monitoring of CMAP amplitude and morphology. With accidental surgical trespass, spontaneous neural activity changes into phasic “bursts” or “train” activity, which suggests injury potential. Evoking the nerves with electrical stimulation facilitates identification and hence preservation of the cranial nerve. Although it is possible to record EMG potentials during partial neuromuscular blockade, it is recommended that muscle relaxants not be administered during cranial nerve monitoring.

Intracranial Pressure Monitoring

Since Lundberg's²¹⁷ report in 1960, continuous ICP monitoring has been used to guide the perioperative management of patients with head injury, large brain tumor, ruptured intracranial aneurysm, cerebrovascular occlusive disease, and hydrocephalus. With continuous ICP monitoring, it is possible to optimize CPP (MAP-ICP) in critically ill neurosurgical patients. It also allows early detection and prompt treatment of brain hemorrhage, swelling, and herniation. An important intraoperative indication for ICP monitoring is to detect intracranial hypertension in the multiple trauma patients during a non-neurosurgical procedure.

Techniques used to monitor ICP include ventricular catheters, subdural-subarachnoid bolts or catheters, various epidural transducers, and intraparenchymal fiberoptic devices (Fig. 28-12). The intraventricular catheter is the standard method of monitoring ICP. This technique requires a small scalp incision and a burr hole through the skull. A soft, nonreactive plastic catheter is introduced into the lateral ventricle and connected by sterile tubing filled with saline solution to an external transducer. The intraventricular catheter measures CSF pressures reliably. It allows therapeutic CSF drainage and can also be used for compliance testing. There are, however, several potential problems with this technique. This device depends on the transmission of ICP through fluid-filled tubing that can occlude, thus damping or obliterating the recording. In a patient with severe brain swelling or a large mass lesion and small ventricles, it may be technically difficult to locate the lateral ventricle. Besides not being able to pass the catheter into the CSF, there is a possibility of brain tissue damage, hematoma, and infection. Studies report a low infection rate for the first 4 days after catheter placement.^{218,219} and ²²⁰ Because of this, catheter removal is recommended on or before the fifth day, with replacement at a different site if continued ICP monitoring is necessary.²¹⁹

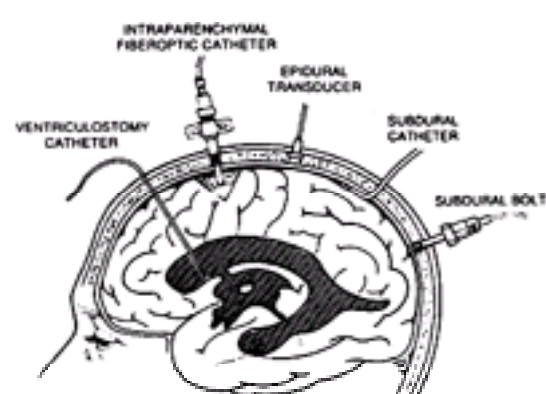

Figure 28-12. Techniques used to measure intracranial pressure.

The subdural-subarachnoid bolt usually consists of some type of hollow screw fixed to the calvarium, with the tip passing through the incised dura.²²¹ The advantages of the bolt are that it does not require brain tissue penetration or knowledge of ventricular position, and can be placed in any skull location that avoids major venous sinuses. There are several disadvantages to use of this technique. The bolt cannot be used to lower ICP by CSF drainage or to test compliance reliably. As with the intraventricular catheter, the bolt is connected to a transducer with tubing filled with sterile saline. Not only can the tubing block, but also brain substance can obstruct the tip of the bolt; in either situation, the recording may be damped or lost. Drilling side holes just proximal to the tip of the bolt compensates for this problem to some extent. Subdural devices are easily inserted, but can malfunction if they are not coplanar to the brain surface or if they become loose. The major complication of this procedure is infection, commonly meningitis, osteomyelitis, or a localized infection.²¹⁸ Epidural bleeding and focal seizures, if the bolt is inserted too deeply, can also occur.

Two primary types of epidural transducers have been developed. One uses a device that has a pressure-sensitive membrane mounted close to or contacting the dura; the other type, known as the Ladd epidural transducer, is based on the principle of the Numoto pressure switch.²²² Although the risk of infection to the brain is lower because of the extradural placement, there are several disadvantages associated with using these devices. Placement in this potential space is more difficult, and there is a risk of bleeding. Technical problems in positioning and calibrating the transducer *in situ* can also occur. Another shortcoming of the epidural transducer is that intracranial compliance testing and therapeutic CSF drainage cannot be performed.

A relatively recent development in ICP monitoring has been that of a miniaturized fiberoptic device. This sensing device is mounted at the end of a 4-French fiberoptic bundle and can be inserted through a 2-mm burr hole. It senses changes in the amount of light reflected off a pressure-sensitive diaphragm located at the tip of a fiberoptic catheter. Mean pressure can be displayed digitally or as a pressure waveform. With this device, it is possible to insert the tip of the catheter into the subdural, intraparenchymal, or intraventricular compartments. Because it is a solid-state monitor, the problems of infection, leaks, catheter occlusion, and drift that attend fluid- or air-filled systems are minimized or avoided. Animal and human studies show that pressure recordings obtained with the fiberoptic catheter are accurate and reliable.^{223,224} The main disadvantage of this device is that it cannot be recalibrated *in situ*. Because cumulative drift becomes significant with long-term use (*i.e.*, 5 days or more), it is suggested that the monitor be replaced after 5 days.²²⁴ Another limitation of the fiberoptic device is that it cannot be used for CSF drainage or compliance testing unless used in conjunction with a ventriculostomy.

Intraparenchymal ICP monitoring techniques allow direct measurement of brain tissue pressure, which may be important in edema formation and regional capillary blood flow. Intraparenchymal devices use a fiberoptic catheter that is inserted within cortical gray mater. In comparison to ventriculostomies, these monitors are easier to insert, have a smaller diameter, and are less disruptive of brain tissue.²²⁵ Because there is no fluid column, the risk of infection is probably smaller.

New generations of fiberoptic ICP monitors allow simultaneous measurement of ICP, local CBF using laser Doppler flowmetry,²²⁶ brain tissue oxygen pressure (PO₂), carbon dioxide pressure (PCO₂), and pH.²²⁷ By simultaneously monitoring ICP, local CBF, and brain tissue oxygenation, early signs of ischemia can be identified and the effectiveness of therapeutic maneuvers more fully determined. The various ICP monitors are seldom used intraoperatively. They are most valuable in managing

critically ill neurosurgical patients in the intensive care unit.

All of the clinically available monitors have recognized advantages and disadvantages. Despite the problems associated with these devices, ICP monitoring provides useful information for evaluating the patient's condition, progress, and need for therapy. Research efforts continue to improve monitoring techniques in terms of reliability, accuracy, and safety.

Cerebral Oxygenation/Metabolism Monitors

Brain Tissue Oxygenation

A multiparameter sensor is available for measuring brain tissue PO_2 , PCO_2 , pH , and temperature using a combined electrode–fiberoptic system.²²⁷ The sensor was originally designed for continuous intra-arterial blood gas monitoring. It is supplied as a sterile, disposable device comprising two modified optical fibers for the measurements of PCO_2 and pH , a miniaturized Clark electrode for PO_2 measurement, and a thermocouple for determining temperature. Coupled with a dialysis catheter, the device permits measurement of other metabolic markers, including lactate, glucose, and excitotoxic amino acids. This sensor is invasive, requiring insertion into the cortex tissue of interest under direct visualization. The measurements obtained are limited to the parenchyma where the electrode is inserted.

Jugular Bulb Venous Oximetry

Continuous or intermittent estimation of the global balance between cerebral oxygen demand and supply can be achieved by jugular bulb venous oximetry. This is done by measuring the oxygen saturation of jugular venous blood ($SjvO_2$) through percutaneous retrograde cannulation of the internal jugular vein with an intravascular catheter with embedded optical fibers. Normal $SjvO_2$ is 60–70%. In the absence of anemia and any change in oxygen saturation, increases in $SjvO_2$ to above 75% are indicative of absolute or relative hyperemia; that is, supply is in excess of metabolic requirement. This can occur as a result of reduced metabolic need (e.g., a comatose or brain-dead patient) or from excessive flow (e.g., severe hypercapnia). A value less than 50% reflects increased oxygen extraction and indicates a potential risk of ischemic injury. This may be due to increased metabolic demand (e.g., fever or seizure) not matched by an equivalent increase in flow, or it may be due to an absolute reduction in flow. Changes in the oxygenation of systemic blood also influence the saturation of blood in the jugular bulb.

This monitor is used intraoperatively and postoperatively to diagnose cerebral ischemia from inadequate perfusion pressure or excessive hyperventilation. Its major limitation is that it does not detect focal ischemia.

Transcranial Oximetry

Near-infrared spectroscopy (NIRS) is a noninvasive optical method for monitoring cerebral regional oxygenation.^{228,229} It is based on the principle that light in the near-infrared range (700–900 nm) readily penetrates skin and bone, but reflects off certain chromophores in the brain, such as oxy- and deoxyhemoglobin and cytochrome AA³. Therefore, by monitoring the absorption of light at several wavelengths in the near-infrared range, brain tissue concentrations of oxy- and deoxyhemoglobin, total hemoglobin, and hemoglobin oxygen saturation can be measured. The tissue field beneath the sensor contains capillaries, arteries and veins, reflecting a mixed vascular saturation, which NIRS monitors. Cerebral oximetry may prove useful in monitoring ischemia in several clinical neurosurgical conditions, including carotid endarterectomy, head injury, and subarachnoid hemorrhage. Its major limitations include intersubject variability, variable optical path length, potential contamination from extracranial blood, and lack of a definable threshold. At present, it is considered a trend monitor, with each patient acting as his/her own control. In situations of potential regional ischemia, for example, carotid endarterectomy and temporary clip application during intracranial aneurysm surgery, bilateral monitoring should be used.

NEURORADIOLOGY

Common neuroradiology procedures are computed tomography (CT), magnetic resonance imaging (MRI), angiography, and myelography, although a variety of invasive interventional procedures are becoming common as well. These require the patient's total immobility. Therefore, in uncooperative patients, specifically children, fearful adults, and retarded or obtunded patients, general anesthesia will be required. All the standard equipment and monitors required for the administration of a general anesthetic and possible cardiopulmonary resuscitation must be present.

Computed Tomography Scan

The CT scan produces a series of cross-sectional images by computerized processing of X-ray absorption measurements (photon attenuation data as measured by sodium iodide crystals rotating about the patient's head).²³⁰ Performance of a brain scan requires that the patient lie on a table with his or her head inside a rotating gantry that makes a 180° arc, producing one axial slice or cut. Depending on the generation of the scanner, the rotation may take from a few seconds to 4.5 minutes per cut. Eight cuts are usually required for a complete examination of the head. When contrast enhancement is indicated, the dye may be infused intravenously and the scan repeated. The patient must remain supine and immobile throughout the entire scan.

CT scanning is an excellent modality for detecting skull fractures and acute subarachnoid hemorrhage. It is relatively insensitive for viewing structures within the posterior fossa because image degradation results from artifact produced by the interface of bone and brain parenchyma. For trauma patients, spiral acquisition CT is becoming more popular. Larger anatomic regions can be imaged as the patient is moved at a continuous, constant speed through the scanning field with the X-ray tube rotating continuously.

Most CT examinations are performed without an anesthesiologist present. Oral or intravenous sedation is used for many pediatric examinations and is usually administered by radiology personnel.²³¹ Iodinated contrast medium, which is particularly valuable in studies of vascular malformations, vascularized tumors, and blood–brain defects, may also be administered orally or intravenously. When general anesthesia is requested, the patient's "nothing-by-mouth" status must be determined. Other issues that need to be resolved before the administration of general anesthesia are remote access to the patient and the establishment of monitoring and equipment that meets the same standard of care that exists in the operating room.

The CT scanner uses ionizing radiation. The radiation exposure during CT is similar to that of a conventional skull X-ray (1.0–2.5 rad).²³² Exposure values for personnel attending the patient are minimal (e.g., 1–2 mrad · hr⁻¹ for the anesthesiologist positioned next to the scan). However, radiation monitoring badges and lead aprons should be worn by personnel who participate in CT scanning on a regular basis.

Magnetic Resonance Imaging

Magnetic resonance imaging is a noninvasive diagnostic technique that is superior to CT in many CNS disorders.²³³ This technique employs a strong magnetic field and pulsed radiofrequency energy to generate images. When a biologic specimen is placed within a static magnetic field, certain atomic nuclei (nuclei with an odd number of protons, such as ¹H nuclei) act like magnets and are aligned. The atoms are then subjected to a radiofrequency pulse that deflects their orientation. When the radiofrequency pulse is discontinued, the nuclei rotate back into alignment with the static magnetic field. The energy released as the nuclei "relax" is used to create the MR image. The magnet of the MRI system is in the form of a tube that can accommodate the human body. The patient must remain still during investigation, which may last 1 hour, to prevent imaging artifacts.

The MRI is an extremely valuable diagnostic tool that provides excellent contrast between gray and white brain matter. The images can be displayed in axial, coronal, or sagittal planes. Because there is no dental or bony artifact, the MRI is superior to the CT scan in examining the posterior fossa. Other areas optimally imaged by MRI include the pineal gland region, sella and parasellar structures, the limbic system, cranial nerves, internal auditory canal, the cerebellopontine angle, and leptomeninges. Magnetic resonance angiography (MRA) provides images of arterial and dural sinus blood flow. Magnetic resonance spectroscopy provides noninvasive biochemical measurements of specific brain metabolites and can be helpful in the early detection of stroke.

The intense magnetic field creates unique challenges for the anesthesiologist. The high-static magnetic field (0.12–2.00 tesla [T]) and the radiofrequency energy transmitted during image acquisition may damage or cause malfunction of electrical, electronic, or mechanical life support and monitoring equipment. Conversely, the radiofrequency energy generated by these devices can interfere with MR signal detection, producing artifacts that degrade the image. Another problem unique to MRI is that ferromagnetic substances placed within the magnetic field are propelled toward the scanner. A list of MRI-compatible equipment and monitors has been published.²³⁴

Laryngoscopes are not magnetic, but the batteries are. Therefore, to use a laryngoscope within the scanning room, plastic- or paper-coated batteries must be used. A

prebent RAE tube is recommended owing to limited vertical space within the scanner. Very long breathing tubes are required, and either pipeline gases or a remotely placed anesthesia machine can be used. Aluminum cylinders can be used safely within the scanning room. MRI-compatible anesthesia machines and ventilators are available.²³⁴ The anesthesia machine can be bolted to the wall or modified by removal of ferromagnetic components. The ventilators are pneumatically driven, volume-cycled, and have fluidic controls. The ventilator is completely powered by high-pressure oxygen delivered by a wall source or from large cylinders placed outside the imaging room, and electronic parts have been replaced with plastic, aluminum, or nonmetallic alloys.

The implementation of monitoring during MRI is difficult because of remote access to the patient and the interactions between various monitoring devices and the MR scanner, as previously described. For example, standard ECG monitors produce problems with image degradation from wire leads acting as antennas and with artifact produced by radiofrequency pulses and static magnetic fields. Burns under ECG electrodes have been reported. MR-compatible ECG monitors, cables, fasteners, and electrodes have been developed.²³⁴ However, this ECG provides only heart rate and rhythm and cannot be used to monitor ischemia. Additional suggestions for improving ECG monitoring include placing electrodes close together near the three-dimensional center of the imager and twisting the leads. Both noninvasive and invasive pressure monitoring have been successfully used during MRI. Blood pressure is easily measured with an ordinary cuff and long pressure tubing without metal connections. The blood pressure dial must be kept away from the magnetic field. Automated blood pressure devices without metal connectors have also been used. Using nonmetallic components, pressure transducers connected to intravascular catheters for central venous, pulmonary artery, and arterial pressure monitoring can function near the magnet. Transducers are affixed along the side of the magnet at its midpoint to minimize artifact. Shielded electric extension cables couple the transducers to the monitors located outside the scanning room. There have been reports of image degradation with the pulse oximeter. Placing the oximeter a distance from the magnet and the probe on the patient's toe, which is usually outside the magnet, and using a fiberoptic cable may improve image quality. Monitoring of heart rate and respiration can be achieved using nonmetallic precordial or esophageal stethoscopes; however, the drum-like noise of the scanner may obscure auscultated heart and breath sounds. A standard vascular Doppler has also been used to monitor heart rate. Capnography is possible with long tubing and high-powered suction. Changes in respiratory rate are easily observed, but the end-tidal CO₂ reading may be less than the actual value. Although temperature monitoring is particularly important in the cold MRI suite, especially in pediatric patients, it has been difficult to implement. The wires conducting the signal from the thermistor may function as an antenna for radiofrequency signals and produce imaging artifact and burns. Nonferromagnetic disposable temperature strips may be used. All efforts to minimize patient heat loss should be implemented: using bags of warmed intravenous fluids, heating pads, airway humidification, and covering the patient.

Guidelines for using the MRI have been issued by the National Radiological Protection Board.²³⁵ It is recommended that women in the first trimester of pregnancy not be scanned because of possible developmental consequences. Patients with demand pacemakers should not be scanned because the varying magnetic field can induce electric currents in the pacemaker wires, which may be mistaken for the natural electrical activity of the heart, inhibiting pacemaker output. Metallic objects such as vascular clips or shrapnel can move and become displaced when exposed to the magnetic field. Patients who have a large metallic implant or prosthesis can be scanned until the heat at the site of the implant or prosthesis becomes uncomfortable. There is a possibility that induced currents can affect myocardial contractility or produce arrhythmias. Full resuscitation facilities should be available.

Positron Emission Tomography

Biochemical or physiologic processes involved in cerebral metabolism can be imaged with positron emission tomography (PET). After receiving intravenous radionuclide, such as fluorodeoxyglucose (FDG), the patient is scanned in a specialized detector system. This system detects the positron energy emitted from the radionuclide. Computerized reconstruction procedures produce tomographic images. The information from PET can be overlaid on CT or MR images to improve anatomic localization of detected activity. When the MRI is normal in a patient with seizures, PET might provide localizing information prior to focal resection treatment. The injection of FDG renders the patient radioactive for 24 hours. The usual protocol involves two initial scans lasting 15–20 minutes followed by another scan in 2–3 hours. PET scanners do not require nonferromagnetic monitors and equipment.

Cerebral Angiography

Angiography is used to delineate the vasculature of the brain. Catheters are usually introduced through the common femoral artery, which has replaced direct carotid artery puncture. Digital subtraction angiography reduces the required volume of intra-arterial contrast and the overall duration of the procedure.

There are several risks and problems associated with angiography, including an incidence of neurologic problems related to angiography itself. In addition, arterial spasm, hematoma, and local infection can occur at the site of needle puncture. Subintimal dissection or occlusion of the vessel may result from injection into the vessel wall. Iodine-containing contrast media produce vasodilation and a burning sensation in the distribution of the injected vessel. Septicemia, cerebral embolism, anaphylactic reactions to the iodinated contrast material, and, rarely, seizures or death are all potential complications of cerebral angiography.

The introduction of low-ionic and nonionic contrast material has reduced both the discomfort and toxicity associated with angiography. Because of this, patients usually do not require general anesthesia and are able to tolerate the procedure with minimal or no sedation. When general anesthesia is requested for children or uncooperative adults, the angiogram quality may be enhanced by hyperventilation. Hypocarbica is thought to improve study quality by slowing the cerebral circulation and improving delineation of tumor blood vessels, perhaps through an inverse steal phenomenon.

Myelography

Myelography requires spinal lumbar puncture, the injection of contrast material, and the prone position. It is uncommon for the anesthesiologist to be involved in myelography except for studies in children or uncooperative adults. Metrizamide is a water-soluble contrast agent that has been used for myelograms. Because of its rapid absorption from the CSF, metrizamide does not require aspiration at the end of the procedure, but it is associated with allergic reactions and mental changes, ranging from headache to confusion to convulsions. Any drug that lowers the epileptogenic threshold (e.g., phenothiazines or ketamine) should be avoided in patients receiving metrizamide. Other nonionic contrast media such as iohexol and iopamidol may be used instead of metrizamide because they are associated with a lower osmotic load and a reduced incidence of adverse reactions. However, these agents are much more expensive than standard contrast media.²³⁶

Interventional Neuroradiology

Interventional neuroradiology has developed from traditional neuroradiology and neurosurgery to procedures that treat CNS disease by endovascular access.²³⁷ Procedures such as therapeutic embolization and superselective angiography of vascular malformations, balloon angioplasty of occlusive cerebrovascular disease or cerebral vasospasm, therapeutic carotid occlusion for giant aneurysms and brain tumors, and others may be performed. Because these procedures are inherently dangerous, anesthesiologists can help prevent and manage morbidity and mortality.

Most interventional neuroradiology procedures are accomplished with conscious sedation. General anesthesia may be used for small children, uncooperative adult patients, and for certain procedures. The agents chosen for conscious sedation must alleviate pain and discomfort and provide anxiolysis, patient immobility, and a rapid return to consciousness for neurologic testing. Both neuroleptanesthesia (e.g., titration of 2–4 mg · kg⁻¹ fentanyl, 2.5–5 mg droperidol, and 3–5 mg midazolam iv) and a propofol infusion technique have been used successfully. The goal of drug titration is to render the patient unconscious with a patent airway.

Before initiating sedation, the patient is made comfortable with padding under head, neck, and body. Two large-bore intravenous catheters are inserted, and all standard monitoring is applied. Oxygen (2–4 l · min⁻¹) is delivered by nasal cannula with the capability of monitoring end-tidal carbon dioxide. Arterial pressure can be monitored through the cannulated femoral artery for intracranial and spinal cord procedures and whenever blood pressure manipulation is required. Awake neurologic assessment and other CNS monitors (e.g., EEG, evoked potentials, or transcranial Doppler) may be used. During and after these procedures, careful management of coagulation is required to prevent thromboembolic complications. Special techniques such as deliberate hypotension or hypertension and hypercapnia may be requested for selective procedures.

Complications during instrumentation of the cerebral vasculature can be sudden and dramatic. Simultaneous with airway maintenance, it is important to determine whether the problem is hemorrhagic or occlusive. Hemorrhagic disasters require immediate heparin reversal and low normal blood pressure. Occlusive disasters require deliberate hypertension, titrated to neurologic examination, with or without direct thrombolysis. Other resuscitative measures that might be initiated include rapid fluid infusion, 15° head-up position, hyperventilation, diuretics, anticonvulsants, hypothermia (33–34°C), and thiopental infusion titrated to EEG burst suppression.

Adverse Reactions From Contrast Media

Most contrast media are radiopaque, iodine-containing salts that may be administered orally or, more commonly, injected intravascularly, lymphatically, or directly into the CSF. (Paramagnetic contrast material, typically not iodinated, is available for MR studies.) Neurotoxic, nephrotoxic, and allergic reactions have been reported after administration.^{238,239} Neurotoxic reactions are more likely to complicate angiographic investigations and include dizziness, convulsions, unconsciousness, hemiplegia, blindness, and aphasia.²³⁸ These effects are related to the hyperosmolality of the contrast agent. Contrast media may temporarily impair the blood–brain barrier or cross it during disease, causing CNS damage by a direct necrotizing effect.²⁴⁰ A critical factor appears to be the concentration of the agent. If slurring of speech or

confusion is observed, the procedure should be terminated. The occurrence and persistence of more serious CNS problems may require therapy with steroids, low-molecular-weight dextran, or vasopressor-induced elevation of systemic blood pressure to improve blood flow to areas that may be ischemic. The use of low-osmolality, nonionic contrast agents reduces the risk of CNS toxicity during angiography. Iodinated contrast agents are also nephrotoxic. After an initial mild vasodilation, the renal vascular tree vasoconstricts. Therefore, patients with pre-existing renal insufficiency, diabetes mellitus, and low cardiac output are at risk for developing contrast agent-induced nephrotoxicity.

Allergic reactions to contrast media vary from pruritus, burning on injection, and mild skin rashes to wheezing, dyspnea, syncope, and cardiovascular collapse.²³⁹ These reactions most likely result from nonimmunologic release of histamine and other vasoactive mediators from mast cells and basophils. A prospective study conducted by the International Society of Radiologists Committee on Contrast Media²⁴¹ reported an approximate 5% incidence of systemic reactions to intravascular contrast media administration. Nineteen fatal reactions (0.006% of 302,082 studies) were reported in this group. In patients with a history of allergy (particularly to iodine or seafood), the incidence of reaction increases to 10–15%. In patients with a history of previous reaction to iodinated contrast agents, the risk of subsequent reaction increases to 17–35%.²³⁹

Prophylaxis with steroids and antihistamines is recommended in patients with a history of allergies or specific reaction to contrast media. These patients should be evaluated by an allergist and medicated before injection of contrast. Several regimens have been proposed, all including a corticosteroid (e.g., prednisone) and an antihistamine (diphenhydramine) in various combinations and doses before, during, and after the investigation.^{239,242} One regimen suggests the administration of prednisone (50 mg po) beginning the evening before (for a total of three doses, 6 hours apart) and diphenhydramine (50 mg iv) immediately before exposure.²⁴²

Mild allergic reactions require little more than reassurance and perhaps intravenous diphenhydramine. More severe reactions (e.g., respiratory distress, hypotension, or syncope) can be treated initially with subcutaneous epinephrine. Be prepared, however, for all degrees of resuscitation, because emergent therapy for bronchospasm, laryngeal edema, hypotension, arrhythmias, and full cardiopulmonary arrest may be required.

ANESTHETIC MANAGEMENT OF NEUROSURGICAL PATIENTS

The administration of anesthesia to neurosurgical patients requires an understanding of the basic principles of neurophysiology and the effects of anesthetic agents on intracranial dynamics, as reviewed in the previous sections of this chapter.

Preoperative Evaluation

During the preoperative evaluation, the patient's overall medical condition must be considered and integrated into the formulation of an anesthetic management plan. Neurosurgical procedures tend to be lengthy, requiring unusual positioning of the patient and the institution of special techniques such as hyperventilation, cerebral dehydration, and deliberate hypotension. Not all patients can tolerate the position desired by the surgeon; this must be addressed and, if possible, evaluated preoperatively. Furthermore, in patients with cardiac disease, routine institution of osmotherapy or hyperventilation may compromise organ function. Such patients must be medically optimized and, when indicated, cardiac monitoring should be instituted. Except for neurosurgical emergencies (e.g., head trauma or impending herniation), most neurosurgical procedures can be delayed to treat medically unstable conditions.

The preoperative evaluation must include a complete neurologic examination with special attention to the patient's level of consciousness, presence or absence of increased ICP, and extent of focal neurologic deficits. The signs and symptoms frequently associated with intracranial hypertension are headache, nausea, papilledema, unilateral pupillary dilation, and oculomotor or abducens palsy. With advanced stages of intracranial hypertension, the patient exhibits a depressed level of consciousness and irregular respiration. The clinical signs do not reliably indicate the level of ICP. Only a direct CSF pressure measurement can be used to quantitate the pressure; however, indirect evidence of elevated ICP can be determined by evaluating the MRI or CT scan for a mass lesion accompanied by a midline shift of 0.5 cm or greater and/or encroachment of expanding brain on CSF cisterns.

The location of the lesion in the supratentorial or infratentorial compartment will determine the clinical presentation and anesthetic management. Supratentorial disease is usually associated with problems in the management of intracranial hypertension, whereas infratentorial lesions cause problems related to mass effects on vital brain stem structures and elevated ICP due to obstructive hydrocephalus.

Fluid and electrolyte abnormalities are common in patients with reduced levels of consciousness. Patients are usually dehydrated and develop electrolyte abnormalities because of decreased fluid intake, iatrogenic water restriction, neuroendocrine abnormalities, and diuresis from diuretics, steroid-related hyperglycemia, and radiographic contrast agents. Fluid and electrolyte abnormalities must be corrected before induction of anesthesia to prevent cardiovascular instability.

COMMON INTRACRANIAL PATHOLOGY

Supratentorial Intracranial Tumors

Supratentorial tumors (meningiomas, gliomas, and metastatic lesions) change intracranial dynamics predictably. Initially, when the lesion is small and slowly expanding, volume-spatial compensation occurs by compression of the CSF compartment and nearby cerebral veins, which prevents increases in ICP. As the lesion grows, however, compensatory mechanisms are exhausted and further increases in tumor mass cause progressively greater increases in ICP. Primary or metastatic tumors or chronic subdural hematomas can present as chronic mass lesions. Because of the ability of the intracranial compartment to compensate up to a point, patients may exhibit minimal neurologic dysfunction despite the presence of a large mass, elevated ICP, and shifts in the position of brain structures.

Significant changes in ICP can occur with supratentorial tumors if they develop a central area of hemorrhagic necrotic tissue or a wide border of brain edema. As the tumor enlarges, it can outstrip its blood supply, developing a central hemorrhagic area that may expand rapidly, increasing ICP. Brain edema surrounding the tumor increases the effective bulk of the tumor and represents an additional portion of the brain that is not autoregulating. In such situations of compromised intracranial compliance, small increases in arterial pressure may produce large increases in CBF, which can markedly increase intracranial volume and ICP with the attendant complications.

Anesthetic Techniques and Drugs

The goal of neuroanesthetic care for patients with supratentorial tumors is to maximize therapeutic modalities that reduce intracranial volume. ICP must be controlled before the cranium is opened, and optimal operating conditions obtained by producing a slack brain that facilitates surgical dissection. Various maneuvers and pharmacologic agents have been used to reduce brain bulk (Table 28-10). For example, administration of diuretics or steroids, hyperventilation, and systemic blood pressure control may be implemented preoperatively to reduce cerebral edema and brain bulk, thereby reducing ICP. The application of these methods selectively or together, when necessary, is often accompanied by marked clinical improvement. In acute intracranial hypertensive states, adequate oxygenation with mechanical ventilation and hyperventilation provide the foundation for neuroresuscitative care.

Diuretics: Osmotic, tubular
Corticosteroids
Hyperventilation on demand
Optimize hemodynamics (MAP, CVP, PCWP, HR)
Avoid overhydration, target normovolemia
Position to improve cerebral venous return
Anesthetic agents (thiopental, propofol)
Mild hypothermia

Table 28-10. CLINICAL CONTROL OF INTRACRANIAL HYPERTENSION

Clinical Control of Intracranial Hypertension. Rapid brain dehydration and ICP reduction can be produced by administering diuretics. Two diuretics are employed:

the osmotic diuretic mannitol and the loop diuretic furosemide. Mannitol is given as an intravenous infusion in a dose of 0.25–1.0 g · kg⁻¹. Its action begins within 10–15 minutes and is effective for approximately 2 hours. Larger doses produce a longer duration of action but do not necessarily reduce ICP more effectively. Furthermore, larger doses and repeated administration can result in metabolic derangement. Mannitol is effective when the blood–brain barrier is intact. By increasing the osmolality of blood relative to the brain, mannitol pulls water across an intact blood–brain barrier from brain to blood to restore the osmolar balance. When the blood–brain barrier is disrupted, mannitol may enter the brain and increase osmolality. Mannitol could pull water into the brain as the plasma concentration of the agent declines and cause a rebound increase in ICP. This rebound increase in ICP may be prevented by maintaining a mild fluid deficit. Mannitol has been shown to cause vasodilation of vascular smooth muscle, which is dependent on dose and administration rate.^{243,244} Mannitol-induced vasodilation affects intracranial and extracranial vessels and can transiently increase cerebral blood volume and ICP while simultaneously decreasing systemic blood pressure.^{245,246} Because mannitol may initially increase ICP, it should be given slowly (310 minute infusion) and in conjunction with maneuvers that decrease intracranial volume (e.g., steroids or hyperventilation).

Hypertonic agents such as mannitol should be administered cautiously in patients with pre-existing cardiovascular disease. In these patients, the transient increase in intravascular volume may precipitate left ventricular failure. Furosemide may be a better agent to reduce ICP in patients with impaired cardiac reserve. Prolonged use of mannitol may produce dehydration, electrolyte disturbances, hyperosmolality, and impaired renal function.

The loop diuretic furosemide reduces ICP by inducing a systemic diuresis, decreasing CSF production, and resolving cerebral edema by improving cellular water transport.^{245,246} Furosemide lowers ICP without increasing cerebral blood volume or blood osmolality; however, it is not as effective as mannitol in reducing ICP.²⁴⁵ Furosemide can be given alone as a large initial dose (0.5–1 mg · kg⁻¹) or as a lower dose with mannitol (0.15–0.30 mg · kg⁻¹). A combination of mannitol and furosemide diuresis has been shown to be more effective than mannitol alone in reducing ICP and brain bulk, but causes more severe dehydration and electrolyte imbalances.^{245,246} With combined therapy, it is necessary to monitor electrolytes intraoperatively and replace potassium as indicated.

Corticosteroids reduce edema around brain tumors,^{29,247} however, steroids require many hours or days before a reduction in ICP becomes apparent. The administration of steroids preoperatively frequently causes neurologic improvement that can precede the ICP reduction. One explanation for this is that the neurologic improvement is accompanied by partial restoration of the previously abnormal blood–brain barrier. Postulated mechanisms of action for steroidal reduction in brain edema are brain dehydration, blood–brain barrier repair, prevention of lysosomal activity, enhanced cerebral electrolyte transport, improved brain metabolism, promotion of water and electrolyte excretion, and inhibition of phospholipase A₂ activity.²⁴⁸ The potential complications of continuous perioperative steroid administration are hyperglycemia, glucosuria, gastrointestinal bleeding, electrolyte disturbances, and increased incidence of infection. Therefore, the potential risks and benefits of continuous steroid administration need to be evaluated in these patients.

Hyperventilation has been the mainstay of acute and subacute management of intracranial hypertension. As discussed previously, hyperventilation reduces brain volume by decreasing CBF through cerebral vasoconstriction. For every 1 mm Hg change in PaCO₂, CBF changes by 1–2 ml · 100 g⁻¹ · min⁻¹. The duration of effectiveness of hyperventilation for lowering ICP may be as short as 4–6 hours, depending on the pH of the CSF. Hyperventilation is only effective when the CO₂ reactivity of the cerebrovasculature is intact. Impaired responsiveness to changes in CO₂ tension occurs in areas of vasoparalysis, which are associated with extensive intracranial disease such as ischemia, trauma, tumor, and infection.

The typical target PaCO₂ is 30–35 mm Hg. A PaCO₂ below 20 mm Hg (or 25–30 mm Hg in some pathologic conditions) may be associated with ischemia due to extreme cerebral vasoconstriction. By monitoring global cerebral oxygenation with, say, jugular venous oxygen saturation (SjO₂), the therapeutic effectiveness of hyperventilation can be determined and more safely applied.²⁴⁹

The autoregulation of CBF has been discussed, as has the relationship between blood pressure and ICP when autoregulation is disturbed. The therapeutic goals are to maintain CPP and to control intracranial dynamics so that cerebral ischemia, edema, hemorrhage, and herniation are avoided. Severe hypotension results in cerebral ischemia and should be treated with volume replacement, inotropes, or vasopressors as dictated by clinical need. Severe hypertension, conversely, can worsen cerebral edema and cause intracranial hemorrhage and herniation. The b-adrenergic blockers, propranolol and esmolol, and the combined a- and b-adrenergic blocker, labetalol, are effective in reducing systemic blood pressure in patients with raised ICP with minimal or no effect on CBF or ICP.

Restricted fluid intake was a traditional approach to intracranial decompression therapy, but is now rarely used to lower ICP. Severe fluid restriction over several days is only modestly effective in reducing brain water content²⁵⁰ and can cause hypovolemia, resulting in hypotension, inadequate renal perfusion, electrolyte and acid–base disturbances, hypoxemia, and reductions in CBF. In patients who are dehydrated preoperatively, intravascular volume must be restored to normovolemia before induction of anesthesia to prevent hypotension in response to anesthetic agents and positive-pressure ventilation. Fluid resuscitation and maintenance fluids in the routine neurosurgical patient are provided with glucose-free iso-osmolar crystalloid solutions to prevent increases in brain water content. For routine craniotomy, the patient receives hourly maintenance fluids and replacement of urine output. Blood loss is replaced at approximately a 3:1 ratio (crystalloid:blood) down to a hematocrit of approximately 25–30% depending on the patient's physiologic status.

Solutions containing glucose are avoided in all neurosurgical patients with normal glucose metabolism, since these solutions exacerbate ischemic damage and cerebral edema.^{251,252} and ²⁵³ Hyperglycemia augments ischemic damage by promoting neuronal lactate production, which worsens cellular injury. Intravenous fluids containing glucose and water (D₅W_{0.45%} NaCl or D₅W) are particularly problematic because the glucose is metabolized and the free water remains in the intracranial fluid compartment, resulting in brain edema. Brain water can interfere with surgical exposure and, after closure of the skull, can compromise cerebral perfusion. In normal patients, both preoperative dexamethasone treatment and general anesthesia–induced gluconeogenesis may elevate resting glucose levels. Therefore, blood glucose levels should be monitored during craniotomy and maintained at near low-normal range.²⁵¹ This should be accomplished mainly by withholding glucose.

For most neurosurgical patients, a neutral head position, elevated 15–30°, is recommended to decrease ICP by improving venous drainage. Flexing or turning of the head may obstruct cerebral venous outflow, causing a dramatic ICP elevation that has been shown to resolve with resumption of a neutral head position. Lowering the head impairs cerebral venous drainage, which can quickly result in an increase in brain bulk and ICP.

The application of positive end-expiratory pressure (PEEP) to mechanically ventilated patients can potentially increase ICP. This effect occurs when PEEP increases mean intrathoracic pressure, impairing cerebral venous outflow and cardiac output. When PEEP is required to maintain oxygenation, it should be applied cautiously and with appropriate monitoring to minimize decreases in cardiac output and increases in ICP. PEEP levels of 10 cm H₂O or less have been used without significant increases in ICP or decreases in CPP.²⁵⁴ When higher levels of PEEP are required to optimize the PaO₂-PEEP-CPP relationship, both central venous pressure and ICP monitoring are indicated.

The administration of pharmacologic agents that increase cerebral vascular resistance can acutely reduce ICP. Thiopental, propofol, and etomidate are potent cerebral vasoconstrictors that can be used for this purpose. The effects of these agents on CBF, cerebral metabolic rate for oxygen (CMRO₂), ICP, and CPP are reviewed in this chapter. These agents are usually administered during induction of anesthesia but may also be administered in anticipation of noxious stimuli or to treat persistently elevated ICP in the intensive care unit.

Although rarely used to reduce ICP, hypothermia does this by decreasing brain metabolism, CBF, cerebral blood volume, and CSF production.^{127,128} Drugs that centrally suppress shivering, muscle relaxants, and mechanical ventilation are required when hypothermic techniques are employed. Intraoperatively, a modest degree of hypothermia, approximately 34°C, is recommended as a way to confer neuronal protection during focal ischemia.²⁵⁵ Hypothermic techniques are also employed to cool febrile neurosurgical patients. Hyperthermia is particularly dangerous in neurosurgical patients because it increases brain metabolism, CBF, and the propensity for cerebral edema.

Premedication

Lethargic patients do not receive premedication. Patients who are alert and anxious may receive an anxiolytic (e.g., midazolam 5 mg po) before coming to the operating room. If there is any doubt about the patient's level of consciousness, the patient may be given sedation or analgesics in the operating room after an intravenous route is established. For the preinduction insertion of invasive monitoring devices in an awake, conversant patient, premedicants (e.g., small doses of opioids) should be considered to alleviate the discomfort from needle punctures.

Monitoring

In addition to the routine monitors, measurement of intra-arterial blood pressure, arterial blood gases, central venous pressure, and urine output is recommended for all major neurosurgical procedures. An arterial cannula is inserted before induction of anesthesia to continuously monitor blood pressure and to estimate CPP. When the arterial pressure transducer is at midhead level (usually the level of the external auditory meatus), MAP approximates the MAP at the level of the circle of Willis. Cerebral perfusion pressure is calculated as the difference between MAP and central venous pressure in patients without intracranial hypertension or the ICP in those

with intracranial hypertension. When the cranium is open, ICP equals atmospheric pressure and CPP equals MAP. With direct arterial pressure monitoring, the hemodynamic consequences of the pharmacologic agents administered during anesthesia are recognized instantly. In addition, the arterial catheter provides ready access for intraoperative measurement of arterial blood gases, hematocrit, serum electrolytes, glucose, and osmolality. Arterial blood gas measurement is necessary to verify the adequacy of hyperventilation. In the elderly and those with ventilation/perfusion mismatch, end-tidal CO₂ may correlate poorly with the PaCO₂. Therefore, the difference between PaCO₂ and end-tidal CO₂ must be determined for a given patient in a given position. Radial, femoral, or brachial arteries are suitable for short-term cannulation; however, after ulnar artery collateral blood flow is tested, cannulation of the radial artery is preferred.

Because most neurosurgical patients are dehydrated preoperatively and then subjected to intraoperative diuresis, the measurement of cardiac preload and urine output is important. A right atrial catheter reflects cardiac preload and is used to determine the preoperative fluid deficit and rate of intraoperative fluid infusion. When possible, the central venous pressure catheter should be inserted through an antecubital vein instead of the jugular or subclavian veins. This avoids increased ICP from both the head-down position and decreased cerebral venous outflow. The position of the antecubital central venous pressure can be verified by chest X-ray, transducer pressure waveform, or p-wave configuration on the ECG.

Urine output is also measured as an indicator of perioperative fluid balance. During craniotomy, a diuresis occurs initially following the administration of osmotic or loop diuretics. Reduced urine output may reflect either hypovolemia or release of antidiuretic hormone.

Preoperative ICP monitoring is rarely used in patients for elective supratentorial tumor operations. ICP monitoring is an invasive procedure that can cause bleeding or infection. When performed with local anesthesia before induction, the procedure can be uncomfortable to the patient.

Muscle Relaxants

An increase in ICP has been reported after administration of succinylcholine in animals and humans.^{256,257} and ²⁵⁸ Intravenous administration of succinylcholine is reported to produce activation of the EEG and increases in CBF and ICP in dogs with normal brains.²⁵⁷ These cerebral effects have been attributed to succinylcholine-induced increases in muscle afferent activity that produce cerebral stimulation. In many, but not all, patients with compromised intracranial compliance, succinylcholine has been shown to increase ICP.^{258,259} This increase can be blocked with a full, paralyzing dose of vecuronium or a pretreatment (defasciculating) dose of metocurine.^{258,259} The nondepolarizing agent apparently eliminates the massive afferent input to the brain after succinylcholine.

To achieve muscle relaxation for intubation of the trachea, succinylcholine is not recommended for elective neurosurgical cases; however, succinylcholine remains the best agent for achieving total paralysis for the rapid-sequence intubation of the trachea. Therefore, in an emergency room or ICU setting, when there is a risk of aspiration or a need for immediate reassessment of neurologic status, succinylcholine should be used. Simultaneously, an effort should be made to control anesthetic depth to protect against the ICP-elevating effects of such noxious stimuli as laryngoscopy, intubation, or tracheal suctioning. In the hemiplegic (or paraplegic) patient, succinylcholine is avoided because of the risk of hyperkalemia.²⁶⁰ Succinylcholine-induced hyperkalemia has also been reported after closed head injury and ruptured cerebral aneurysms in patients who were not hemiplegic or paraplegic.^{261,262}

Nondepolarizing muscle relaxants are used during induction and maintenance of anesthesia in neurosurgical patients. Agents that release histamine are avoided, however. Histamine alone may lower blood pressure and increase ICP, thus lowering CPP. When the blood-brain barrier is disrupted, histamine can produce cerebrovasodilation and increases in CBF.²⁶³ Depending on the dose and rate of administration, most of the benzylisoquinolinium compounds (*α*-tubocurarine, metocurine, atracurium, mivacurium) have the potential to release histamine and thus increase ICP. Doxacurium and cisatracurium²⁶⁴ produce minimal to no histamine release over a wide dose range. Atracurium in intubating doses is reported to have no significant effect on ICP, blood pressure, or CPP in neurosurgical patients.²⁶⁵ The release of laudanosine by atracurium does not appear to have clinical significance in humans. Laudanosine has been reported to produce seizure activity in animals.²⁶⁶

The steroidal compounds (pancuronium, pipecuronium, vecuronium, and rocuronium) may be better relaxants for neurosurgical patients because they do not directly affect ICP. Pancuronium does not produce an increase in CBF, CMRO₂, or ICP in dogs.²⁶⁷ However, pancuronium's vagolytic effects can cause increases in heart rate and blood pressure, which may elevate ICP in patients with disturbed autoregulation. Pipecuronium, another long-acting agent, is reported to have no significant effect on ICP or CPP in patients with intracranial tumors²⁶⁸ and no hemodynamic side-effects. In patients with elevated ICP, vecuronium is currently the agent of choice for intubation and surgical paralysis. Vecuronium has no effect on ICP, heart rate, or blood pressure in neurosurgical patients.²⁶⁹ To achieve relatively rapid airway control (within 90 seconds), a priming dose of vecuronium (0.01 mg · kg⁻¹) can be administered followed by a higher dose (0.10 mg · kg⁻¹), or high doses of vecuronium (to 0.4 mg · kg⁻¹) can be safely administered without hemodynamic consequence.²⁷⁰ Rocuronium also has no effect on ICP in neurosurgical patients, but may have some mild vagolytic activity in higher doses (0.9 mg · kg⁻¹).²⁷¹

Induction, Maintenance, and Emergence

When the patient is brought into the operating room, a gross neurologic examination should be repeated and documented because changes in the patient's neurologic status can occur overnight. In patients with elevated ICP by clinical exam, CT scan and/or ICP measurement, osmotherapy may be indicated before induction of anesthesia. After appropriate monitoring devices are applied, the cooperative patient is asked to hyperventilate while preoxygenation is provided. Before laryngoscopy and intubation of the trachea, the patient is smoothly and deeply anesthetized with agents that reduce ICP. In the presence of elevated ICP, thiopental is commonly used to induce anesthesia; however, alternative agents such as propofol, etomidate, or midazolam can be used depending on the patient's medical condition. The following induction sequence is suggested: The intravenous administration of thiopental (3–5 mg · kg⁻¹) or propofol (1.25–2.5 mg · kg⁻¹) is followed by an opioid (fentanyl, 3–5 mg · kg⁻¹) and muscle relaxant. If no airway difficulties are anticipated, vecuronium (0.1 mg · kg⁻¹) is administered while controlled hyperventilation with 100% oxygen is instituted. In patients who have been vomiting because of elevated ICP, cricoid pressure is applied during mask ventilation. To deepen the anesthetic, fentanyl is administered in 50-mg increments to a total dose of 10 mg · kg⁻¹, depending on the blood pressure response. Lidocaine (1.5 mg · kg⁻¹) is also administered intravenously 90 seconds before intubation to suppress laryngeal reflexes.²⁷² When the peripheral muscle twitch response disappears, an additional 2–3 mg · kg⁻¹ bolus of thiopental is administered, and endotracheal intubation is performed as rapidly and smoothly as possible. An esmolol infusion or bolus may also be used to reduce the heart rate and blood pressure response to laryngoscopy and intubation. After induction of anesthesia, ventilation of the lung is controlled mechanically and adjusted to maintain PaCO₂ between 30 and 35 mm Hg. Arterial blood gases are measured after intubation to establish the arterial end-tidal CO₂ gradient.

The most commonly administered maintenance anesthetics for patients with supratentorial tumors are nitrous oxide–opioid and nitrous oxide–volatile inhalation agents. In practice, the opioid most frequently employed is fentanyl, and the volatile agent most frequently employed is isoflurane. Nitrous oxide, 50–70% in oxygen, is typically administered to decrease the total dose of intravenous agent or the required concentration of volatile agent. The cerebrovascular effects of nitrous oxide are not benign,^{49,50} and studies report that at equipotent doses, isoflurane has less adverse effects on ICP²⁷³ and CBF²⁷⁴ than nitrous oxide.

In patients with elevated ICP or low compliance, some clinicians avoid the administration of either nitrous oxide or high concentrations of isoflurane (*i.e.*, greater than 1.0%). Alternatively, an opioid–thiopental or propofol anesthetic technique may be employed with midazolam or low-dose isoflurane added for amnesia. When severe intracranial hypertension exists and the brain is tight despite adequate hyperventilation and the administration of steroids and diuretics, a totally intravenous technique is recommended, *e.g.*, a thiopental infusion (2–3 mg · kg⁻¹ · hr⁻¹) and fentanyl boluses or infusion (1–4 mg · kg⁻¹ · hr⁻¹).

Emergence from anesthesia should be as smooth as possible, avoiding straining or bucking on the endotracheal tube. Bucking can cause arterial hypertension and elevated ICP during termination of anesthesia, which can lead to postoperative hemorrhage and cerebral edema. To avoid bucking during emergence, muscle relaxants are not reversed until the head dressing is applied. Intravenous lidocaine (1.5 mg · kg⁻¹) can be administered 90 seconds before suctioning and extubation to minimize cough, straining, and hypertension. Antihypertensive agents such as labetalol and esmolol are also administered during emergence to control systemic hypertension.

In the usual craniotomy for excision of a supratentorial tumor, the conduct of the anesthetic is aimed at awakening and extubating the patient at the end of the procedure. The removal of a large tumor improves the patient's intracranial compliance, and hypercarbia required to drive ventilation in the emerging patient is usually well tolerated. The patient is extubated only when fully reversed from paralysis, and when he or she is awake and following commands. If the patient is not responsive, the endotracheal tube remains in place until the patient is awake and following commands. A brief neurologic examination is performed before and after extubation of the trachea. The patient is positioned with the head elevated 30° and transferred to the recovery room with oxygen by mask and oxygen saturation monitoring. Close monitoring and care, including frequent neurologic examinations, are continued in the recovery room.

Infratentorial Intracranial Tumors

The perioperative management of infratentorial tumors poses significant surgical and anesthetic challenges because of the relatively confined space within the posterior fossa. The posterior fossa contains the medulla, pons, cerebellum, major motor and sensory pathways, primary respiratory and cardiovascular centers, and

lower cranial nerve nuclei. Because of the posterior fossa's small size, a localized tumor can significantly compromise these vital brain stem structures and cranial nerves. Consequently, when evaluating patients with infratentorial tumors, the anesthesiologist should be aware that these patients have the potential to develop profound neurologic damage. Patients may exhibit depressed levels of consciousness secondary to increased ICP from obstructive hydrocephalus and/or exhibit signs of brain stem compression with depressed respiration and cranial nerve palsies. Preoperative endotracheal intubation and respiratory support may be required.

Special Anesthetic Considerations

Patient Position. A major challenge of infratentorial surgery is preventing further neurologic damage from the position of the patient and exploration. There is considerable controversy among neurosurgeons as to the best position for infratentorial surgery.

Exploration of the posterior fossa has been traditionally performed in the sitting position because it provides excellent surgical exposure and facilitates venous and CSF drainage. From the standpoint of the anesthesiologist, the sitting position provides better ventilation and easier access to the chest, airway, endotracheal tube, and extremities. Furthermore, facial and conjunctival edema is reduced. However, the sitting position is associated with significant risks. In older or debilitated patients, the sitting position can produce cardiovascular instability, resulting in hypotension with cerebral and cardiovascular compromise. A significant risk of venous air embolism occurs in patients operated on in the sitting position, and an attendant risk of paradoxical air embolism may also occur in patients with a patent foramen ovale or other right-to-left shunt.

Other problems associated with the sitting position are peripheral nerve injury, pneumocephalus, jugular venous obstruction, and quadriplegia. Peripheral nerve injuries to the ulnar, sciatic, or lateral peroneal nerves can result if care is not taken in positioning and padding the respective pressure points. Pneumocephalus occurs frequently in patients who have surgery performed in the sitting position.²⁷⁵ Pneumocephalus may develop into tension pneumocephalus postoperatively, producing serious neurologic dysfunction. Nitrous oxide has been implicated in the genesis of tension pneumocephalus.²⁷⁶ Because of this, when used, nitrous oxide should be discontinued before dural and cranial closure and avoided if surgery recurs within 7 days. Jugular venous obstruction causing swelling of the face and tongue may result from hyperflexion of the neck. To avoid this, head flexion should be limited by placing two fingers between the mandible and sternum. Paraplegia, triplegia, and quadriplegia have been reported following surgery in the sitting position. This complication has been attributed to mechanical compression of the cervical spinal cord or vertebral blood vessels and stretching of spinal cord blood vessels, causing ischemia during head flexion.²⁷⁷ If hypotension occurs, the brainstem and cervical spinal cord are rendered even more vulnerable to an ischemic insult. During positioning for posterior fossa exploration, cases of position-related brain stem and cervical spinal cord ischemia have been reported.^{278,279} Therefore, flexion of the head on the cervical spine may be hazardous in some patients with large posterior fossa tumors and in elderly or arthritic patients. A preoperative examination of the mobility of the cervical spine, including a review of radiologic studies to determine the width of the cervical canal, should be performed to establish whether the patient can tolerate the position required for surgery. In addition, the application of SEP monitoring during positioning for surgery may be used to detect position-related ischemia.

Other positions used for posterior fossa exploration are the lateral, prone, and "park bench" or three-quarters prone positions. These alternative positions have been advocated because of the lower incidence of air emboli and greater cardiovascular stability associated with them. Potential disadvantages of these positions are malignant cerebellar edema and venous hemorrhage. To date, there is no evidence that operative position affects postoperative outcome. In a study that reviewed 579 posterior fossa craniectomies, patients in the sitting position had less blood loss and postoperative cranial nerve dysfunction than patients operated on in the horizontal position (supine, prone, lateral, and park bench), and there was no difference in the incidence of hypotension and postoperative cardiopulmonary complications between groups.²⁸⁰ The incidence of venous air embolism in this series of patients was significantly greater in sitting versus horizontal patients (45% vs. 12%), but it was not associated with a significantly increased morbidity or mortality.²⁸⁰ The authors concluded that there are significant advantages and disadvantages to both sitting and horizontal positions and that these positions can be used safely.

Because of various advantages and disadvantages to both sitting and horizontal positions, no one best position exists for all patients requiring exploration of the posterior fossa. The selection of the most appropriate position for an individual patient should be based on the location of the tumor, surgical exposure, the patient's medical condition, and consideration of the risks and benefits.

Monitoring. During posterior fossa exploration, surgical retraction or manipulation of the brain stem or cranial nerves can cause significant cardiac dysrhythmia or alterations in blood pressure. Adequate warning of brain stem compromise is obtained by monitoring the ECG for alterations in cardiac rate and rhythm. In addition, direct arterial pressure monitoring provides continuous information on sudden changes in systemic blood pressure and an estimate of CPP. (To estimate CPP in the sitting position, the arterial transducer should be zeroed to the highest point on the skull.) The hemodynamic consequences of dysrhythmias or air embolism are also instantly recognized with direct arterial pressure monitoring.

Electrophysiologic monitoring of SEPs is used to detect ischemia and compromise of the brain stem or cranial nerves. For example, BAEPs are monitored during surgery for acoustic neuroma to help preserve function of cranial nerve VIII or during posterior fossa procedures to monitor brain stem ischemia. Depending on the tumor's location, SSEPs may also be used to detect brain stem compromise. Position-related ischemia has been observed during monitoring with either BAEPs or SSEPs.^{278,279} Electromyography is used during resection of acoustic neuromas and microvascular decompression to test seventh nerve function when the face is not accessible to palpation or visual assessment.

Venous Air Embolism. Venous air embolism may occur whenever the operative field is elevated 5 cm or more above the right atrial level. Whereas the incidence of air embolism is on average 40–45% in patients operated on in the sitting position, entrainment of air also occurs during operations performed in the lateral, supine, or prone positions. The primary pathophysiologic event in venous air embolism is intense vasoconstriction of the pulmonary circulation, which results in ventilation/perfusion mismatch, interstitial pulmonary edema, and reduced cardiac output as pulmonary vascular resistance increases.

Air may also pass directly through the pulmonary circulation or through right-to-left intracardiac shunts (e.g., probe-patent foramen ovale) to the coronary and cerebral circulation when right atrial pressure exceeds left atrial pressure. A patent foramen ovale exists in 20–30% of the population on autopsy study.²⁸¹ In the sitting position, a reported 50% of patients develop right atrial pressure greater than left atrial pressure and thus have the potential for paradoxical air embolism.²⁸² The calculated risk of paradoxical air embolism is 5–10%. Preoperative screening with precordial two-dimensional contrast echocardiography during a Valsalva maneuver and cough has been suggested as a method to identify patients with patent foramen ovale.^{283,284} If a patent foramen ovale is detected preoperatively, a position other than sitting is recommended for surgery because of the risk of paradoxical air embolism.

Monitors used for detecting venous air embolism are listed in [Table 28-11](#). The two-dimensional transesophageal echocardiogram detects air bubbles with an echocardiographic probe placed behind the heart. The transesophageal echocardiogram is slightly more sensitive than the precordial Doppler,²⁸⁵ but is invasive and cumbersome. The transesophageal echocardiogram has the advantage of monitoring air in the right and left cardiac chambers and the aorta, and thus can be used to detect both venous and arterial air embolism.

| | |
|-----------------|---|
| Most Sensitive | |
| ↓ | Transesophageal echocardiography |
| | Precordial Doppler |
| | Increase in pulmonary artery pressure |
| | Decrease in end-tidal CO ₂ |
| | Increase in end-tidal N ₂ (specific) |
| ↓ | |
| Least Sensitive | |

Table 28-11. MONITORS FOR DETECTION OF VENOUS AIR EMBOLISM

The precordial Doppler ultrasound transducer is the most sensitive noninvasive monitor of venous air embolism. It detects amounts of air as small as 0.25 ml. The transducer is positioned along the right parasternal border between the third and sixth intercostal spaces to maximize audible signals from the right atrium. Proper placement is confirmed by rapid injection of 5–10 ml of saline into a right atrial catheter. The resultant turbulent flow changes the Doppler sounds to a high-pitched noise similar to the sounds produced by intravascular air.

Pulmonary artery (PA) catheterization has been advocated for patients who undergo surgery in the sitting position. Passage of air into the pulmonary circulation leads to mechanical obstruction and reflex vasoconstriction from local hypoxemia. The PA catheter detects the resultant hypertension. (The change in pulmonary artery pressure correlates with the hemodynamic significance of the embolus because pulmonary artery pressure increases proportionally with the volume of air entering the pulmonary arteries.) Pulmonary artery pressure measurement is slightly more sensitive than capnography for detecting venous air embolism, but it is invasive. The PA catheter lumen is poorly designed for air aspiration. In addition, the fixed distance between the PA catheter tip and the right atrial port makes it difficult to position for both pulmonary capillary wedge pressure measurement and air aspiration. The catheter can be used to identify patients at risk for paradoxical air embolism, *i.e.*, patients who develop right atrial pressure greater than pulmonary capillary wedge pressure. When this occurs, measures to elevate pulmonary capillary wedge pressure, such as volume loading or repositioning, are undertaken.

In the operating room, exhaled gases are measured by infrared analysis, mass spectrometers, and analyzers based on Raman scattering. The infrared absorption technique is the most popular method of measuring the concentration of CO₂ in the airway. The capnograph is very useful for diagnosing venous air embolism. Small volumes of intravascular air produce a ventilation/perfusion mismatch, which is reflected in a reduced end-tidal CO₂. The capnograph complements the capabilities of the precordial Doppler by differentiating hemodynamically insignificant emboli that are heard with the Doppler from significant emboli. Doppler sounds without reduction in end-tidal CO₂ usually indicate insignificant amounts of air.

End-tidal N₂ monitoring is specific for detecting air but is slightly less sensitive than end-tidal CO₂ in detecting subclinical air embolism.²⁸⁶ As intravascular air in the pulmonary circulation crosses the capillary–alveolar membrane, it is exhaled, increasing the end-tidal N₂ concentration. The advantage of knowing the value of the end-expired N₂ is the ability to calculate the volume of air entrained. When a patient is ventilated with an air–oxygen mixture, the increase in end-tidal N₂ with venous air embolism may not be evident. In addition, other causes of increases in end-tidal N₂ must be eliminated, such as a leak in the breathing circuit or an incomplete seal around the endotracheal tube cuff.

A central venous pressure catheter is inserted whenever there is a risk for venous air embolism. When the catheter is correctly positioned, entrained air can be aspirated from the right atrium. It is suggested that the optimal position for the tip of a single orifice catheter is 3.0 cm above the superior vena cava and the right atrial junction.²⁸⁷ The position of the right atrial catheter may be confirmed by a chest film, by using a saline-filled catheter as a unipolar lead and following the configuration of the P waves on the ECG, or by transducing a venous waveform. Multi-orifice right atrial catheters are more effective than single-orifice catheters in aspirating air from the circulation.

Early diagnosis of air embolism is essential for successful treatment. The precordial Doppler unit is considered the basic monitoring device for detection of air embolism and is most effective when used in conjunction with end-tidal monitoring. The clinical significance of air embolism detected by Doppler ultrasonography can be assessed by a decrease in end-expired CO₂ or an increase in pulmonary artery pressure. A Doppler in conjunction with either a capnograph or a PA catheter usually detects air before physiologic alteration begins. Treatment is directed at preventing further influx of air. Whenever air embolism is suspected, the surgeon is notified immediately. The surgical field is flooded with saline and packed, and bone edges are waxed. Nitrous oxide, if present, is discontinued to prevent further expansion of embolized air. Neck veins are compressed as a means of increasing jugular venous pressure, which prevents further air entry and helps to localize the source of air. Aspiration of air from the right atrial catheter is attempted. With significant air embolism, patient position should be changed to lower the head to heart level when possible. If necessary, vasopressors and volume infusion are administered to treat hypotension. Positive end-expiratory pressure or Valsalva maneuver are avoided because they increase right atrial pressure and the likelihood of paradoxical embolus from venous air embolism.

Anesthetic Management. When selecting an anesthetic technique for patients in the sitting position, conditions of particular concern are cardiovascular stability and risk of air embolism. In changing an anesthetized patient from the supine to sitting position, a mild transient postural hypotension occurs in about one third of cases and marked hypotension in about 2–5% of cases.^{288,289} General anesthesia with positive-pressure ventilation is associated with a reduction in blood pressure mainly caused by a decrease in cardiac output. As patients are placed into the sitting position, venous return is impeded, causing further reductions in cardiac output and blood pressure.^{288,289} Therefore, efforts are directed at promoting venous return and maintaining cardiac output during the anesthetic management of these patients. An anesthetic technique that causes the least impairment of cardiovascular performance should be administered when patients are placed in the sitting position. Measures to avoid hypotension are also instituted. These include adequate preoperative hydration, wrapping the legs with elastic bandages, and flexing the patient's hips and knees at heart level. The patient's position is slowly changed, titrating position against systemic blood pressure. Administration of fluids (balanced salt solutions) and small amounts of vasopressors may be necessary.

Because nitrous oxide expands embolized air, some have advocated general anesthesia without nitrous oxide for anesthetizing patients in the sitting position. This, however, would necessitate the use of a volatile anesthetic agent. In some patients, the use of a volatile agent may increase the risk of focal or generalized ischemia from an increase in ICP and an anesthetic-induced reduction in blood pressure. Therefore, the risks and benefits of using nitrous oxide versus a volatile agent for neurosurgical procedures with an increased potential for air embolism should be discussed and individualized. Nitrous oxide (50%) administration to patients undergoing surgery in the sitting position is reported to have no significant effect on the incidence or severity of venous air embolism, provided nitrous oxide is discontinued immediately on Doppler detection of air.²⁹⁰ In general, a balanced anesthetic technique (nitrous oxide–oxygen–opioid–muscle relaxant) combined with controlled hyperventilation is recommended for maximal cardiovascular stability and control of intracranial hypertension. If air embolism occurs, nitrous oxide is discontinued. Nitrous oxide may be reintroduced cautiously with concurrent Doppler monitoring to determine whether the embolized air remains a threat.

Postoperative Concerns. The potential for significant cardiorespiratory and neurologic deterioration exists in the immediate postoperative period following posterior fossa exploration. Therefore, direct arterial pressure and ECG monitoring should be continued for the first 24–48 hours postoperatively, and neurologic examinations should be performed frequently.

Central apnea requiring postoperative ventilatory support may result from damage to respiratory centers caused by extensive posterior fossa exploration. If respiratory centers have been manipulated but not destroyed, respiratory impairment is temporary. Postoperative impairment of swallowing and pharyngeal sensation may occur secondary to stretch or manipulation of cranial nerves IX, X, and XII. These patients are at increased risk for aspiration pneumonia or hypoxia and therefore should remain intubated until airway protective reflexes return.

Systemic hypertension frequently occurs after posterior fossa surgery and requires immediate treatment to prevent brain edema and hematoma formation. Postoperative hypertension usually resolves within the first 24 hours. Atrial and ventricular ectopic beats may also occur within the first 24 hours.

Because of the proximity of respiratory and cardiovascular centers, any edema, hematoma, or infarction of the brain stem and cerebellum can produce serious compromise. When a patient fails to awaken satisfactorily from anesthesia, bleeding or acute swelling of the structures in the posterior fossa must be suspected. In addition, patients who are awake and talking may become unresponsive secondary to obstructive hydrocephalus or brain stem compression. Decreased level of consciousness is an early reliable sign of brain stem compression. More serious signs are systemic hypertension, bradycardia, and irregular or absent respirations. Reintubation and prompt surgical intervention to relieve pressure on the brain stem are necessary.

The preoperative level of consciousness and intraoperative conditions will determine whether the patient is extubated at the end of the procedure. A patient with a depressed level of consciousness preoperatively should not be expected to improve immediately after surgery. In general, patients who require preoperative mechanical ventilation usually require postoperative mechanical ventilation. Furthermore, if the surgical procedure is extensive, producing an engorged, swollen brain, postoperative mechanical ventilation is usually necessary.

Pituitary Tumors

The pituitary gland is located at the base of the skull in the sella turcica, a bony cavity within the sphenoid bone, and it is divided into anterior (adenohypophysis) and posterior (neurohypophysis) lobes. A fold of dura (the diaphragma sellae) on the superior surface of the sella is pierced by the infundibular stalk, which connects the posterior lobe of the pituitary gland to the hypothalamus. The hypothalamus regulates hormone release from the anterior pituitary through regulatory peptides (hypothalamic releasing and inhibiting factors) that reach the anterior pituitary by a complex portal vascular system. Control of hypothalamic secretion is complex and occurs from neuronal and chemical influences, including feedback from target organ hormones. The large glandular anterior pituitary secretes at least seven hormones. The smaller posterior pituitary stores and secretes two hormones, antidiuretic hormone and oxytocin, which are synthesized in specialized hypothalamic neurons and transported as granules in axons down the pituitary stalk to the posterior pituitary gland. The anterior and posterior pituitary hormones are listed in [Table 28-12](#).

| Anterior Pituitary | Posterior Pituitary |
|------------------------------|----------------------|
| Growth hormone | Antidiuretic hormone |
| Prolactin | Oxytocin |
| Gonadotropins: | |
| Follicle-stimulating hormone | |
| Luteinizing hormone | |
| Adrenocorticotropin (ACTH) | |
| β -Lipotropin | |
| Thyrotropin (TSH) | |

Table 28-12. PITUITARY GLAND HORMONES

Pituitary tumors can be divided into two general categories, nonfunctioning and hypersecreting. Nonfunctioning pituitary tumors are usually diagnosed when they become large and produce symptoms related to mass effects by impinging on adjacent structures. Headache, impaired vision, cranial nerve palsies, increased ICP, and hypopituitarism may result. The most common nonfunctioning tumors are chromophobe adenomas, craniopharyngiomas, and meningiomas. As these tumors enlarge, they can cause selective or global impairment of pituitary function by compressing the normal gland. A sudden enlargement of the pituitary caused by spontaneous hemorrhage or infarction into the tumor produces a symptom complex known as pituitary apoplexy, a life-threatening condition characterized by acute neurologic deficits and a rapid decline in pituitary function. Therapy includes rapid administration of corticosteroids and emergency surgical decompression.

Functioning pituitary adenomas produce an excess of one or more of the anterior pituitary hormones, and therefore are usually diagnosed when the tumors are small. The most frequently occurring are prolactinomas followed by growth hormone- and adrenocorticotropin-secreting adenomas. Adenomas secreting thyrotropin or follicle-stimulating hormone and luteinizing hormone are rare. Adenomas secreting both growth hormone and prolactin are common, however. Prolactinomas may produce the amenorrhea-galactorrhea syndrome in females and decreased libido and impotence in males. Excessive production of growth hormone before puberty results in gigantism; after puberty, in acromegaly. Cushing's disease develops from an adrenocorticotropin-secreting adenoma that causes bilateral adrenal hyperplasia.

Special Anesthetic Considerations

Preoperative Evaluation. The preoperative evaluation of patients with pituitary tumors requires an assessment of endocrine function and associated medical disorders. Endocrine tests are performed in the basal state and are supplemented by appropriate provocative tests (Table 28-13). These tests diagnose hyperfunctioning or hypofunctioning tumors, the extent of endocrine disturbance, and the adequacy of treatment. A thorough discussion of endocrinologic testing can be found elsewhere.²⁹¹

| ANTERIOR PITUITARY FUNCTION TESTS |
|---|
| Basal levels of pituitary hormones: GH, prolactin, ACTH, TSH, FSH, LH |
| Serum levels: cortisol (AM and PM), thyroxine, testosterone, estradiol |
| Urinary levels: 17-ketosteroids, 17-hydroxycorticosteroids, free cortisol, estrogens |
| Provocative and suppression tests as indicated: |
| GH reserve—glucagon stimulation |
| GH suppression—glucose suppression (acromegaly) |
| Prolactin reserve—dopamine or thyrotropin-releasing hormone provocative testing |
| Low- and high-dose dexamethasone suppression (Cushing's syndrome) |
| Metyrapone test (Cushing's syndrome) |
| POSTERIOR PITUITARY FUNCTION TESTS |
| ADH reserve: Serum and urine osmolality before and after 8–12 hours' water deprivation. |

Table 28-13. PREOPERATIVE ENDOCRINE STUDIES FOR PITUITARY TUMORS

In Cushing's disease, the increased corticotropin and cortisol can produce multiple systemic effects such as diabetes mellitus with insulin-resistant hyperglycemia, hyperaldosteronism with hypokalemia and metabolic alkalosis, hypertension, mild congestive heart failure, and obesity. These patients require preoperative evaluation and management of hypertension, diabetes, and electrolyte imbalances, as well as a cardiovascular evaluation for ischemic heart disease and congestive heart failure.

Patients with acromegaly exhibit a general overgrowth of skeletal, connective, and soft tissues. Hands and feet become markedly enlarged and facial features become coarse. All major organs increase in size, including the heart, lungs, liver, and kidneys. These patients also require an evaluation for systemic hypertension, diabetes, ischemic heart disease, cardiomegaly, and congestive heart failure, with appropriate medical management instituted before surgery. Significant anatomic airway changes can occur in acromegalics, making airway management difficult. Facial bone hypertrophy, particularly of the mandible and nose, thick tongue and lips, and hypertrophy of nasal turbinates, soft palate, tonsils, epiglottis, and larynx create difficulties with mask fit and visualization of the larynx. Glottic stenosis caused by soft tissue overgrowth may cause preoperative hoarseness and dyspnea. These patients usually require a smaller endotracheal tube than anticipated based on the size of the patient's facial features, and may be predisposed to postextubation edema. Stretching or compression of the recurrent laryngeal nerves from laryngeal soft tissue or thyroid gland enlargement may result in vocal cord paralysis. Because of these anatomic changes, a thorough preoperative airway examination is required. Patients complaining of hoarseness, dyspnea, or inspiratory stridor should undergo indirect laryngoscopy and X-ray examination of the neck to analyze airway conformation and lumen diameter. Based on this evaluation, preparations for difficult airway management and intubation should be anticipated. For patients with difficult airways and glottic abnormalities, an awake fiberoptic intubation is recommended. This obviates the need for a tracheostomy in all but the most severe cases. Patients without upper airway or vocal cord involvement can be managed in the routine manner.

Pressure effects on the normal pituitary gland from parasellar tumors or other lesions can cause panhypopituitarism. Patients who have panhypopituitarism require replacement therapy with appropriate hormones. These patients should be euthyroid before surgery. Glucocorticoid replacement is required when thyroxine replacement is begun to avoid stressing the insufficient adrenocortical axis. Because glucocorticoids are also necessary to facilitate renal excretion of a water load, diabetes insipidus is usually not observed in the patient with pituitary insufficiency until cortisol replacement therapy is instituted. Preoperatively, the patient with panhypopituitarism will be receiving oral steroid and thyroxine therapy and, when indicated, intranasal instillation of synthetic vasopressin.

During the preanesthetic evaluation, the size and location of the tumor and its effect on intracranial dynamics should be determined. Pituitary microadenomas do not produce mass effects. Pituitary tumors with suprasellar extension, craniopharyngiomas, and other suprasellar tumors may exert a mass effect. In these patients, the CT scan or MRI and the neurologic examination are evaluated for signs of increased ICP. All patients scheduled for pituitary surgery are given supplemental short-acting glucocorticoid therapy perioperatively. Because the surgery involves manipulation or removal of the anterior pituitary, transient or permanent deficiency of adrenocorticotropin and cortisol secretion may result. To assess function of the optic nerves and chiasm, a visual examination, including examination of the visual fields, is performed. When transsphenoidal surgery is planned, an otolaryngologic examination of the nasal passages and nasopharynx is also performed, and a nasal culture is obtained to guide antibiotic therapy in the event of postoperative infection.

Surgical Considerations. Since the introduction of the operating microscope, transsphenoidal excision has been recommended for all pituitary tumors that do not have marked suprasellar extension. Advantages of the transsphenoidal approach include the following: lower morbidity and mortality rates with decreased incidence and severity of diabetes insipidus; elimination of frontal lobe retraction and external scars; magnified visualization and removal of small tumors, which spares normal tissue; decreased frequency of blood transfusions; and shorter hospitalization. Relative disadvantages include the possibility of CSF leakage and meningitis (which is rare with the use of antibiotics), inability to visualize neural structures adjacent to a large tumor, inaccessibility of tumors extending into middle and anterior fossae, and the possibility of bleeding from cavernous sinuses or carotid arteries (which can lead to intracranial hemorrhage, brain stem compression, and significant blood loss). The transcranial approach to the sella permits direct visualization of suprasellar structures: the vascular sinus ring, optic chiasm, hypothalamus, and pituitary stalk. This approach is recommended for pituitary tumors of uncertain diagnosis and those that have significant suprasellar extension with optic nerve or hypothalamic involvement. With this approach, there is potential for damage to the olfactory nerves, frontal lobe vasculature, and optic nerves and chiasm. In addition, the incidence

of permanent diabetes insipidus and anterior pituitary insufficiency is increased.

Anesthetic Considerations. The anesthetic management of patients undergoing pituitary surgery is not fundamentally different from that of patients undergoing other craniotomies. Basic neuroanesthetic principles apply whether the transsphenoidal or transcranial approach is used. With the transcranial approach, however, intraoperative measures to control ICP are instituted because of pressure effects, the necessity for brain retraction, and the potential for greater blood loss.

During transsphenoidal procedures, central venous pressure is not routinely monitored. When the patient is positioned with a significant head-up tilt, however, air embolism may occur during this procedure. Therefore, precordial Doppler monitoring and right atrial catheterization are recommended for detection and treatment of air embolism when a significant surgical site–cardiac gradient (15° or more) exists.

Evoked potential monitoring of VEPs may be used during pituitary surgery to monitor direct compression or compromise of blood supply to optic nerves and chiasm. Technical difficulties that cause intraoperative recording problems include changes in pupil size, deviation of eyes, goggle size and bulkiness, and stimulus delivery (light flashes). Because VEPs are entirely cortical in origin, they are also more vulnerable to the effects of general anesthetics.

For transsphenoidal procedures, a sublabial incision and dissection through the nasal septum is performed; therefore, oral endotracheal intubation is required. The nasal septum is usually prepared with 4% cocaine pledgets placed in the nares, followed by injection of 2% lidocaine with epinephrine 1:200,000 to the submucosa. This combination develops a dissection plane, decreases bleeding, and buffers the hypertensive response to nasal dissection. Initially, the cocaine and epinephrine may cause hypertension, tachycardia, and dysrhythmias, and drugs to treat these responses should be available. After oral endotracheal intubation with a RAE tube, the oropharynx is packed with saline-soaked gauze to minimize blood pooling in the glottis, esophagus, and stomach. Intraoperative C-arm fluoroscopy of the skull (lateral views) is used during this procedure, rendering the patient's head and arms relatively inaccessible once the patient is draped.

Potential intraoperative complications during transsphenoidal procedures relate to the anatomic landmarks surrounding the sella turcica. The cavernous sinuses occupy the lateral walls of the sella and contain venous structures, the internal carotid artery, and cranial nerves III, IV, V, and VI. The optic chiasm, with its associated optic nerves and tracts, lies directly above the diaphragma sella in front of the pituitary stalk. Surgical manipulation in the region surrounding the sella can result in the following: hemorrhage from the venous sinuses or internal carotid artery, arterial spasm or thrombotic occlusion secondary to arterial manipulation, venous air embolism if head-up tilt is excessive, cranial nerve weakness secondary to trauma or stretching, and visual complications secondary to damage of the optic nerve or chiasm.²⁹²

The chosen anesthetic technique should permit gross visual acuity examination before patient extubation. If vision is the same or improved, extubation can proceed. If acuity is worse, further diagnostic studies and emergent decompressive surgery may be required. After transsphenoidal surgery, the patient will awaken with nasal packing, necessitating mouth-breathing postoperatively. Therefore, these patients must be fully awake and following commands before extubation of the trachea.

Postoperative Concerns. In the immediate postoperative period after either transsphenoidal or transcranial procedures, the primary concerns are corticosteroid coverage and fluid balance. Dexamethasone followed by prednisone is given for 5 days after surgery or until postoperative testing shows an intact pituitary–adrenal axis. Fluid balance is assessed by strict attention to hourly fluid intake and output and urine specific gravity. Development of diabetes insipidus is uncommon during surgery but may occur early in the postoperative course. Diabetes insipidus is commonly seen during the first 12 hours postoperatively and usually lasts for 2–4 days. Diagnosis is based on the following: polyuria (2–15 l · day⁻¹), hypernatremia, high serum osmolality (>300 mOsm · kg⁻¹), decreased urine osmolality (200 mOsm · kg⁻¹), and decreased urine specific gravity (1.005 or less). Therapy includes replacement of urine losses with intravenous fluids. When urine volumes are excessive, exogenous vasopressin is given, e.g., aqueous vasopressin (5–10 IU, iv or im, q 6 hr) or the synthetic analog of ADH, desmopressin acetate (0.5–2 mg, iv, q 8 hr; 1–4 mg, sc q 6–12 hr; or nasal inhalation 10–20 mg).

Other complications of pituitary tumor surgery include CSF rhinorrhea, hypothalamic injury or stroke, cerebral ischemia, and meningitis. After transsphenoidal surgery, patients must be carefully monitored in the recovery room for airway obstruction caused by bleeding and secretions in the pharynx. Frequent neurologic examinations are performed to note any changes in mental status. Patients who have had an uncomplicated hospital course after transsphenoidal surgery are often discharged within 5–6 days.

CEREBROVASCULAR MALFORMATIONS

Intracranial Aneurysms

Subarachnoid hemorrhage (SAH) from rupture of an aneurysm arising from the circle of Willis produces significant morbidity and mortality.^{293,294} Of the estimated 28,000 victims each year in North America, 10,000 die before they can receive medical attention. Of the 18,000 patients who survive to receive medical attention, about half will die or become severely disabled. Only one third of all patients will be functional survivors. The peak age-related incidence for rupture is in the fifth decade of life, and the incidence for females is slightly higher than that for males. Potential risk factors for the development and rupture of aneurysms have been identified. Hypertension, a risk factor for aneurysm formation, is also a significant factor in aneurysm rupture.²⁹⁵

A patient with aneurysmal SAH may be classified according to one of several grading systems: Botterell's original classification,²⁹⁶ the modification by Hunt and Hess²⁹⁷ (Table 28-14), or the more recent World Federation of Neurosurgeons (WFNS) SAH scale²⁹⁸ (Table 28-15). These classifications are used by neurosurgeons to estimate surgical risk and outcome. Higher grades, or patients who are clinically more impaired, are associated with the presence of cerebral vasospasm, intracranial hypertension, and increased surgical mortality. In general, the poorer the grade on hospital admission, the worse the prognosis.

| Grade | Criteria |
|-------|--|
| 0 | Unruptured aneurysm |
| I | Asymptomatic, or minimal, headache and slight nuchal rigidity |
| II | Moderate to severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy |
| III | Drowsiness, confusion, or mild focal deficit |
| IV | Stupor, moderate to severe hemiparesis, early decerebration, vegetative disturbance |
| V | Deep coma, decerebrate rigidity, moribund |

Adapted from Hunt WE, Hess RM: Surgical risk as related to time of intervention in the repair of intracranial aneurysms. *J Neurosurg* 28:14, 1968.

Table 28-14. HUNT AND HESS CLASSIFICATION OF PATIENTS WITH SUBARACHNOID HEMORRHAGE

| WFNS Grade | GCS Scale* | Motor Deficit |
|------------|------------|-------------------|
| I | 15 | Absent |
| II | 13–14 | Absent |
| III | 13–14 | Present |
| IV | 7–12 | Present or absent |
| V | 3–6 | Present or absent |

SAH = subarachnoid hemorrhage; GCS = Glasgow Coma Scale.
* Refer to Table 28-18 for definition of scale.
Adapted from Drake CG, Hunt WE, Sank K et al: Report of World Federation of Neurological Surgeons Committee on a universal subarachnoid hemorrhage grading scale. *J Neurosurg* 68:985, 1988.

Table 28-15. WORLD FEDERATION OF NEUROSURGEONS (WFNS) SAH SCALE

The management of unruptured intracranial aneurysms is controversial. In a report from the International Study of Unruptured Intracranial Aneurysms, it was revealed that surgery did not reduce the rate of disability and death in patients with unruptured aneurysms smaller than 10 mm in diameter and no history of SAH.²⁹⁹

The presence of blood in the subarachnoid space causes an abrupt, marked rise in ICP, which often results in systemic hypertension and dysrhythmias. The abrupt increase in ICP accounts for the acute onset of a sudden, severe headache. The classic presentation of aneurysmal SAH is that of severe headache associated with stiff neck, photophobia, nausea, vomiting, and often transient loss of consciousness. With this presentation, the diagnosis of SAH is obvious. In about 50% of patients, a small bleed or “warning leak” precedes a major aneurysmal rupture.³⁰⁰ Warning symptoms and signs tend to be mild and nonspecific (headache, dizziness, orbital pain, slight motor or sensory disturbance) and are generally ignored or misdiagnosed by both patient and physician.

The diagnosis of SAH is made by the combination of clinical findings and a CT scan. This is followed by angiography of both carotid and vertebral arteries to define the cause. Aneurysms are classified according to location and size. They arise at a branch or bifurcation, usually at a point where a major vessel makes a turn changing the axial flow of blood.

There are several potential complications of SAH and surgical treatment of aneurysms. The most important of these are intracranial hypertension, rebleeding, vasospasm, and hydrocephalus. *Intracranial hypertension* is present to some degree in most patients following a SAH. In the uncomplicated case, intracranial hypertension does not require specific treatment. Intracranial pressure gradually returns to normal by the end of the first week. If an intracerebral hemorrhage, intraventricular hemorrhage, vasospasm, or hydrocephalus develops, intracranial hypertension may be severe and require treatment. Patients may require emergency ventriculostomy, steroids, diuretics, or intubation and hyperventilation. Intracranial pressure should be lowered gradually, especially in patients with unclipped aneurysms. Abrupt lowering of ICP by lumbar puncture, ventricular drainage, or rapid infusion of mannitol can induce rebleeding.

Rebleeding occurs most commonly during the first 24 hours following initial SAH. The chance of rebleeding is about 4% within the first day; after 48 hours, it is 1.5% per day, with a cumulative rebleeding rate of 19% by the end of 2 weeks.³⁰¹ Recurrent aneurysmal hemorrhage is a devastating complication associated with increased morbidity and mortality.

Because of the incidence of rebleeding with conservative management of SAH, early aneurysm clipping (days 0–3) is currently recommended for patients who are alert on admission. The debate over “early versus late” surgery was largely resolved following the report of The International Cooperative Study on the Timing of Aneurysm Surgery (ICSTAS).^{295,302} In this trial, overall management results demonstrated a similar mortality (20%) and good outcome (60%) for patients with surgery planned for early (0–3 days) and late (11–14 days) intervals. The least favorable outcome and highest mortality occurred in patients with planned surgery for days 7–10 after SAH. Patients who were alert on admission did best with early surgery. When only the North American patients were analyzed, early surgery (days 0–3) provided the best results in lower grade patients.³⁰³ There was no difference in the incidence of intraoperative rupture between early and late surgery, and although there was a relationship between “tightness” of the brain during surgery and the interval from SAH to operation, aneurysm dissection was no more difficult in early than in late surgery.³⁰² The timing of surgery does not influence the risk for cerebral vasospasm.³⁰⁴

Cerebral vasospasm is a major cause of morbidity and mortality in SAH patients.^{295,305} Angiographic evidence of vasospasm can be detected in up to 70% of patients. However, clinical vasospasm with ischemic deficits is observed in approximately 30% of patients, most often between days 4 and 12, with a peak at 6–7 days following SAH.²⁹⁵ The clinical syndrome of vasospasm is often heralded by worsening headache and increasing blood pressure. It is characterized by progressive symptoms of confusion and lethargy, followed by focal motor and speech impairments corresponding to the arterial territory involved. The syndrome may resolve gradually or progress to coma and death within a period of hours to days. The diagnosis of vasospasm is confirmed by angiography. The transcranial Doppler (TCD) is a safe, repeatable, noninvasive method to identify and quantify vasospasm, and can be used to evaluate the effectiveness of various therapies.

The mechanism responsible for vasospasm is unknown; however, structural and pathologic changes have been demonstrated in the vessel wall.³⁰⁶ There is also evidence that vasospasm after SAH correlates with the amount of blood in the subarachnoid space, and removal of extravasated blood decreases the occurrence and severity of ischemic deficits.^{305,306} The component in blood implicated in causing cerebral arterial vasospasm is oxyhemoglobin.

Many drugs have been investigated for prevention or treatment of vasospasm, but most are ineffective. The calcium channel blocker nimodipine has become standard prophylactic therapy. However, the efficacy of prophylactic nimodipine after SAH has been seriously challenged.³⁰⁷ A recent meta-analysis showed a reduction in vasospasm in nimodipine groups, but a corresponding reduction in mortality was slight and not statistically significant compared to control groups. “Triple-H” therapy—hypervolemia, hypertension, and hemodilution—has become the mainstay of treatment for ischemic neurologic deficits caused by cerebral vasospasm.^{308,309} and ³¹⁰ To improve cerebral blood flow to areas of impaired autoregulation, cerebral perfusion pressure is increased by intravascular volume expansion and induced hypertension. Intravascular volume expansion is accomplished with infusion of crystalloid, colloid, or blood to a pulmonary capillary wedge pressure of 12–18 mm Hg or a central venous pressure of 10–12 mm Hg. If this regimen does not reverse the deficit, a vasopressor (e.g., dopamine, dobutamine) is introduced to raise systemic blood pressure until the neurologic deficits subside or reverse. This therapy can worsen cerebral edema, increase ICP, and cause hemorrhagic infarction. Systemic complications include pulmonary edema and cardiac failure in patients at risk. Hemodilution, the last component of triple-H therapy, decreases blood viscosity and improves cerebral blood flow. The optimal hematocrit thought to maximize the oxygen delivery to tissues has been estimated at 33%, but may be higher in ischemic brain.

Another method for treating symptomatic vasospasm is cerebral angioplasty. Transluminal angioplasty can be used to dilate constricted major cerebral vessels in patients who are refractory to conventional treatment.^{311,312} Superselective intra-arterial infusion of papaverine dilates distal vessels not accessible to angioplasty.³¹³ These procedures are usually performed under general anesthesia to minimize movement and permit accurate placement of the intra-arterial balloon used to dilate the cerebral vessels. The risks of angioplasty include aneurysm rupture, intimal dissection, vessel rupture, ischemia, and infarction.

Special Anesthetic Considerations

Preoperative Evaluation. When the neurologic examination is performed, the patient's clinical grade is noted (see [Table 28-15](#)). The patient's CT scan or MR image is evaluated to assess the presence and severity of intracranial hypertension. The severity, acuteness, and stage of the SAH as well as the presence of intracranial hypertension and the timing of surgery will determine the anesthetic management. Because the circle of Willis is proximal to the hypothalamus, a SAH in this area can cause a variety of disturbances related to hypothalamic dysfunction (e.g., ECG changes, temperature instability, various changes in endocrine [pituitary] function, various electrolyte disturbances).³¹⁴ Sympathetic overactivity and overstimulation of both adrenal cortex and medulla can contribute to hypertension and diabetes, requiring treatment with insulin.

Electrolyte abnormalities frequently occur secondary to the *syndrome of inappropriate antidiuretic hormone* (SIADH) secretion or diabetes insipidus. Hyponatremia is the most common electrolyte disturbance detected and is often associated with a high urinary sodium and osmolality, which is expected with SIADH. Unlike a patient with SIADH, however, the patient with SAH usually has a contracted intravascular volume despite hyponatremia. This cerebral salt-wasting syndrome may be caused by release of atrial natriuretic factor from damaged brain. The recommended therapy is to maintain normovolemia with isotonic saline solutions. Other factors contributing to intravascular volume contraction in these patients are supine diuresis secondary to increased thoracic blood volume, negative nitrogen balance, decreased erythropoiesis, increased catecholamine levels, and iatrogenic blood loss. Fluid balance and electrolyte abnormalities should be corrected prior to surgery.

Most aneurysm surgery requires significant intravascular volume shifts (diuresis followed by volume loading) and extensive systemic blood pressure manipulations (deliberate hypotension or hypertension). Therefore, patients with a history of hypertension, ischemic heart disease, and/or congestive heart failure must be in optimal condition to tolerate the hemodynamic changes required for this surgery. Depending on the degree of cardiovascular disease, inadvertent or deliberate hypotension may be poorly tolerated. When patients have significant hypertension, the blood pressure should be lowered gradually to normotensive levels to avoid cerebral ischemia. Agents such as propranolol, labetalol, or esmolol are used in neurosurgical patients because these agents do not affect cerebral blood volume or ICP. When the systemic blood pressure is lowered, a critical level below which neurologic deficits occur may be observed. Systemic blood pressure below this level should be avoided intraoperatively.

Electrocardiographic abnormalities are commonly associated with ruptured cerebral aneurysms.³¹⁵ The ECG changes include ST-segment depression or elevation, T-wave inversion or flattening, U waves, prolonged Q-T intervals, and dysrhythmia. The ECG changes are not necessarily associated with increased operative morbidity and mortality or consistent increases in serum myoglobin or creatine kinase. They usually resolve within 10 days following SAH and require no special treatment. When indicated, troponin levels should be drawn to determine the clinical significance of these abnormalities. When cardiac dysrhythmia and occasional frank subendocardial ischemia result in cardiac failure, appropriate treatment must be instituted.

Anesthetic Management. The anesthetic goals for intracranial aneurysm surgery are to avoid aneurysm rupture, maintain cerebral perfusion pressure and transmural aneurysm pressure, and provide a “slack” brain. Patients in WFNS scale I or II who appear anxious should receive premedication. Cerebral perfusion pressure is maintained by using drugs in doses that avoid sudden or profound decreases in systemic blood pressure or increases in ICP. Similarly, transmural pressure, which is

defined as the difference between mean arterial pressure and ICP, must be maintained. (The pressure within an aneurysm is equal to the systemic blood pressure.) The relationship between transmural pressure and wall stress or tension of the aneurysm is linear. An increase in mean arterial pressure or fall in ICP will increase transmural pressure, wall stress, and risk of aneurysm rupture. Methods to control brain volume and ICP, such as hyperventilation, diuretics, spinal drainage, and head position, facilitate surgical exposure and minimize the retraction pressure that can cause tissue injury.

Standard monitoring plus an arterial pressure catheter is routinely used. A CVP or PA catheter is recommended in WFNS scale III or higher to provide a more accurate measure of the patient's volume status and cardiac function intraoperatively and postoperatively in the prevention or management of cerebral vasospasm. Electrophysiologic monitoring with the EEG or SSEPs may be used to monitor the adequacy of cerebral perfusion during induced hypotension or temporary/permanent aneurysm clip application. When barbiturates are administered for brain protection, the EEG is used to guide the dose required to achieve a burst suppression pattern.

To minimize the risk of hypertension and aneurysmal rupture during induction of anesthesia, intravenous lidocaine and the β -adrenergic antagonist, esmolol, or labetalol are recommended. Following induction, ventilation is mechanically controlled to maintain normocarbica if ICP is normal. If intracranial hypertension is present, the PaCO₂ can be lowered to 25–30 mm Hg. A deep plane of anesthesia must be established prior to insertion of head pins, scalp incision, turning the bone flap, and opening the dura in order to avoid a hypertensive response. When intracranial hypertension is present, anesthesia should be deepened with additional doses of thiopental and fentanyl until the skull is opened. Several techniques can be instituted during aneurysm surgery to provide a “slack” brain and facilitate dissection. These are hyperventilation of the lungs, osmotic diuresis, barbiturate administration, and CSF drainage during the procedure. A lumbar subarachnoid catheter or spinal needle is inserted after induction to allow CSF drainage during the procedure. Excessive loss of CSF must be avoided during insertion of the lumbar drain because it can decrease ICP, thus increasing aneurysmal transmural pressure and the potential for rupture. Removal of CSF after opening the dura is done cautiously with guidance by the surgeons.

The drugs most frequently used to maintain anesthesia during aneurysm surgery are fentanyl and thiopental (bolus dosing or infusions) in conjunction with isoflurane in oxygen. A propofol infusion instead of thiopental may also be used for these procedures. In conditions of poor intracranial compliance, a continuous infusion of thiopental (1–3 mg · kg⁻¹ · hr⁻¹ following a bolus dose of 5 mg · kg⁻¹) is recommended as the primary anesthetic for aneurysm surgery in conjunction with a fentanyl infusion (1–4 mg · kg⁻¹ · hr⁻¹) and 0.5 MAC concentration of isoflurane in oxygen. The total dose of fentanyl should not exceed 10–12 mg · kg⁻¹, unless postoperative ventilation is planned. Potential disadvantages to using thiopental are blood pressure instability and prolonged recovery from anesthesia. With this technique, a pulmonary artery catheter should be inserted to monitor and optimize cardiovascular performance and intravascular volume. Following an uneventful aneurysm clip application, the thiopental infusion is discontinued to prevent a delay in recovery.

Prior to aneurysm clipping, isotonic crystalloid solutions without glucose are administered to replace overnight fluid losses and provide hourly maintenance fluid requirements. When the aneurysm is secured, intraoperative fluid deficits are replaced and additional volume is administered. At the time of aneurysm dissection, blood is available for transfusion in case the aneurysm ruptures. A bolus of thiopental (3–5 mg · kg⁻¹) may be given before temporary occlusion of a major intracranial vessel and before aneurysm clipping. If temporary occlusion lasts longer than 10 minutes, recirculation should be established, and additional thiopental administered before reapplying the temporary clip. Following aneurysm clipping, the central venous pressure and pulmonary capillary wedge pressure are raised to 10–12 mm Hg or 12–18 mm Hg, respectively, with crystalloid, colloid, or blood. A postoperative hematocrit of 30–35% is desirable. As discussed previously, intravascular volume expansion with hemodilution is recommended to reduce the risk of postoperative cerebral vasospasm.

When considering the use of deliberate hypotension during aneurysm dissection, the risk–benefit ratio must be assessed for each patient. The potential benefit of hypotension must be weighed against the risk of causing cerebral ischemia or ischemia to other organs. Patients with a history of cardiovascular disease, occlusive cerebrovascular disease, intracerebral hematoma, fever, anemia, and renal disease are not good candidates for induced hypotension. Such patients should only be subjected to moderate reductions in systemic blood pressure (20–30 mm Hg), if at all. The most commonly used agents to induce hypotension are sodium nitroprusside, isoflurane, and esmolol. Overall, induced hypotension has declined in use and has been replaced by temporary clipping.^{316,317} The temporary occlusion of a feeding artery produces an acute reduction in focal blood flow and a slack aneurysm, thus eliminating the need for induced hypotension and its systemic effects. Depending on the location of the aneurysm, either somatosensory evoked potentials or brain stem auditory evoked potentials can be used to monitor the safety of temporary occlusion.³¹⁶

The major intraoperative complication of aneurysm surgery is hemorrhage. When an aneurysm ruptures intraoperatively, there is potential for major ischemic damage from hypotension and the surgical efforts to control bleeding. Hemorrhagic death is also possible. When the leak is small and the dissection is complete, it may be possible for the surgeon to gain control with suction and then apply the permanent clip to the neck of the aneurysm. Alternatively, temporary clips can be applied proximal and distal to the aneurysm to gain control. Thiopental may be given to provide some protection prior to the placement of the temporary clip. During temporary occlusion, normotension should be maintained to maximize collateral perfusion. If temporary occlusion is not planned or not possible and blood loss is not significant, the mean arterial pressure may be transiently decreased to 50 mm Hg or lower to facilitate surgical control. When bleeding is excessive, aggressive fluid resuscitation and blood transfusion must commence immediately. Administration of cerebroprotective agents may not be possible because of associated hemodynamic effects. Under these conditions, induced hypotension is not advised as the intravascular volume must be restored first.

Intraoperative Cerebral Protection. Thiopental has been the drug of choice for intraoperative cerebral protection during aneurysm surgery. In animal models, barbiturates have shown protection during incomplete focal ischemia, but not during global ischemia.³¹⁸ Barbiturates are the only agents shown to be useful in humans.^{97,318}

Many practitioners institute mild intraoperative hypothermia (32–34°C) during aneurysm surgery⁸⁸ to enhance the brain's ability to tolerate ischemia. Its value is unproven, and its use may produce harmful side effects.^{319,320} A large multi-institutional study is underway to determine whether mild intraoperative hypothermia will benefit this patient population.

The primary goals at the conclusion of surgery are to avoid coughing, straining, hypercarbia, and hypertension. For patients in Grades I and II who have no intraoperative complications, the endotracheal tube should be removed in the operating room and a neurologic examination performed. Patients who have intraoperative complications or have depressed consciousness preoperatively (Grades III–V) should remain intubated and receive mechanical ventilation until their neurologic status improves.

Postoperative Concerns. Variation in systemic blood pressure is common postoperatively and contributes significantly to morbidity and mortality in patients following aneurysm repair. Causes of hypertension include preexisting hypertension, pain, and CO₂ retention from residual anesthesia. The treatment of postoperative hypertension is critical to prevent the formation of cerebral edema or hematoma. Antihypertensive drugs should be administered after respiratory depression and pain are eliminated as causes. The hypertensive response usually subsides within 12 hours. When indicated, preoperative antihypertensive drugs are reinstated and maintained.

After clipping of the aneurysm, cerebral vasospasm continues to pose a threat to neurologic integrity. Postoperative hypotension must be avoided, and the patient's intravascular volume must be accurately assessed with either a central venous pressure or pulmonary artery catheter. As previously discussed, a higher than normal intravascular fluid volume should be maintained.

Arteriovenous Malformations

An arteriovenous malformation (AVM) of the brain consists of a tangle of congenitally malformed blood vessels that forms an abnormal communication between the arterial and venous systems. The arterial afferents flow directly into venous efferents without the usual resistance of an intervening capillary bed; thus, oxygenated blood is shunted directly into the venous system, leaving surrounding brain tissue transiently or permanently ischemic. These lesions predominate in males over females (2:1), with the onset of complaints between the ages of 10 and 40. The chief clinical features are parenchymal hemorrhage or SAH, focal epilepsy, and progressive focal neurologic sensory-motor deficits occurring in a child or young adult. A vein of Galen AVM in infants may present with hydrocephalus and/or high-output cardiac failure. The natural history of AVMs is not completely understood.^{321,322} The risk of hemorrhage is approximately 1–3% per year. The rate of rebleeding is 6% in the first year after a hemorrhage and about 2% per year thereafter.^{321,322} Mortality from initial hemorrhage is high, with reports between 10 and 30%. Recurrence of hemorrhage with a fatal outcome is a constant danger. There are several options for the management of AVMs, including surgical excision, embolization, stereotactic radiosurgery (proton beams, gamma rays, or linear accelerator), a combination of the above, and leaving AVMs alone. Arteriovenous malformations of suitable size and location can be managed successfully with surgical excision. Surgical mortality ranges from 0.6% to 14% and correlates with size, location, and pattern of involvement of the AVM.³²² Early postoperative morbidity ranges from 17% to 28%; however, outcome studies report improvement in morbidity over time.³²³ To avoid intraoperative or postoperative massive brain swelling or hemorrhage of large AVMs, operations may be staged or follow preoperative embolization.

Special Anesthetic Considerations

In addition to providing anesthesia for craniotomy and resection of the AVM, anesthesia may be required for radiologic embolization of the AVM. Closed embolization of cerebral AVMs is uncomfortable and invasive. This procedure may be performed under local anesthesia with sedation or under general anesthesia. It has been performed successfully with various combinations of sedative drugs (fentanyl, droperidol, midazolam, or propofol) that allow neurologic examinations during the procedure and permit immediate diagnoses of complications.^{327,322} Children, uncooperative patients, and those with intracranial hypertension or airway problems usually require general anesthesia. General anesthesia does not allow direct neurologic assessment. Potential complications of embolization procedures are embolic or ischemic stroke and hemorrhage from the AVM, either acute or delayed. New onset or pre-existing seizures may occur during the embolization procedure, requiring treatment with benzodiazepines or barbiturates.

The anesthetic management of patients with AVMs is similar to the management of patients for aneurysm surgery. Depending on the presentation, the anesthetic approach is modified. For example, a large bleed may present with symptoms relating to mass effects and require maneuvers to reduce ICP. High flow through a large intact AVM may cause a “steal” with resulting cerebral ischemia and require different techniques to improve CPP. With more extensive lesions, hypothermia and high-dose barbiturates have been recommended for brain protection. Induced hypotension may also be required to reduce lesion size and blood flow.

Hyperemic complications, defined as perioperative edema or hemorrhage, may occur after removal of the AVM. Although the mechanism is unclear, one theory proposes that breakthrough cerebral edema and hemorrhage result when blood flow from the surgically obliterated AVM is diverted to the surrounding brain. The smaller vessels in the brain surrounding the AVM are not accustomed to the higher pressure-flow state, and autoregulation is exceeded, resulting in severe brain swelling, edema, and hemorrhage. The clinical syndrome of cerebral hyperperfusion with normal CPP has been called normal perfusion pressure breakthrough.³²⁴ Other studies report information that is not consistent with this theory.^{325,326} Immediate treatment should include the simultaneous application of high-dose barbiturates, osmotic diuretics, hyperventilation, and maintenance of a low-normal MAP. Hypothermia may also be instituted. When marked brain swelling occurs intraoperatively, the patient should remain intubated, hyperventilated, and sedated postoperatively. Hypertension during emergence and postoperatively must be controlled, preferably with b-blockers, to prevent bleeding into the bed of the AVM.

DELIBERATE HYPOTENSION

With the exception of profound acute hypotension for AVM embolization,³²⁷ more effort is currently being directed toward avoiding the need to induce hypotension during neurosurgery than toward developing new hypotensive drugs and pharmacologic combinations. That trend is likely to continue until substantial intraoperative brain protection becomes practical, at which time the popularity of induced hypotension may swing back to its former status as a routine procedure during neurosurgery. Meanwhile, “for urgent and rational indication in the carefully selected case,”³²⁸ a clinician’s best choice among the better known agents is probably the drug or drug combination with which he or she has the most experience. (See [Table 28-16](#) for clinical information on frequently used agents.)

| Drug | Dose | Mechanism of Action | Advantages | Disadvantages |
|----------------------|-------------------|---------------------------------------|-----------------------|---|
| Sodium nitroprusside | 0.5-10 µg/kg/min | Nitro vasodilator direct vasodilation | Rapid onset (1-2 min) | 1. Cyanide toxicity 2. Rebound hypertension 3. Coronary steal 4. Hypotension |
| Propofol | 1-2 mg/kg/min | Nitro vasodilator direct vasodilation | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Trimethaphan | 1-4 mg/min | ganglionic blockade | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Remifentanyl | 0.5-1.0 µg/kg/min | µ-opioid receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Etomidate | 0.2-0.6 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Midazolam | 0.1-0.2 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Thiopental | 3-5 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Barbiturates | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Propofol | 1-2 mg/kg/min | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Halothane | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Enflurane | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Isflurane | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Sevoflurane | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Desflurane | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Urethane | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |
| Chloral hydrate | 0.5-1.0 mg/kg | GABA _A receptor | Rapid onset (1-2 min) | 1. Hypotension 2. Bradycardia 3. Myocardial depression 4. Respiratory depression |

Table 28-16. OSAGE, MECHANISM OF ACTION, ADVANTAGES, AND DISADVANTAGES OF COMMONLY USED AGENTS FOR INDUCING HYPOTENSION

Commonly Used Drugs

Sodium Nitroprusside

Sodium nitroprusside [Na₂Fe(CN)₅NO · 2H₂O] continues to be the most widely used drug for intravenous induction of hypotension. Like all nitrovasodilators, sodium nitroprusside decreases peripheral vascular resistance by metabolic or spontaneous reduction to nitric oxide.³²⁹ Recent laboratory evidence suggests that sodium nitroprusside preferentially increases CBF to the ischemic penumbra and may offer a protective effect in that regard.³³⁰ Adequate blood flow to vital organs is maintained at perfusion pressures above 50 mm Hg. Sodium nitroprusside has rapid onset, a short half-life, and primarily dilates resistance vessels without affecting cardiac output.

Adverse effects may result from sodium nitroprusside infusion. These include cyanide and thiocyanate toxicity, rebound hypertension, intracranial hypertension, blood coagulation abnormalities, increased pulmonary shunting, and hypothyroidism. In addition, myocardial, liver, and skeletal muscle oxygen reserves are decreased by sodium nitroprusside and mitochondria may be damaged.³³¹ Death from sodium nitroprusside-induced severe acidosis has occurred after infusion of 750 mg over a 5-hour period.³³²

Cyanide is produced when sodium nitroprusside is metabolized (see [Fig. 28-13](#)); 1 mg of sodium nitroprusside contains 0.44 mg of cyanide. Toxic blood levels (>100 mg · dl⁻¹) occur when >1 mg · kg⁻¹ sodium nitroprusside is administered within 2 hours or when >0.5 mg · kg⁻¹ · hr⁻¹ is administered within 24 hours. The presenting signs of cyanide toxicity include elevated mixed venous O₂ (PvO₂), requirements for increasing dose (tachyphylaxis and metabolic acidosis). Death from sodium nitroprusside secondary to cyanide has been reported in a pediatric patient when blood cyanide level was 400 mg · dl⁻¹.³³³ Greater risk of cyanide toxicity exists in patients who are nutritionally deficient in cobalamin (vitamin B₁₂ compounds) or in dietary substances containing sulfur. Measurement of blood cyanide and pH will enable detection of abnormalities in high-risk patients for whom larger than recommended amounts of sodium nitroprusside have been used. Treatment should consist of intravenous thiosulfate except in those patients with abnormal renal function, for whom hydroxocobalamin is recommended (see [Fig. 28-14](#)). A cyanide antidote kit is commercially available. Circulating levels of thiocyanate increase when renal function is compromised, and CNS abnormalities result when thiocyanate levels reach 5–10 mg · dl⁻¹. Fortunately, captopril can be used to lower the dose requirement of sodium nitroprusside and thereby reduce the consequent buildup of cyanide (see [Fig. 28-15](#)).^{334,335} Another recently advocated strategy for reducing the potential for cyanide toxicity is to maintain sodium nitroprusside-like pharmacodynamics while greatly reducing sodium nitroprusside dosage in a 1:10 mixture with trimethaphan.^{336,337} Diltiazem,³³⁸ metoprolol,³³⁹ and esmolol have also been shown to effectively reduce sodium nitroprusside requirements, but esmolol does so at the cost of dose-dependent reductions in left ventricular contractility.³⁴⁰

Figure 28-13. Red blood cell biotransformation of sodium nitroprusside. SNP = sodium nitroprusside; Hgb = hemoglobin; mHgb = methemoglobin; SCN = thiocyanate; HCN = hydrogen cyanide.

Figure 28-14. Tissue cytochrome oxidase combines with cyanide to form cytochrome oxidase–cyanide complex. Methemoglobin frees cyanide from the complex, forming cyanmethemoglobin. Other potential pathways to prevent toxicity include the addition of thiosulfate or hydroxocobalamin. The dashed line indicates treatment of cyanide toxicity.

Figure 28-15. Blood cyanide in two groups of patients whose blood pressure was decreased by sodium nitroprusside. Patients pretreated with captopril ($3 \text{ mg} \cdot \text{kg}^{-1}$) had significantly less cyanide than those not treated, even though a similar degree of hypotension was obtained. Total sodium nitroprusside infused was significantly less in patients treated with captopril. (From Woodside J Jr, Garner L, Bedford RJ: Captopril reduces the dose requirement for sodium nitroprusside-induced hypotension. *Anesthesiology* 60:413, 1984.)

Systemic and pulmonary hypertension occur after abrupt discontinuance of sodium nitroprusside.³⁴¹ This results from increased plasma renin activity caused either by ischemic or dilated renal vessels. Gradual sodium nitroprusside discontinuance, preoperative propranolol, and converting enzyme inhibitors (captopril) will attenuate this response until increased plasma renin activity returns to normal (plasma half-life 30 minutes).

Based on results obtained in dogs, Michenfelder and Milde have argued that sodium nitroprusside dilates capacitance vessels regardless of anesthetic background, and dilates cerebral resistance vessels in addition when autoregulation is blunted by a volatile agent.^{342,cf 343} More recently, Stånge *et al* have found evidence in pigs that sodium nitroprusside directly impairs cerebral autoregulation.³⁴⁴ Under either circumstance, if venous return is impeded by a mass lesion, sodium nitroprusside will cause an increase in cerebral blood volume. Accordingly, sodium nitroprusside causes increased ICP in patients with decreased intracranial compliance³⁴⁵ (see [Table 28-17](#)). In the closed cranium an increase in ICP can cause hemispheric reductions in CBF due to regional reductions in cerebral perfusion pressure³⁴⁶ ($\text{CPP} = \text{MAP} - \text{ICP}$). In the open cranium with open dura, sodium nitroprusside-induced cerebral vasodilatation is not likely to affect regional CBF,³⁴⁶ but may cause brain swelling and disturb local perfusion, especially in areas under retraction and areas that are distant from the site of small to moderate size craniotomies.

| Measurement (mm Hg) | Before Sodium Nitro Prusside | After Sodium Nitro Prusside |
|---------------------|------------------------------|-----------------------------|
| MAP | 104 ± 2.55 | $70.0 \pm 3.61^*$ |
| ICP | 14.58 ± 1.76 | 27.61 ± 3.16 |
| CPP | 89.32 ± 3.57 | 43.23 ± 4.60 |

* Mean arterial pressure (MAP) reduced by 33%; ICP, intracranial pressure; CPP, cerebral perfusion pressure.
From Cottrell JE, Patel KD, Turndorf H, Ransohoff J: Intracranial pressure changes induced by sodium nitroprusside in patients with intracranial mass lesions. *J Neurosurg* 48:329, 1978.

Table 28-17. CEREBRAL PERFUSION PRESSURE AFTER HYPOTENSION INDUCED BY SODIUM NITROPRUSSIDE

Sodium nitroprusside can cause platelet disintegration and inhibition of platelet aggregation; however, recent evidence indicates that this complication is reversible and transitory.³⁴⁷ Nevertheless, sodium nitroprusside-induced abnormalities in blood coagulation can exacerbate increased intraoperative bleeding caused by vasodilation.³⁴⁸

Increased pulmonary shunting occurs in patients with normal pulmonary function after sodium nitroprusside-induced hypotension, but fibrosed pulmonary vessels of patients with chronic obstructive lung disease show little response to sodium nitroprusside, and shunting increases are not significant.³⁴⁹ Subsequent work has demonstrated a significant relationship between age and sodium nitroprusside sensitivity, with lower doses capable of inducing equally profound hypotension in older patients.³⁵⁰ It is possible that further elucidation of this age-dose relationship will allow more appropriate age-specific administration of sodium nitroprusside with a consequent amelioration of sodium nitroprusside-related complications.

Nitroprusside is obtained in a 5-ml amber rubber-stoppered vial containing 50 mg of sodium nitroprusside dihydrate. It can be dissolved in 5% dextrose in water (D_5W) to the concentration desired; 50 mg of sodium nitroprusside in 250, 500, or 1000 ml of D_5W makes a concentration of 200, 100, or $50 \text{ mg} \cdot \text{ml}^{-1}$, respectively. Once dissolved, sodium nitroprusside deteriorates in the presence of light. The container, therefore, should be wrapped in aluminum foil. An unstable sodium nitroprusside ion in aqueous solution reacts with a variety of substances within 3–4 hours, forming colored salts. Other drugs should not be infused in the same solution as sodium nitroprusside.

Because vascular response to sodium nitroprusside can be dramatic, it should be administered with an infusion pump. The usual dose of sodium nitroprusside is $0.5\text{--}10 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. The infusion should begin at $1 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and increased to achieve the desired MAP. If adequate reduction of blood pressure is not obtained with $10 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ within 10–15 minutes, the infusion should be stopped to avoid cyanide toxicity. Direct arterial pressure monitoring should be used during sodium nitroprusside infusion.

Nitroglycerin

Nitroglycerin directly dilates capacitance vessels and has a short half-life and no clinically significant toxic metabolites. As with sodium nitroprusside, decreased intracranial compliance contraindicates nitroglycerin use before dural opening unless steroids, diuretics, or sedatives have improved compliance. Even with the dura

open, both nitrates entail some risk of increased cerebral blood volume and significant brain swelling.^{341,351} Also similar to sodium nitroprusside, after nitroglycerin-induced hypotension, pulmonary shunting increases in patients with normal pulmonary function in contrast to those with chronic obstructive pulmonary disease. One research report indicates that nitroglycerin reduces cardiac index compared with sodium nitroprusside at MAP of 40 mm Hg.³⁵²

Nitroglycerin is supplied in a variety of formulations from various manufacturers, some of which require dilution. As obtained from the manufacturer, nitroglycerin is relatively stable when exposed to light and can be kept up to 2 years without refrigeration. The drug is administered continuously for deliberate hypotension or to control increased blood pressure, using a direct intravenous infusion without dilution. Nitroglycerin is adsorbed by plastic bags and should be infused from glass bottles or from high-density polyethylene syringes and tubings. An infusion pump is best for infusion at a beginning rate of $1\text{--}2\text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, with increases to achieve the desired blood pressure level. Good hypotensive response is usually seen at $2\text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Upper limits of infusion have not been set, since toxic effects have not been described, but the concentration of the infused solution should not exceed $400\text{ mg} \cdot \text{mL}^{-1}$.

Trimethaphan

Trimethaphan blocks sympathetic ganglia, resulting in resistance and capacitance vessel relaxation, which usually decreases arterial pressure. Trimethaphan's short plasma half-life makes for easy control, but histamine release has been reported to cause bronchospasm³⁵³ and potential ICP increases.³⁵⁴ The speed of infusion and altered autoregulation may also influence trimethaphan's effect on ICP.³⁵⁵ Myoneural blockade has been reported after administration of trimethaphan, probably due to its chemical resemblance to neuromuscular blocking agents.

Trimethaphan is not recommended for hypotension below 55 mm Hg MAP because EEG suppression occurs below this level,³⁵⁶ though that effect may be less frequent when isoflurane is used as a background anesthetic.³⁵⁷ Laboratory results show that cortical CBF and tissue oxygenation are reduced during profound trimethaphan-induced hypotension (MAP 30–35 mm Hg) relative to sodium nitroprusside-induced hypotension,³⁵⁸ and that trimethaphan hypotension below MAP 50 mm Hg causes increased brain lactate concentrations.³⁵⁹ These findings accord well with recent evidence that trimethaphan reduces local CBF during neuroleptanalgesia in humans, even when MAP is maintained at 70 mm Hg.³⁶⁰ When these cerebral effects are considered in light of experimental evidence that trimethaphan-induced hypotension reduces arterial baroreflex response to rapid blood loss from exsanguination,³⁶¹ it seems reasonable to conclude that trimethaphan should not be used as a sole agent for producing hypotension during neurosurgical procedures.

Esmolol and Labetalol

Esmolol, an ultrashort-acting cardioselective β -adrenergic blocker with an estimated half-life of approximately 9 minutes, has been used to decrease blood pressure by itself^{362,363} or in combination with other drugs.³⁶⁴ Esmolol's cardiac depressant properties indicate caution in attempting to use it as a primary hypotensive agent.

Labetalol, a combined α - and β -adrenergic blocker, has also been used as a sole hypotensive agent in humans.^{365,366} Like esmolol, labetalol is probably better used in combination therapies^{367,368} when inducing hypotension, not only because of bradycardia, but also because of its lack of potency.³⁶⁴ Both esmolol and labetalol have properties that make them appropriate for reduction of hypotension in neurosurgical patients (they do not dilate cerebral vessels, increase heart rate, cause rebound hypotension, or produce toxic metabolites under laboratory conditions),³⁶⁹ but neither is adequate when used alone for induction of surgical hypotension.

Prostaglandin E₁

Prostaglandin E₁ (PGE₁) is a naturally occurring substance that induces rapid hypotension by dilating vascular smooth muscle via a specific PGE receptor. Unlike other direct vasodilators, PGE₁ does not cause reflex tachycardia, but its hypotensive effects have been reported to persist for up to an hour following discontinuation.³⁷⁰ Cerebral blood flow and carbon dioxide reactivity remain stable during PGE₁ hypotension. Kadoi and coauthors have provided evidence that cerebral flow/metabolism coupling and regional cerebral oxygenation are maintained during PGE₁-induced hypotension to MAP 67 mm Hg.³⁷¹

Nicardipine

Nicardipine induces hypotension by selectively blocking calcium channels in the musculature of coronary, peripheral, and, to a lesser degree, cerebral vasculature. Like PGE₁, nicardipine reduces the risk of reflex tachycardia³⁷² and has a prolonged duration of action.³⁷³ Unlike PGE₁, nicardipine is as potent as nitroprusside. Caution must be exercised when titrating nicardipine for deliberate hypotension because its effect is difficult to reverse.

Halothane, Enflurane, Isoflurane, Desflurane, and Sevoflurane

The volatile anesthetics induce hypotension when their respective inspired concentrations are increased. Decreased blood pressure results from varying degrees of myocardial depression and peripheral vascular dilatation. Potential adverse effects include autoregulatory loss of vital organ blood flow, reduction in CPP as MAP decreases, ICP increase in patients with intracranial masses, increased cerebral edema, and accumulation of anaerobic metabolites.

Halothane-induced hypotension entails the risk of adverse myocardial depression,³⁷⁴ loss of autoregulation,³⁷⁵ and increases in ICP that cannot be resolved through hyperventilation.^{376,377} In addition to reducing cardiac output, high-dose or prolonged enflurane anesthesia has been shown to increase CSF production in the laboratory³⁷⁸ and induce seizures in some patients, especially during hypocapnia.

Laboratory evidence suggests that desflurane hypotension causes substantial reduction in CPP and CBF with a concomitant decrease in CMRO₂.³⁷⁹ Recent results derived from humans indicated that the blood pressure response to changes in inspired concentration of sevoflurane is more rapid than the response to changes in concentrations of isoflurane.³⁸⁰

The only inhalation agent currently recommended for deliberate hypotension is isoflurane.³⁸¹ MacNab *et al* have determined that, relative to sodium nitroprusside, isoflurane blunts the stress response to induced hypotension.³⁸² The hypotension that results from isoflurane is primarily a consequence of peripheral vascular dilation, with maintenance of cardiac output except at higher inspired concentrations. Reports of worsening of ST-segment changes and shunting of blood from collateral-dependent regions in the myocardium have caused concern about using isoflurane in patients with myocardial disease.³⁸³ Pulmonary shunting and dead space are not increased during isoflurane-induced hypotension.

Because of isoflurane's ability to reduce CMRO₂ while maintaining CBF,³⁸⁴ cerebral protection seemed likely. However, Bendo *et al*³⁸⁵ have found that isoflurane is not as protective as thiopental in the *in vitro* hippocampal slice model, and Nehls *et al*³⁸⁶ have demonstrated that isoflurane does not afford protection after focal ischemia. Gelb *et al* have tested the hypothesis that isoflurane-induced hypotension provides a measure of protection relative to sodium nitroprusside-induced hypotension during middle cerebral artery occlusion in monkeys.³⁸⁷ Unfortunately, they found no difference in neurologic scores or lesion size between the isoflurane and sodium nitroprusside groups. These results are consonant with Sano and coauthors' laboratory finding that isoflurane does not provide more cerebral protection than halothane,³⁸⁸ and Bendo and coauthors' finding that isoflurane-induced hypotension in dogs causes more cerebral edema than does equivalent hypotension induced with labetalol.³⁸⁹

In a nonhuman primate, Van Aken *et al*³⁹⁰ have demonstrated loss of autoregulation for 60 minutes after discontinuance of isoflurane and increases in CBF, which could worsen edema and ischemia and increase neurologic deficits. Endlund and coauthors have found that adenylate kinase, a marker of brain cell injury, increased 400% in the CSF of patients in whom hypotension was induced by isoflurane to MAP 50–65 mm Hg for 20–170 minutes.³⁹¹ Although high-dose isoflurane *per se* is not implicated by this result due to lack of a control or alternative hypotensive regimen, recent evidence indicates that equivalent degrees of hypotension can be obtained with less than 1% isoflurane if either labetalol³⁹² or the angiotension-converting enzyme enalapril³⁹³ is used in conjunction.

HEAD INJURY

Head injury is a leading cause of disability and death in young people. The annual incidence of head injury in the United States is approximately 200 per 100,000 of the population.³⁹⁴ Approximately 500,000 people each year sustain severe head injury, which includes those requiring hospitalization (450,000) and those who die before reaching the hospital (50,000). Of the 450,000 admitted to the hospital, significant residual disability remains in about 100,000 people each year. Head injury occurs most frequently in young adults aged 15–24 years. Males are affected two to three times more often than females in all age groups and are more likely to sustain severe head injury. More than 50% of patients with severe head injury have multiple injuries resulting in significant blood loss, systemic hypotension, and hypoxia.³⁹⁵ Causes of head injury include motor vehicle accidents, falls, physical assault, firearm accidents, domestic accidents, birth trauma, and work-related and sports injuries.

Motor vehicle accidents cause more than 50% of all head injuries and more than 70% of all fatal head injuries.³⁹⁴

Classification of severe head injury is based on the Glasgow Coma Scale (Table 28-18), which defines neurologic impairment in terms of eye opening, speech, and motor function.^{396,397} The total score that can be obtained is 15, and severe head injury is determined by a score of 8 or less persisting for 6 hours or more. The Glasgow Coma and Glasgow Outcome Scales permit comparison between series of traumatically head-injured patients based on initial clinical presentation and eventual outcome.^{394,398} The prognosis after head injury depends on the type of lesion sustained, the age of the patient, and the severity of the injury as defined by the Glasgow Coma Scale. In general, mortality is closely related to the initial score on the coma scale. For any given lesion and score, however, the elderly have a poorer outcome than do younger patients.³⁹⁴

Table 28-18. MODIFIED GLASGOW COMA SCALE

Following head trauma, the primary injury results from the biomechanical effect of forces applied to the skull and brain at the time of the insult and is manifested within milliseconds. Currently, there is no treatment for the primary injury. Secondary injury occurs minutes to hours after the impact and represents complicating processes initiated by the primary injury, such as ischemia, brain swelling and edema, intracranial hemorrhage, intracranial hypertension, and herniation. Factors that aggravate the initial injury include hypoxia, hypercarbia, hypotension, anemia, and hyperglycemia. These contributing factors to secondary injury are preventable. Seizures, infection, and sepsis that may occur hours to days after injury will further aggravate brain damage and must also be prevented or treated promptly.

Secondary insults complicate the course of more than 50% of head-injured patients.^{395,399} An outcome study using data from the Traumatic Coma Data Bank revealed that hypotension occurring after head injury is profoundly detrimental, with greater than 70% of patients experiencing significant morbidity and mortality (Table 28-19).⁴⁰⁰ Furthermore, the combination of hypoxia and hypotension is significantly more detrimental than that of hypotension alone (>90% of patients with severe outcome or death). These findings confirm the importance of avoiding hypovolemic shock in head-injured patients. The management goal in head-injured patients is to initiate timely and appropriate therapy to prevent secondary brain injury. When the initial injury is not fatal, subsequent neurologic damage and systemic complications should be preventable in most patients.

| Secondary Insults | Outcome Percentage | | | |
|-------------------|--------------------|------------------|----------------------|------|
| | Number of Patients | Good or Moderate | Severe or Vegetative | Dead |
| Total cases | 699 | 43 | 21 | 37 |

Table 28-19. IMPACT OF HYPOXIA AND HYPOTENSION* ON OUTCOME AFTER SEVERE HEAD INJURY (GCS ≤ 8)

Primary injury or biomechanical trauma to brain parenchyma includes concussion, contusion, laceration, and hematoma. Not all severely head-injured patients require surgery. Generalized brain injury with edema or contusion is a common finding in patients, whether or not a surgically correctable mass lesion is present. Diffuse cerebral swelling occurs because of sudden intracerebral congestion and hyperemia. Twenty-four hours or more after the initial insult, cerebral edema develops in the extracellular spaces of the white matter. Nonoperative treatment of diffuse cerebral swelling includes hyperventilation, diuresis with mannitol and furosemide, and barbiturates in conjunction with ICP monitoring.

Depressed skull fractures and acute epidural, subdural, and intracerebral hematomas usually require craniotomy. Chronic subdural hematomas are often evacuated through burr holes. Depressed skull fractures under lacerations should be elevated and debrided within 24 hours to minimize the risk of infection. Bony fragments and penetrating objects should not be manipulated in the emergency room, because they may be tamponading a lacerated vessel or dural sinus. Traumatic epidural hematoma is an infrequent complication of head injury, usually the result of a motor vehicle accident. The initial injury tears middle meningeal vessels or dural sinuses and causes unconsciousness. When a spasm and clot occur in the vessel(s), the bleeding stops and the patient recovers, experiencing a lucid interval. Over the next several hours, the vessel bleeds and the patient rapidly deteriorates (especially with arterial bleeding). In rapidly deteriorating conditions, treatment should not be delayed pending radiologic evaluation. Emergency evacuation is necessary. Venous epidural hematomas develop more slowly, and there may be time for diagnostic testing. The clinical presentation of acute subdural hematomas ranges from minimal deficits to unconsciousness and signs of a mass lesion (hemiparesis, unilateral decerebration, and pupillary enlargement). A lucid interval may occur. The most common cause of subdural hematoma is trauma, but it may occur spontaneously and is associated with coagulopathies, aneurysms, and neoplasms. It is considered acute if the patient becomes symptomatic within 72 hours, subacute between 3-15 days, and chronic after 2 weeks. Subacute and chronic subdural hematoma are usually observed in patients over age 50 years. There may be no history of head trauma. The clinical presentation in these patients may vary from focal signs of brain dysfunction to a depressed level of consciousness or development of an organic brain syndrome. Intracranial hypertension is usually associated with acute subdural hematoma. Intensive medical therapy to correct elevated ICP and control brain edema and swelling may be required before, during, and after hematoma evacuation. With intracerebral hematomas, the clinical picture may vary from minimal neurologic deficits to deep coma. Large, solitary intracerebral hematomas should be evacuated. Lesions causing delayed neurologic deterioration from fresh hemorrhage are also evacuated but carry a poor prognosis. Depending on the degree of cerebral injury, patients with intracerebral hematomas may require intensive medical therapy to control intracranial hypertension and cerebral edema. Coup and contracoup injuries usually cause cerebral contusion and intracerebral hemorrhage. In general, contused brain tissue is not removed; occasionally, however, contused tissue over the frontal or temporal poles may be removed to control edema formation and prevent herniation.

Emergency Therapy

Emergency therapy should begin at the site of the accident, in the ambulance, and most certainly, in the emergency room. The first step is to secure an open airway and ensure adequate ventilation to prevent secondary injury from hypoxia and hypercarbia. Before securing the airway in a head-injured patient, a quick assessment of the patient's neurologic status and concomitant injuries should be made.

The incidence of cervical spine injuries in surviving head injury victims is 1-3% in adults and 0.5% in children.^{401,402} Victims of head-first falls or high-speed motor vehicle accidents have a 10% or greater chance of cervical spine fractures. Radiographic evaluation with a cross-table lateral view can miss 20% of cervical spine fractures.⁴⁰² To increase the reliability of radiographic evaluation, anteroposterior and odontoid views, in addition to a lateral view, have been recommended. Reportedly, this combination misses only 7% of fractures.⁴⁰² When a cervical spine fracture has not been excluded by radiographic evaluation, cervical alignment with in-line stabilization* is recommended during emergent intubation. (Axial traction is no longer recommended because of the risk of distraction injury to the spinal cord.⁴⁰¹) If facial fractures and soft tissue edema prevent direct visualization of the larynx, a fiberoptic intubation or intubation with an illuminated stylet may be attempted. In the

presence of severe facial and/or laryngeal injuries, a cricothyrotomy may be required. Nasal intubations are avoided in the presence of a suspected basal skull fracture, severe facial fractures, and bleeding diathesis.

For patients without facial injuries, the simplest and most expeditious approach to intubation is preoxygenation followed by rapid-sequence induction with cricoid pressure and maintenance of in-line stabilization. All head-injured patients are assumed to have a full stomach. Awake, oral intubation without anesthetic agents may be possible in the severely injured patient, but this is difficult in the awake or uncooperative, combative patient. Depending on the patient's cardiovascular status, virtually any of the intravenous induction agents, except ketamine, can be used. The choice of muscle relaxants is controversial. Succinylcholine can increase ICP. In the setting of acute airway compromise, full stomach, and need to perform subsequent neurologic examinations, the benefits of rapid onset and elimination of succinylcholine may outweigh the risk of transiently increasing ICP.

Following control of the airway in the head-injured patient, attention should focus on resuscitation of the cardiovascular system. Transient hypotension after head injury is not uncommon, but sustained hypotension usually results from hemorrhage secondary to other systemic injuries. These injuries must be sought and aggressively treated.

When multiple trauma complicates head injury, there is no ideal crystalloid resuscitation fluid. A major concern during resuscitation is the development of cerebral edema. Animal investigations reveal that total serum osmolality is a key factor in brain edema formation.^{403,404} When serum osmolality is reduced, cerebral edema develops in normal and abnormal brain. This occurs because the blood-brain barrier is relatively impermeable to sodium. Solutions containing sodium in concentrations lower than that in serum cause water movement into the brain, increasing brain water. Thus, hypoosmolar solutions (0.45% NaCl and lactated Ringer's solution) are more likely than isoosmolar fluids (0.9% saline) to increase brain water content. Large-volume fluid resuscitation with isoosmolar crystalloids reduces colloid oncotic pressure and increases peripheral tissue edema. However, in animal investigations, the brain behaves differently than other tissues, and profound lowering of colloid oncotic pressure with maintenance of serum osmolality does not result in edema in normal brain⁴⁰³ and in some head-injury models.^{404,405} These results can be explained by the unique structure of the blood-brain barrier and the fact that colloid oncotic pressure gradients generate weak forces in comparison with osmolar gradients.⁴⁰³ Some doubt has been cast on the applicability of these laboratory findings to clinical practice. The cryogenic-injury model used in these experiments may not be equivalent to head injury in patients. In head-injured patients, brain capillary permeability may be rendered similar to that of peripheral tissues when the blood-brain barrier is damaged. In addition, the time course of these experiments did not allow observation of edema developing 24–48 hours after initial resuscitation, which occurs in head-injured patients. A recent investigation using the percussive head injury model in rats has shown that reduction in colloid pressure can aggravate cerebral edema under certain conditions.⁴⁰⁶ Therefore, it seems reasonable to avoid a profound reduction in colloid oncotic pressure in clinical practice. Iso-osmolar colloid solutions, such as 5% albumin or 6% hetastarch, can be administered to maintain oncotic pressure and intravascular volume. Fresh whole blood, when available, is the ideal colloid resuscitation fluid for hypovolemic patients with ongoing blood loss.

Hypertonic saline solutions may be very useful for volume resuscitation in head-injured patients because they lower ICP and may improve regional CBF.^{407,408} Hypertonic saline produces an osmotic diuretic effect on the brain that is similar to that of other hyperosmolar solutions (e.g., mannitol). With long-term use, however, there is concern over the physiologic implications of elevated serum sodium, such as a depressed level of consciousness and/or seizures.

During fluid resuscitation of the head-injured patient, the goals are to maintain serum osmolality, avoid profound reduction in colloid oncotic pressure, and restore circulating blood volume. Immediate therapy is directed at preventing hypotension and maintaining CPP above 70 mm Hg.⁴⁰⁹ When indicated, an ICP monitor is inserted to guide fluid resuscitation and prevent severe elevations in ICP. Iso-osmolar crystalloid solutions, colloid solutions, or both are administered acutely to restore circulating blood volume. Glucose-containing solutions should not be administered because of a significant association between plasma glucose levels and worse neurologic outcome in head-injured patients.⁴¹⁰ Substantial blood loss requires transfusion with crossmatched or fresh whole blood. A minimal hematocrit between 30 and 33% is recommended to maximize oxygen transport.

Hypertension, tachycardia, and increased cardiac output often develop in patients with isolated head trauma, especially young adults.⁴¹¹ ECG abnormalities and fatal arrhythmias have been reported. The hyperdynamic circulatory responses and ECG changes may result from a surge in epinephrine that accompanies head injury.⁴¹² Either labetalol or esmolol can be used to control hypertension and tachycardia in this situation.

In some patients, severe intracranial hypertension precipitates reflex arterial hypertension and bradycardia (Cushing's triad). A reduction in systemic blood pressure in these patients can further aggravate cerebral ischemia by reducing CPP. Systemic blood pressure must be lowered cautiously when intracranial hypertension is severe. In such cases, a reduction of ICP may interrupt this reflex response.

After stabilization of head-injured patients, including control of airway and systemic blood pressure, therapeutic interventions to control intracranial hypertension are instituted. The head is elevated 15° and maintained in a neutral position without rotation or flexion. Hyperventilation to a PaCO₂ of 30–35 mm Hg is instituted as a very rapid and effective intervention. Mannitol, 0.25–1 g · kg⁻¹, is given to lower ICP acutely, or a combination of furosemide and mannitol may be administered. Barbiturates are used to control ICP when other measures have failed.⁴¹³ Appropriate monitoring must be instituted and hypotension avoided.

Mechanical hyperventilation to a PaCO₂ 25–30 mm Hg has been routinely employed in head-injured patients based on an assumption that hyperventilation, by reducing CBF, will reduce ICP, thereby preserving CPP and CBF. Clinical investigations, using CBF and jugular bulb oxygen saturation monitoring, have reported a subset of head-injured patients with markedly reduced CBF in relation to their metabolic requirements.^{414,415} In these patients hyperventilation may further decrease CBF and aggravate cerebral ischemia.⁴¹⁶

The 1995 Brain Trauma Foundation algorithm (Table 28-20) for the treatment of intracranial hypertension no longer recommends hyperventilation to a PaCO₂ of 25–30 mm Hg as a first-tier therapy.^{417,418} When hyperventilation is initiated for the control of intracranial hypertension, the PaCO₂ should be maintained in the range of 30–35 mm Hg in order to accomplish ICP control while minimizing the associated risk of ischemia. Hyperventilation to PaCO₂ values less than 30 mm Hg should be considered only when secondary therapy of refractory intracranial hypertension is required.

Table 28-20. SEVERE HEAD INJURY: TREATMENT OF INTRACRANIAL HYPERTENSION

Continuous measurement of jugular bulb oxygen saturation can be used in clinical practice to determine which patients will receive benefit or harm from hyperventilation.^{249,419} In emergency situations, we should continue to hyperventilate patients in whom the clinical control of intracranial hypertension is the primary concern. However, when the clinical situation no longer requires it or there is evidence of cerebral ischemia, normocapnic ventilation should be instituted.

Anesthetic Management

The patient is evaluated by CT scan and taken directly to the operating room. There is usually minimal time available for resuscitation and preanesthetic assessment. Information that should be obtained preoperatively is described in Table 28-21. The anesthetic management is a continuation of the initial resuscitation, including airway management, fluid and electrolyte balance, and ICP control. The routine monitors for major neurosurgical procedures are applied. Anesthetic management is directed at avoidance of secondary brain injury. Intraoperative hypotension secondary to blood loss or precipitated by anesthetic drugs should be avoided by appropriate volume expansion. Maintenance of ventilation (PaCO₂ between 30 and 35 mm Hg) and oxygenation (PaO₂ > 60 mm Hg) is extremely important. Positive

end-expiratory pressure may be used, if necessary (5–10 cm H₂O does not adversely affect ICP).

Intraoperative brain swelling or herniation from the operative site may complicate hematoma decompression. Such causes as improper patient positioning, contralateral intracerebral hematoma, venous drainage obstruction from packing, and acute hydrocephalus from intraventricular hemorrhage must be eliminated. In this setting, the adequacy of hyperventilation must also be verified. A large alveolar-arterial CO₂ gradient may exist, so that end-tidal CO₂ may not reflect arterial CO₂. The respiratory system and equipment should be reviewed to ensure normal peak inspiratory and expiratory pressures. Hemopneumothorax, high intra-abdominal pressures, a kinked endotracheal or expiratory tube, or a stuck expiratory valve can produce marked peak inspiratory or expiratory pressures as well as hypoxemia and hypercarbia. Fluid and electrolyte balance must be reevaluated in patients with cerebral swelling. Mannitol loses its effect after 1–3 hours, and it may be necessary to repeat the mannitol bolus to increase osmolarity. Volume overload and hyponatremia may also cause cerebral swelling and must be corrected. If cerebral swelling persists, the anesthetic should be converted to opioid and thiopental infusions with oxygen and air. Thiopental may be given in a series of boluses over 5–10 minutes to a total dose of 5–25 mg · kg⁻¹, followed by an infusion of 4–10 mg · kg⁻¹ · h⁻¹. To avoid barbiturate-induced myocardial depression and hypotension, it may be necessary to increase preload and add a vasopressor such as dopamine. Malignant brain swelling may require removal of brain tissue and a temporary scalp closure with a loose dural patch to minimize ICP after closure.

Emergence from anesthesia usually involves transporting an intubated, ventilated, and anesthetized patient to the intensive care unit. Even in an uncomplicated craniotomy for evacuation of hematoma, a period of postoperative ventilation is recommended because brain swelling is maximal 12–72 hours after injury. Hypertension and coughing or bucking on the endotracheal tube should be avoided because it can lead to significant intracranial bleeding. Labetalol or esmolol can be used to treat hypertension, and supplemental barbiturates are given to sedate the patient. Current guidelines for the perioperative treatment of intracranial hypertension resulting from severe head injury are shown in [Table 28-20](#).⁴¹⁸

Systemic Sequelae

The systemic effects of head injury are diverse and can complicate management.⁴²⁰ These include cardiopulmonary problems (airway obstruction, hypoxemia, shock, adult respiratory distress syndrome, neurogenic pulmonary edema, ECG changes), hematologic problems (disseminated intravascular coagulation), endocrinologic problems (pituitary dysfunction, *i.e.*, diabetes insipidus, SIADH), metabolic problems (nonketotic hyperosmolar hyperglycemic coma), and gastrointestinal problems (stress ulcers, hemorrhage). Conditions not discussed elsewhere in this chapter will be reviewed.

Aspiration, pneumonia, fluid overload, and trauma-related adult respiratory distress syndrome are common causes of pulmonary dysfunction in head-injured patients. A fulminant pulmonary edema may also occur. Neurogenic pulmonary edema is characterized by marked pulmonary vascular congestion, intra-alveolar hemorrhage, and a protein-rich edema fluid. Specific features of this syndrome are its rapid onset, its relationship to hypothalamic lesions, and the ability to prevent or attenuate it by α -blockers and CNS depressants. Neurogenic pulmonary edema is thought to result from massive sympathetic discharge from injured brain secondary to intracranial hypertension. Traditional therapy for pulmonary edema of cardiac origin is ineffective, and the outcome is frequently fatal. Therapy consists of immediate pharmacologic or surgical relief of intracranial hypertension, supportive respiratory care, and careful fluid management.

In head-injured patients, several clotting abnormalities may be present. Disseminated intravascular coagulation has been reported after mild and severe brain trauma and anoxic brain damage, and it presumably develops after release of brain tissue thromboplastin into the systemic circulation.⁴²¹ Treatment of the underlying disease process usually results in spontaneous recovery of the coagulation defects. Occasionally, administration of cryoprecipitate, fresh frozen plasma, platelet concentrates, and blood may be required.

Anterior pituitary insufficiency after head injury is a rare occurrence. However, patients exhibiting post-traumatic diabetes insipidus may develop a delayed impairment of anterior pituitary hormones, requiring replacement therapy. Posterior pituitary dysfunction occurs more frequently after head trauma. Diabetes insipidus may occur after craniofacial trauma and basal skull fracture. Its clinical presentation includes polyuria, polydipsia, hypernatremia, high-serum osmolality, and dilute urine. Frequently, post-traumatic diabetes insipidus is transient, and treatment is based on water replacement. If the patient cannot maintain fluid balance, exogenous vasopressin may be administered. The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is associated with hyponatremia, serum and extracellular fluid hypoosmolality, renal excretion of sodium, urine osmolality greater than serum osmolality, and normal renal and adrenal function. The patient develops symptoms and signs of water intoxication (anorexia, nausea, vomiting, irritability, personality changes, and neurologic abnormalities). SIADH secretion usually begins 3–15 days after trauma, lasting no more than 10–15 days with appropriate therapy. Treatment includes water restriction with or without hypertonic saline.

Many factors in neurosurgical patients predispose to nonketotic hyperosmolar hyperglycemic coma, such as steroids, prolonged mannitol therapy, hyperosmolar tube feedings, phenytoin, and limited water replacement.⁴²⁰ Diagnostic criteria for nonketotic hyperosmolar hyperglycemic coma are hyperglycemia, glucosuria, absence of ketosis, plasma osmolality > 330 mOsm · kg⁻¹, dehydration, and CNS dysfunction. Hypovolemia and hypertonicity are the immediate threats to life. Serum sodium may be high, normal, or low, depending on the state of hydration. Serum potassium is low. Serial laboratory tests are essential. Once sodium deficits are replaced and blood pressure and urine output are stable, water deficits are replaced with 0.45% saline. Hyperglycemia usually responds to relatively small doses of insulin. Intermittent furosemide therapy may be given for cerebral edema prophylaxis in the elderly, the adult-onset diabetic, or the patient with compromised renal function.

* In-line stabilization requires an assistant to stabilize the patient's head by positioning his or her hands along the side of the head with fingertips on the mastoid holding the occiput down on a backboard.

Anesthesiologists directly manipulate pulmonary function to a greater extent than any other organ system. Thus, a sound and thorough working knowledge of applied pulmonary physiology is essential to the safe conduct of anesthesia. This chapter discusses pulmonary anatomy, the control of ventilation, oxygen and carbon dioxide transport, ventilation-perfusion relationships, lung volumes and pulmonary function testing, abnormal physiology and anesthesia, the effect of smoking on pulmonary function, and postoperative pulmonary function and complications.

FUNCTIONAL ANATOMY OF THE LUNGS

Volumes by Gray¹ and Netter² illustrate the basic anatomy of the lungs well and give a complete and fully detailed description of human lung anatomy. This chapter emphasizes functional lung anatomy, with structure described as it applies to the mechanical and physiologic function of the lungs.

Thorax

The thoracic cage is shaped like a truncated cone, with small superior and large inferior openings and diaphragms attached at the base. The thoracic vertebral column provides major vertical support for the thorax. Anteriorly, the sternum renders support and is so named because of its sword-like appearance. The sternal angle, an important anatomic landmark, is formed by the junction of the manubrium and the sternal body with the second rib. The sternal angle is located in the horizontal plane that passes through the vertebral column at the T4 or T5 level. This plane separates the superior from the inferior mediastinum. The predominant ventilatory changes in thoracic diameter occur in the anteroposterior direction in the upper thoracic region and in the lateral or transverse direction in the lower portion of the thorax.³

Muscles of Ventilation

The ventilatory musculature has been the focus of considerable scientific attention. The ventilatory muscles are endurance muscles. Poor nutrition, chronic obstructive pulmonary disease (COPD) with gas trapping, and increased airway resistance predispose to the development of ventilatory failure due to ventilatory muscle fatigue.⁴ The ventilatory muscles include the diaphragm, intercostal muscles, abdominal muscles, cervical strap muscles, sternocleidomastoid muscles, and the large back and intervertebral muscles of the shoulder girdle. The primary ventilatory muscle is the diaphragm, with minor contributions from the intercostal muscles. Normally, at rest, inspiration requires work and expiration is passive. As ventilatory effort increases, abdominal muscles assist with rib depression and increase intra-abdominal pressure to facilitate forced exhalation. With a further increase in effort, the cervical strap muscles help to elevate the sternum and upper portions of the chest. Finally, the large back and paravertebral muscles of the shoulder girdle become important during maximum ventilatory effort. Generally, muscles that raise the ribs are functionally inspiratory, whereas muscles that lower the ribs are important primarily during forced expiration. In a person with normal lung parenchyma, both breathing and coughing can be performed exclusively by the diaphragm.

Ventilatory muscles must create sufficient force to lift the ribs to create subatmospheric pressure in the intrapleural space. Breathing is an endurance phenomenon—something that is done repetitively over a long period of time. The type of muscle fiber correlates with fatigability and oxidative capacity.⁵ Fatigue-resistant fibers are characterized by a slow-twitch response to electrical stimulation. They comprise approximately 50% of the diaphragmatic fibers and, because of their high oxidative capacity, function mostly as endurance units.⁶ Fast-twitch muscle fibers, which are susceptible to fatigue, have rapid responses to electrical stimulation. Fast-twitch fibers impart strength; they allow the muscle to produce greater force over a short period of time. Thus, fast-twitch fibers are useful during brief periods of maximal ventilatory effort and slow-twitch fibers provide endurance.⁷

The electrical activity of the ventilatory muscles reflects the function of the muscles during different types of ventilatory effort.⁸ During breathing at rest, the electrical activity of the diaphragm gradually and progressively rises during the early portion of inspiration and gradually falls to zero by late inspiration.⁹ However, during forced exhalation or expulsive efforts such as coughing, diaphragmatic electrical activity remains high even throughout expiration.¹⁰ The intercostal muscles are active primarily during inspiration, and debate continues as to their significance during expiration. The muscles of the abdominal wall, the most powerful muscles of expiration, are important for expulsive efforts such as coughing.¹¹

To perform work, a muscle must be firmly anchored at both its origin and insertion. The diaphragm is unique because its insertion is mobile—an untethered central tendon that originates from fibers directly attached to the vertebral bodies and the costal portions of the lower ribs and sternum. Diaphragmatic contraction results in descent of the diaphragmatic dome and expansion of the thoracic base. These changes result in decreased intrathoracic and intrapleural pressure, with a corresponding increase in intra-abdominal pressure.

The cervical strap muscles elevate and fix the first two ribs. They are active even during spontaneous ventilation at rest. The cervical strap muscles are the most important inspiratory accessory muscles. Their importance is magnified if diaphragmatic function is impaired, as in patients with cervical spinal cord transection. The primary function of the sternocleidomastoid muscle is to elevate the sternum, thereby increasing the anteroposterior diameter of the chest wall. The large back

muscles, such as the pectoralis major and minor, the latissimus dorsi, and the serratus anterior, are used to augment inspiration by enlarging the rib cage during high levels of ventilatory activity.

Lung Structures

With an intact respiratory system, the expandable lung tissue completely fills the pleural cavity. The visceral and parietal pleurae are constantly in contact with each other, creating a potential intrapleural space in which pressure decreases when the diaphragm descends and the rib cage expands. The resultant subatmospheric intrapleural pressure is a reflection of the opposing and equal forces between the lung tissue and chest wall structures. These equal and opposing forces create the functional residual capacity (FRC), the volume of gas in the lungs at passive end-expiration. The intrapleural space normally has a slightly subambient pressure (–2 to –3 mm Hg) at FRC. With inspiration, the intrapleural pressure becomes more negative as the chest wall expands. When the thorax is opened, healthy lung retracts because pressures within both the alveolar spaces and along the visceral pleurae are ambient.

Both the right and left lungs contain oblique fissures that separate the upper from the lower lobes. In addition, the right lung has a horizontal fissure separating the middle and lower lobes. Major divisions of the right and left lung are listed in [Table 29-1](#). Working knowledge of the bronchopulmonary segments is important for localizing lung pathology, interpreting lung radiographs, identifying lung regions during bronchoscopy, and operating on the lung. Each bronchopulmonary segment is separated from its adjacent segments by well-defined connective tissue planes. Therefore, pulmonary pathology initially tends to remain segmental.

| Lung Side/Lobe | Bronchopulmonary Segment |
|----------------|--|
| RIGHT | |
| Upper | Apical Anterior Posterior |
| Middle | Medial Lateral |
| Lower | Superior Medial basal Lateral basal Anterior basal Posterior basal |
| LEFT | |
| Upper | Apical posterior Anterior |
| Lingula | Superior Inferior |
| Lower | Superior Posterior basal Anteromedial basal Lateral basal |

Table 29-1. MAJOR DIVISIONS OF THE LUNG

The lung parenchyma can be subdivided into three airway categories based on functional lung anatomy ([Table 29-2](#)). The conductive airways provide basic gas transport, but no gas exchange takes place in them. The next group of airways, which have smaller diameters, are transitional airways. They are conduits for gas movement, and additionally perform limited gas diffusion and exchange. Finally, the smallest respiratory airways' primary function is gas exchange.

Ventilation–perfusion (\dot{V}_A/\dot{Q}) relationships are defined by the function of the respiratory airways.

| Type | Function | Structure |
|--------------|---|---|
| Conductive | Bulk gas movement | Trachea to terminal bronchioles |
| Transitional | Bulk gas movement Limited gas exchange | Respiratory bronchioles Alveolar ducts |
| Respiratory | Gas exchange | Alveoli Alveolar sacs |

Table 29-2. FUNCTIONAL AIRWAY DIVISIONS

Conventionally, airways with diameters of >2 mm are considered large airways and create 90% of total airway resistance. By the seventh airway generation, the internal diameter has decreased to approximately 2 mm and the cumulative cross-sectional area is 5.0 cm². The number of alveoli increases progressively with age, starting at approximately 24 million at birth and reaching the final adult count of 300 million by the age of 8–9 years. The alveoli are associated with about 250 million precapillaries and 280 billion capillary segments, resulting in a surface area of ~70 m² for gas exchange.

Conductive Airways

In the adult, the trachea is a fibromuscular tube ~10–12 cm long with an outside diameter of ~20 mm. Structural support is provided by 20 U-shaped hyaline cartilages, with the open part of the U facing posteriorly. The cricoid membrane tethers the trachea to the cricoid cartilage at the level of the sixth cervical vertebral body. The trachea enters the superior mediastinum and bifurcates at the sternal angle (the lower border of the fourth thoracic vertebral body). Normally, half of the trachea is intrathoracic and half is extrathoracic. Both ends of the trachea are attached to mobile structures. Thus, the carina can move superiorly as much as 5 cm from its normal resting position. Airway “motion” becomes important in the intubated patient. In the adult, the tip of an orotracheal tube moves an average of 3.8 cm with flexion and extension of the neck but can travel as far as 6.4 cm.¹² In infants and children, tracheal tube movement with respect to the trachea is even more critical: displacement of even 1 cm can move the tube out of the trachea or below the carina.

The tracheal wall includes several cellular structures that are important in removing mucus from the lungs.¹³ The tracheal epithelial layer is composed primarily of pseudostratified columnar ciliated epithelium. Interspersed between the cells are goblet cells and brush cells. Chronic exposure to irritants such as tobacco smoke increases the number of mucus-producing goblet cells and decreases the number of ciliated cells,¹⁴ resulting in an increased volume of secretions and reduced ability to remove them. The cilia beat in an organized and coordinated manner, creating metachronal wave movement of the superficial “gel” mucus layer toward the mouth. Brush cells appear to be the source of low-viscosity fluid for the serous layer. The histologic structures of other larger airways are similar to those in the trachea.

The next airway generation is composed of the right and left main-stem bronchi. The diameter of the right bronchus is generally greater than that of the left. In the adult, the right bronchus leaves the trachea at ~25° from the vertical tracheal axis, whereas the angle of the left bronchus is ~45°. Thus, inadvertent endobronchial intubation or aspiration of foreign material is more likely to occur in the right lung than the left. Furthermore, the right upper lobe bronchus dives almost directly posterior at ~90° from the right main bronchus. Foreign bodies and fluid aspirated by a supine subject usually fall into the right upper lobe. In children less than 3 years old, the angles created by the right and left main-stem bronchi are approximately equal, with takeoff angles of about 55°.

The right main bronchus is ~2.5 cm long before its initial branching into lobar bronchi. However, in 10% of adults, the right upper lobe bronchus departs from the right main-stem bronchus 2.5 cm from the carina. Furthermore, in ~2–3% of adults, the right upper lobe bronchus opens into the trachea, above the carina. Patients with these anomalies require special consideration when placing double-lumen tracheal tubes, especially if one contemplates inserting a right-sided endobronchial tube. After the right upper and middle lobe bronchi divide from the right main bronchus, the main channel becomes the right lower lobe bronchus.

The left main bronchus is ~5 cm long prior before its initial branching point to the left upper lobe and the lingula, then continues on as the left lower lobe bronchus.

Eighteen segmental bronchi form the next generation of airways (see [Table 29-1](#)). Their anatomic positions are important for normal clearance of secretions and for postural drainage. Each successive generation beyond the segmental bronchi undergoes progressive and significant increases in total cross-sectional area ([Table 29-3](#)). Bronchi, defined as airways containing cartilaginous elements, become as small as 1 mm in diameter.

| Airway Generation | Airway Name | Diameter (cm) | Cumulative Cross-Sectional Area (cm ²) |
|-------------------|--------------------------|---------------|--|
| 0 | Trachea | 1.80 | 2.54 |
| 1 | Main-stem bronchi | 1.22 | 2.33 |
| 2 | Lobar bronchi | 0.87 | 2.13 |
| 3 | Segmental bronchi | 0.56 | 2.00 |
| 4 | Subsegmental bronchi 1 | 0.45 | 1.88 |
| 5 | Subsegmental bronchi 5 | 0.36 | 1.76 |
| 16 | Terminal bronchiole | 0.06 | 100 |
| 17 | Respiratory bronchiole 1 | 0.05 | 300 |
| 20 | Alveolar duct 1 | 0.045 | 1000 |
| 23 | Alveolar sac | 0.041 | 11,800 |

Based on data from Weibel ER. Morphometrics of the lung. In: From WHO. *Atlas of Human Morphology*. Section 3, vol 1, p 205. Washington DC, American Physiological Society, 1964.

Table 29-3. DIMENSIONS AND NUMBERS OF AIRWAYS

The bronchioles typically have diameters of 1 mm. They are devoid of cartilaginous support and have the highest proportion of smooth muscle in the wall. There are approximately three to four bronchiolar generations. The final bronchiolar generation is the terminal bronchiole, which is the last airway component that is not directly involved in gas exchange.

Transitional Airways

The respiratory bronchiole, which follows the terminal bronchiole, is the first site in the tracheobronchial tree where gas exchange occurs. Respiratory bronchioles are characterized by intermittent alveolar outpockets, and histologically by a gradual change from cuboidal epithelium to squamous cells. In adults, two or three generations of respiratory bronchioles eventually lead to alveolar ducts. There are usually four to five generations of alveolar ducts, each with multiple openings into alveolar sacs. The final divisions of alveolar ducts terminate in alveolar sacs that open into alveolar clusters.

Respiratory Airways and the Alveolar–Capillary Membrane

Intact alveoli range between 100 and 300 μm in diameter. The intra-alveolar septa form the supportive latticework and are composed of elastic, collagenous, and reticular fibers. The pulmonary capillaries also are incorporated into and supported by this fibrous lattice. The pulmonary capillary beds are the densest capillary networks in the body. The calculated diameter for pulmonary capillaries is between 10 and 14 μm . This extensive vascular branching system starts with pulmonary arterioles in the region of the respiratory bronchioles. Each alveolus is closely associated with ~1000 short capillary segments.

The alveolar–capillary interface is complicated but well designed to facilitate gas exchange. Viewed with electron microscopy, the alveolar wall consists of a thin capillary epithelial cell, a basement membrane, a pulmonary capillary endothelial cell, and a surfactant lining layer. The flattened, squamous Type I alveolar cells cover ~80% of the alveolar surface. Type I cells contain flattened nuclei and extremely thin cytoplasmic extensions that provide the surface for gas exchange. The volume of a Type I cell is twice that of a Type II alveolar cell, but its surface is 50 times greater.¹⁵ Type I cells are highly differentiated and metabolically limited, which makes them highly susceptible to injury. When Type I cells are damaged severely (during acute lung injury or adult respiratory distress syndrome), Type II cells replicate and modify to form new Type I cells.¹⁶

Type II alveolar cells are interspersed among Type I cells, primarily at alveolar-septal junctions. These polygonal cells have vast metabolic and enzymatic activity and manufacture surfactant.¹⁷ The enzymatic activity required to produce surfactant is only 50% of the total enzymatic activity present in Type II alveolar cells.¹⁸ The remaining enzymatic activity modulates local electrolyte balance and endothelial and lymphatic cell functions.¹⁹ Both Type I and Type II alveolar cells have tight intracellular junctions, thus providing a relatively impermeable barrier to fluids.

Type III alveolar cells, alveolar macrophages, are an important element of lung defense. Their migratory and phagocytic activities result in the ingestion of foreign materials within alveolar spaces.²⁰

Finally, numerous finger-like projections of the capillary endothelial cells greatly increase their surface area. They also provide intimate contact between the capillary endothelial cell and the entire circulating blood volume. Capillary endothelial cells are ideally suited for metabolism of circulating substances. Thus, the alveolar–capillary membrane has two primary functions: transport of respiratory gases (oxygen and carbon dioxide) and the widely varied metabolic activities of local and humoral substances.

Collateral Ventilation

Airways ≥ 1 mm in diameter are susceptible to blockage, resulting in accumulation of fluids and secretions and inhibition of gas exchange, especially oxygen transport. The pores of Kohn were the first structures described that provide collateral ventilation. Located in the interspaces between the alveolar–capillary networks, they provide intra-alveolar communication.²¹ Conduits that afford direct communication between small respiratory bronchioles and neighboring alveoli also create collateral ventilation and may be more important. These communications are of larger diameter than the pores of Kohn, 30 μm versus 8–10 μm , and their anatomic position allows access to a greater number of alveoli.²²

Pulmonary Vascular Systems

Two major circulatory systems supply blood to the lungs: the pulmonary and bronchial vascular networks. The pulmonary vascular system delivers mixed-venous blood from the right ventricle to the pulmonary capillary bed via the pulmonary arteries. After gas exchange occurs in the pulmonary capillary bed, oxygen-rich and carbon dioxide-poor blood is returned to the left atrium via the pulmonary veins. The pulmonary veins run independently along the intralobar connective tissue planes. The pulmonary arteries contain a specialized connective tissue that maintains blood vessel patency despite changes in lung volume and intrathoracic pressure during breathing or a change in body position. The pulmonary capillary system adequately provides for the metabolic and oxygen needs of the alveolar parenchyma. However, the bronchial arterial system must provide oxygen to the conductive airways and pulmonary vessels. Anatomic connections between the bronchial and pulmonary venous circulations create an absolute shunt of ~2–5% of the total cardiac output, and represents “normal” shunt.

LUNG MECHANICS

Lung movement is entirely passive and responds to forces external to the lungs. During spontaneous ventilation, the external forces are produced by ventilatory muscles. The lungs' response is governed by the impedance of the chest wall and by the airways. This impedance, or hindrance, falls mainly into two categories: (1) elastic recoil of the lung and gas–liquid interface and (2) resistance to gas flow.

Elastic Work

The lungs' natural tendency is to collapse; thus, normal expiration at rest is passive because gas flows out of the lungs when they elastically recoil. The thoracic cage exerts an outwardly directed force and the lungs exert an inwardly directed force that together result in a subatmospheric intrapleural pressure. Because the outward force of the thoracic cage exceeds the inward force of the lung, the overall tendency of the lung is to remain inflated when it resides within the thoracic cage. At FRC, the outward and inward forces on the lung are equal. Thus, at passive end-exhalation, the respiratory muscles are relaxed and the lung returns to its resting volume within the relaxed thorax: FRC. Gravitational forces create a more subatmospheric pressure in nondependent areas of the lung than in dependent areas. In the upright adult, the difference in intrapleural pressure from the top to the bottom of the lung is ~7 cm H₂O.

Surface tension at an air–fluid interface produces forces that tend to further reduce the area of interface. The gas pressure within a bubble is always higher than the surrounding gas pressure because of the bubble's surface tension. Thus, the bubble remains inflated. The alveoli resemble bubbles in this respect, although alveolar gas communicates with the atmosphere via the airways, unlike a bubble. The Laplace equation describes this phenomenon: $P = 2T/R$, where P is the pressure within

the bubble ($\text{dyn} \cdot \text{cm}^{-2}$), T is the surface tension of the liquid ($\text{dyn} \cdot \text{cm}^{-1}$), and R is the radius of the bubble (cm).

During inspiration, the surface tension of the liquid in the lung increases to $40 \text{ mN} \cdot \text{m}^{-1}$, a value close to that of plasma. During expiration, this surface tension falls to $19 \text{ mN} \cdot \text{m}^{-1}$, a value lower than that of any other known fluid. The alveoli experience hysteresis, that is, different pressure–volume relationships during inspiration and expiration. In contrast to a bubble, the pressure within an alveolus decreases as the radius of curvature decreases. Thus, gas tends to flow from larger to smaller alveoli and thereby maintain stability and prevent lung collapse.

The alveolar transmural pressure gradient, or transpulmonary pressure, is the difference between intrapleural and alveolar pressure and is directly proportional to lung volume. Intrapleural pressure can be safely measured with a percutaneously inserted catheter,²³ but clinicians rarely perform this technique. Esophageal pressure can be used as a reflection of intrapleural pressure, but the esophageal balloon must reside in the midesophagus to avoid inaccurate measurement.²⁴ Commercially available esophageal pressure monitors increase the ease and accuracy of measuring esophageal pressure as a reflection of intrapleural pressure.²⁵ These monitors are useful for estimating the elastic work performed by the patient during spontaneous ventilation, mechanical ventilation, or a combination of spontaneous and mechanical ventilation. By estimating intrapleural pressure on a real-time basis, it is possible to quantitate the patient's work of breathing as one intervenes. For example, if one changes the level of ventilatory support or changes the patient's breathing apparatus, one can assess the alterations in the patient's contribution to the total work of breathing, or to changes in the work of breathing imposed by the breathing apparatus.^{26,27,28,29,30} and [31](#)

Total ventilatory work is a combination of physiologic work and imposed work of breathing. Physiologic work includes elastic work (inspiratory work required to overcome the elastic recoil of the pulmonary system) and resistive work (work to overcome resistance to gas flow in the airway). For a patient in whom breathing apparatus is employed, the concept of total work of breathing encompasses physiologic work plus imposed ventilatory work: the (usually resistive) work performed by the patient to overcome the resistance imposed by the breathing apparatus. Examples of imposed work include the resistance imposed by tracheal tubes and demand valves.³²

If the lungs are slowly inflated and deflated, the pressure–volume curve during inflation differs from that obtained during deflation. The two curves form a hysteresis loop that becomes progressively broader as the tidal volume is increased ([Fig. 29-1](#)). A greater pressure than anticipated is required during inflation, and recoil pressure is less than expected during deflation. Thus, the lung accepts deformation poorly, and, once deformed, assumes its original shape slowly and with effort. This phenomenon, another example of elastic hysteresis, is important for the maintenance of normal lung compliance. However, for the purposes of the following discussion, it will be ignored.

Figure 29-1. Dynamic pressure–volume loop of resting tidal volume. Quiet, normal breathing is characterized by hysteresis of the pressure–volume loop. The lung is more resistant to deformation than expected and returns to its original configuration less easily than expected. The slope of the line connecting the zenith and nadir lung volumes is lung compliance, $\sim 500 \text{ ml per } 3 \text{ cm H}_2\text{O} = 167 \text{ ml per cm H}_2\text{O}$.

The sum of the pressure–volume relationships of the thorax and lung results in a sigmoidal curve ([Fig. 29-2](#)). The vertical line drawn at end-expiration coincides with FRC. Normally, humans breathe on the steepest part of the sigmoidal curve, where compliance is highest. The compliance of the curve is represented by the slope of the curve (DV/DP). In restrictive diseases, the curve shifts to the right, the slope is depressed, or both. These changes result in smaller FRCs and lower lung compliance. When lung compliance is small, larger changes in intrapleural pressure are needed to create the same tidal volume; that is, one has to suck harder to get the same volume of gas into the lungs. The body, being a smart organism, prefers to move less gas with each breath rather than sucking harder to achieve the same tidal volume. Thus, patients with low lung compliance typically breathe with smaller tidal volumes at more rapid rates. Spontaneous ventilatory rate is one of the most sensitive indices of lung compliance. Continuous positive airway pressure (CPAP) will shift the vertical line to the right, thus allowing the patient to breathe on a steeper and more favorable portion of the volume–pressure curve, resulting in a slower ventilatory rate with a larger tidal volume. However, patients with diseases that increase lung compliance experience larger than normal FRC (gas trapping) and their pressure–volume curves shift to the left and steepen. These patients expend less elastic work to inspire, but elastic recoil is reduced significantly. Chronic obstructive lung disease and acute asthma are the most common examples of diseases with high lung compliance. If lung compliance and FRC are sufficiently high that elastic recoil is minimal, the patient must use ventilatory muscles to actively expire. The difficulty these patients experience in emptying the lungs is compounded by the increased airway resistance.

Both compliance and inspiratory elastic work can be measured for a single breath by measuring airway (P_{aw}) and intrapleural (P_{pl}) pressures and tidal volume. If esophageal pressure is measured carefully, the esophageal pressure values can be substituted for P_{pl} values (see above). Lung compliance, C_l , the slope of the volume–pressure curve, is given by the equation

$$C_l = \frac{\Delta V}{\Delta P_l} + \frac{V_t}{P_{li} - P_{le}} = \frac{V_t}{(P_{awi} - P_{pli}) - (P_{awc} - P_{plc})} \quad (1)$$

where P_l is transpulmonary pressure, V_t is tidal volume, P_{aw_e} and P_{aw_i} are expiratory and inspiratory airway pressures, and P_{pl_e} and P_{pl_i} are expiratory and inspiratory intrapleural pressures.

Elastic work (W_{el}) is performed during inspiration only, expiration being passive during normal breathing. The area within the triangle in [Figure 29-2](#) describes the work required to inspire. The equation that yields elastic work (and the area of the triangle) is

$$W_{el} = \frac{1}{2}(V_t)(P_{li} - P_{le}) \\ = \frac{1}{2}(V_t)[(P_{awi} - P_{pli}) - (P_{awc} - P_{plc})] \quad (2)$$

Figure 29-2. Pulmonary pressure–volume relationships at different values of total lung capacity, ignoring hysteresis. The solid line depicts the normal pulmonary pressure–volume relationships. Humans normally breathe on the linear, steep part of this sigmoidal curve, where the slope, which is equal to compliance, is greatest. The vertical line at zero defines FRC, regardless of the position of the curve on the graph. Mild restrictive lung disease, indicated by the dashed line, shifts the curve to the right with little change in slope. However, with restrictive disease, the patient breathes on a lower FRC, at a point on the curve where the slope is less. Severe restrictive pulmonary disease profoundly depresses the FRC and diminishes the slope of the entire curve (*dashed-dotted line*). Obstructive disease (*dotted line*)

elevates both FRC and compliance. (FRC = functional residual capacity; TLC = total lung capacity.)

Resistance to Gas Flow

Both laminar and turbulent flow exist within the respiratory tract, usually in mixed patterns. The physics of each, however, is significantly different and worth consideration.

Laminar Flow

Below critical flows, gas proceeds through a straight tube as a series of concentric cylinders that slide over one another. Thus, fully developed flow has a parabolic profile with a velocity of zero at the cylinder wall and a maximum velocity at the center of the advancing "cone." Peripheral cylinders tend to be stationary and the central cylinder moves fastest. This type of streamlined flow is usually inaudible. The advancing conical front means that some fresh gas reaches the end of the tube before the tube has been completely filled with fresh gas. That is, significant alveolar ventilation can occur when the tidal volume (V_t) is less than anatomic dead space; this fact, noted by Rohrer in 1915,³³ is important in high-frequency ventilation. Gas flowing in a straight, unbranched tube meets resistance that can be calculated by the following equation:

$$R = \frac{8 \times \text{length} \times \text{viscosity}}{\pi \times (\text{radius})^4} = \frac{P_B - P_A}{\text{flow}} \quad (3)$$

where P_B and P_A are barometric and alveolar pressures. The inverse relationship between resistance and the fourth power of the radius explains the critical importance of narrowed air passages. Viscosity is the only physical gas property that is relevant under conditions of laminar flow. Helium has a low density, but its viscosity is close to that of air. Helium will not improve gas flow if the flow is laminar; usually, however, flow is turbulent when there is critical airway narrowing or abnormally high airway resistance.

Turbulent Flow

High flow rates, particularly through branched or irregularly shaped tubes, disrupt the orderly flow of laminar gas. Turbulent flow is usually audible and is almost invariably present when high resistance to gas flow is problematic. Turbulent flow usually presents with a square front so that no fresh gas will reach the end of the tube until the amount of gas entering the tube is almost equal to the volume of the tube. Thus, turbulent flow effectively purges the contents of a tube. Four conditions that will change laminar flow to turbulent flow are high gas flows, sharp angles within the tube, branching in the tube, and a change in the tube's diameter.

During turbulent flow, the driving pressure is proportional to the square of the required gas flow rate, proportional to gas density, independent of viscosity, and inversely proportional to the fifth power of the radius of the tube.

Resistance during laminar flow is inversely proportional to gas flow rate. Conversely, during turbulent flow, resistance increases in proportion to the flow rate. A detailed description of these phenomena is beyond the scope of this chapter, but the reader is referred to descriptions by Nunn.³⁴

Increased Airway Resistance

Bronchiolar smooth muscle hyper-reactivity (true bronchospasm), mucosal edema, mucous plugging, epithelial desquamation, tumors, and foreign bodies all increase airway resistance. The normal response to increased inspiratory resistance is increased inspiratory muscle effort, with little change in FRC.³⁵ Accessory muscles act according to the degree of resistance.

There are two principal compensatory mechanisms for high inspiratory resistance. The muscle spindles' afferent discharge augments the activity in the motor neuron pool of the anterior horn. The conscious subject can detect small increases in inspiratory resistance.³⁶ Additional compensatory increases in effort are driven by an elevated partial pressure of carbon dioxide in arterial blood (P_{aCO_2}).³⁷

Emphysematous patients retain remarkable ability to preserve an adequate alveolar ventilation, even with gross airway obstruction. In patients with preoperative FEV_1 values <1 l, there was no correlation between FEV_1 and P_{aCO_2} , which was normal in most patients. Furthermore, asthmatic patients compensate well for increased airway resistance and also keep the mean P_{aCO_2} in the lower end of normal range.³⁸ Thus, an increased P_{aCO_2} in the setting of increased airway resistance deserves serious attention.

Mild expiratory resistance does not result in activation of the expiratory muscles in conscious or anesthetized subjects. The initial work to overcome expiratory resistance is performed by augmenting inspiratory force until a sufficiently high lung volume is achieved, so that elastic recoil overcomes expiratory resistance.³⁹ The immediate effects of excessive expiratory resistance are to use accessory muscles to force gas from the lungs. This response is useful during acute increases in expiratory resistance. However, patients who chronically use accessory muscles to expire are at risk for ventilatory muscle fatigue if they experience an acute worsening of ventilatory work, most commonly precipitated by pneumonia or heart failure.

CONTROL OF VENTILATION

Mechanisms that control ventilation are extremely complex, requiring integration with many parts of the central and peripheral nervous systems (see Fig. 29-3). LeGallois, who localized the respiratory centers in the brainstem in 1812, demonstrated that breathing does not depend on an intact cerebrum. Rather, breathing depends on a small region of the medulla near the origin of the vagus nerves.⁴⁰ Countless studies in the past two centuries have greatly increased our knowledge and understanding of the anatomic components of ventilatory control. However, experimental work performed in animals is difficult to apply to humans because of interspecies variation.

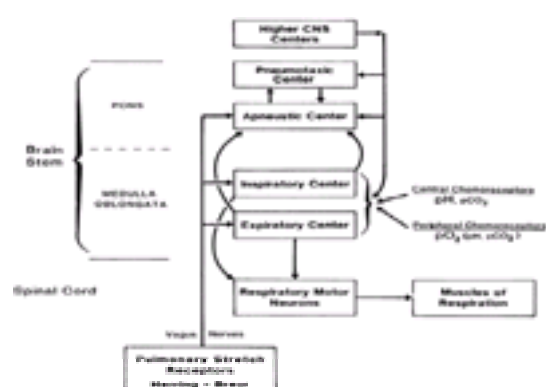

Figure 29-3. Classic CNS respiratory centers. Diagram illustrates major respiratory centers, neurofeedback circuits, primary neurohumoral sensory inputs, and mechanical outputs.

Generation of Ventilatory Pattern

Please refer to Table 29-4 for definitions of terms used in this section. A *respiratory center* is a specific area in the brain that integrates any neural traffic resulting in spontaneous ventilation. Within the pontine and medullary reticular formations there are several discrete respiratory centers that function as the control system (Fig.

| Word | Definition |
|---------------------|---|
| Eupnea | "Good breathing": Continuous respiratory and expiratory movement without interruption |
| Apnea | "No breathing": Cessation of ventilatory effort at passive end-expiration (lung volume = FRC) |
| Apnoeic | Cessation of ventilatory effort with lungs filled at TLC |
| Apnoeic ventilation | Apnoeic with periodic expiratory spasms |
| Biot | Ventilatory gaps interspersed between periods of ventilation apnoeic, also "agonal ventilation" |

Table 29-4. DEFINITION OF RESPIRATORY PATTERN TERMINOLOGY

Initial descriptions of brain stem respiratory functions are based on classic ablation and electrical stimulation studies.^{42,43,44} and ⁴⁵ Another method for localizing respiratory centers entails recording action potentials from different areas of the brain stem with microelectrodes. This method is based on the assumption that local brain activity that occurs in phase with respiratory activity is evidence that the area under study has "respiratory neurons."⁴⁶ These techniques are imperfect for precisely localizing discrete respiratory centers.

Medullary Centers

The medulla oblongata contains the most basic ventilatory control centers in the brain. Specific medullary areas are active primarily during inspiration or during expiration, with many neural inspiratory or expiratory interconnections. The inspiratory centers that reside in the dorsal respiratory group (DRG) are located in the dorsal medullary reticular formation. The DRG is the source of elementary ventilatory rhythmicity^{47,48} and serves as the "pacemaker" for the respiratory system.⁴⁹ Whereas resting lung volume occurs at end-expiration, the electrical activity of the ventilatory centers is at rest at end-inspiration. The rhythmic activity of the DRG persists even when all incoming peripheral and interconnecting nerves are sectioned or blocked completely. Isolating the DRG in this manner results in ataxic, gasping ventilation with frequent maximum inspiratory efforts: apneustic breathing.

The ventral respiratory group (VRG), which is located in the ventral medullary reticular formation, serves as the expiratory coordinating center. The inspiratory and expiratory neurons function by a system of reciprocal innervation, or negative feedback.⁴⁶ When the DRG creates an impulse to inspire, inspiration occurs, and then the DRG impulse is quenched by a reciprocating VRG impulse. This VRG transmission prohibits further use of the inspiratory muscles, thus allowing passive expiration to occur.

Pontine Centers

The pontine centers process information that originates in the medulla. The apneustic center is located in the middle or lower pons. With activation, this center sends impulses to inspiratory DRG neurons and is designed to sustain inspiration. Electrical stimulation results in inspiratory spasm.⁵⁰ The middle and lower pons contain specific areas for phase-spanning neurons.⁵¹ These neurons assist with the transition between inspiration and expiration and do not exert direct control over ventilatory muscles.

The pneumotaxic respiratory center is in the rostral pons. A simple transection through the brain stem that isolates this portion of the pons from the upper brain stem reduces ventilatory rate and increases tidal volume. If both vagus nerves are additionally transected, apnoeic results.⁵² Thus, the primary function of the pneumotaxic center is to limit the depth of inspiration. When maximally activated, the pneumotaxic center secondarily increases ventilatory frequency. The pneumotaxic center performs no pacemaking function and has no intrinsic rhythmicity.

Higher Respiratory Centers

Many higher brain structures clearly affect ventilatory control processes. In the midbrain, stimulation of the reticular activating system increases the rate and amplitude of ventilation.⁵³ The cerebral cortex also affects breathing pattern, although precise neural pathways are not known.⁵⁴ Occasionally, the ventilatory control process becomes subservient to other regulatory centers. For example, the respiratory system plays an important role in the control of body temperature because it supplies a large surface area for heat exchange. This is especially important in animals in which panting is a primary means of dissipating heat. Then, ventilatory pattern is influenced by neural input from descending pathways from the anterior and posterior hypothalamus to the pneumotaxic center of the upper pons.

Vasomotor control and certain respiratory responses are closely linked. Stimulation of the carotid sinus not only decreases vasomotor tone but also inhibits ventilation. Alternatively, stimulation of the carotid body chemoreceptors (see [Chemical Control of Ventilation](#)) results in an increase in both ventilatory activity and vasomotor tone.^{55,56}

Reflex Control of Ventilation

Reflexes that directly influence ventilatory pattern usually do so to prevent airway obstruction. *Deglutition*, or swallowing, involves the glossopharyngeal and vagus nerves. Stimulation of the anterior and posterior pharyngeal pillars of the posterior pharynx induces swallowing. During swallowing, inspiration ceases momentarily, is usually followed by a single large breath, and briefly increases ventilation. The ventilatory centers that coordinate breathing and deglutition have not been identified.⁵⁷

Vomiting significantly modifies normal ventilatory activity.⁵⁸ Swallowing, salivation, gastrointestinal reflexes, rhythmic spasmodic ventilatory movements, and significant diaphragmatic and abdominal muscular activity must be coordinated over a very brief interval. Because of the obvious risk of aspirating gastric contents, it is advantageous to inhibit inspiration during vomiting. Input into the respiratory centers occurs from both cranial and spinal cord nerves.

Coughing results from stimulation of the tracheal subepithelium, especially along the posterior tracheal wall and carina.⁵⁹ Coughing also requires coordination of both airway and ventilatory muscle activity. An effective cough requires deep inspiration, then forced exhalation against a momentarily closed glottis to increase intrathoracic pressure, thus allowing an expulsive expiratory maneuver.

Proprioception in the pulmonary system, the qualitative knowledge of the gas volume within the lungs, probably arises from smooth muscle spindle receptors. These proprioceptors, which are located within the smooth muscle of all airways, are sensitive to pressure changes.⁶⁰ Airway stretch reflexes can be demonstrated during distention of isolated airways, so that airway pressure, rather than volume distention, appears to be the primary stimulation.⁶¹ Clinical conditions in which pulmonary airway stretch receptors are stimulated include pulmonary edema and atelectasis. Certain drugs, such as acetylcholine, pilocarpine, and histamine, which are administered in doses large enough to decrease lung compliance, also enhance the stretch reflex.⁶² In contrast, airway stretch receptors are inhibited by inhalation of vaporized water, intravenously administered antihistamines, and topically administered local anesthetics.

Golgi tendon organs (tendon spindles), which occur in series arrangements within ventilatory muscles, facilitate proprioception. The intercostal muscles are rich in tendon spindles, whereas the diaphragm has a limited number. Thus, the pulmonary stretch reflex primarily involves the intercostal muscles but not the diaphragm.⁶³ When the lungs are full and the chest wall is stretched, these receptors send signals to the brain stem that inhibit further inspiration.

In 1868, Hering and Breuer reported that lightly anesthetized, spontaneously breathing animals would cease or decrease ventilatory effort during sustained lung distention.⁶⁴ This response was blocked by bilateral vagotomy. The *Hering-Breuer reflex* is prominent in lower-order mammals such as rabbits but is only weakly present in humans. The Hering-Breuer reflex is sufficiently active in lower mammals that even 5 cm H₂O CPAP will induce apnea. In humans, however, the reflex is only weakly present, as evidenced by the fact that humans will continue to breathe spontaneously with CPAP in excess of 40 cm H₂O. This inflation reflex is associated with inspiratory muscle inhibition, as documented by marked reductions in electrical activity of both the phrenic nerve and the diaphragmatic muscle itself. The second component of the Hering-Breuer reflex, the deflation reflex, produces increased ventilatory muscle activity following sustained lung deflation. This reflex is not

significant in humans. Both pulmonary and airway stretch reflexes operate secondarily to the pacemaking and modulating effects of the brain stem ventilatory control centers.

Chemical Control of Ventilation

Peripheral Chemoreceptors

In a simplistic view of chemical ventilatory control, the peripheral chemoreceptors primarily respond to lack of oxygen, and the central nervous system (CNS) receptors primarily respond to changes in PCO_2 , pH, and acid–base disturbances.

The peripheral chemoreceptors are composed of the carotid and aortic bodies.^{65,66} The carotid bodies, located at the bifurcation of the common carotid artery, have predominantly ventilatory effects. The aortic bodies, which are scattered about the aortic arch and its branches, have predominantly circulatory effects. The neural output from the carotid body reaches the central respiratory centers via the afferent glossopharyngeal nerves. Output from the aortic bodies travels to the medullary centers via the vagus nerve. Both carotid and aortic bodies are stimulated by decreased PaO_2 , but not by decreased SaO_2 or CaO_2 . When PaO_2 falls below 100 mm Hg, neural activity from these receptors begins to increase. However, it is not until the PaO_2 reaches 60–65 mm Hg that neural activity increases sufficiently to substantially augment minute ventilation. Thus, patients who depend on hypoxic ventilatory drive have PaO_2 values in the mid-60s. Once these patients' PaO_2 values exceed 60–65 mm Hg, ventilatory drive diminishes and PaO_2 falls until ventilation is again stimulated by arterial hypoxemia. When we withdraw mechanical ventilation from the patient who depends on hypoxic ventilatory drive, the PaO_2 must fall below 65 mm Hg so that the patient will regain hypoxic ventilatory drive.

The carotid bodies are also sensitive to decreased pH, but this response is minor. Similarly, changes in PaCO_2 do not stimulate these receptors sufficiently to alter minute ventilation. Increases in blood temperature, hypoperfusion of the carotid bodies themselves, and some chemicals will stimulate these receptors. Sympathetic ganglion stimulation by nicotine or acetylcholine will stimulate the carotid and aortic bodies; this effect is blocked by hexamethonium. Blockade of the cytochrome electron transport system by cyanide will prevent oxidative metabolism and thus stimulate these receptors also.

Ventilatory effects resulting from stimulation of these receptors cause increased ventilatory rate and tidal volume. Hemodynamic changes resulting from stimulation of these receptors include bradycardia, hypertension, increases in bronchiolar tone, and increases in adrenal secretion. The carotid body chemical receptors have been termed *ultimum moriens* (“last to die”). The peripheral receptor's response to hypoxemia is resistant to the influences of anesthesia and tissue hypoxia that may depress central responses. However, the peripheral receptor's response is not sufficiently robust to reliably increase ventilatory rate or minute ventilation to herald the onset of arterial hypoxemia during general anesthesia or recovery from anesthesia.

Central Chemoreceptors

Approximately 80% of the ventilatory response to inhaled carbon dioxide originates in the central medullary centers. Acid–base regulation involving carbon dioxide, H^+ , and bicarbonate is related primarily to chemosensitive receptors located in the medulla close to or in contact with the cerebrospinal fluid (CSF). The chemosensitive areas of the brain stem are in the infralateral aspects of the medulla near the origin of cranial nerves IX and X. The area just beneath the surface of the ventral medulla is exquisitely sensitive to the extracellular fluid H^+ concentration.⁶⁷ Although the central response is the major factor in the regulation of breathing by carbon dioxide, carbon dioxide has little direct stimulating effect on these chemosensitive areas. These receptors are primarily sensitive to changes in H^+ concentration. Carbon dioxide has a potent but indirect effect by reacting with water to form carbonic acid, which dissociates into hydrogen and bicarbonate ions.⁶⁸

Increased PaCO_2 is a more potent ventilatory stimulus than increased arterial H^+ concentration from a metabolic source. Carbon dioxide, but not H^+ , passes readily through the blood–brain and blood–CSF barriers. Local buffering systems immediately neutralize H^+ in arterial blood and body fluids. In contrast, the CSF has minimal buffering capacity. Thus, once carbon dioxide crosses into the CSF, H^+ are created and trapped in the CSF, resulting in a CSF H^+ concentration considerably greater than that found in the blood. Because carbon dioxide crosses the blood–brain barrier readily, the PCO_2 values in the CSF, cerebral tissue, and jugular venous blood rise quickly and to the same degree as the PaCO_2 , although the central values are ~10 mm Hg above those measured in arterial blood.

The ventilatory response to changes in PaCO_2 (increased V_t , increased respiratory rate) is rapid and peaks within 1–2 minutes after the change in PaCO_2 . With the same level of carbon dioxide stimulation, the resultant increase in ventilation declines over a period of several hours, probably as a result of bicarbonate ions that are actively transported from the blood into the CSF through the arachnoid villi.⁶⁹ Central medullary chemoreceptors also respond to temperature change. Cold CSF (with normal pH) or local anesthetic applied to the medullary surface will depress ventilation.

Ventilatory Response to Altitude

Ventilatory response and adaptation to high altitude are good examples of the integration of peripheral and central chemoreceptor control of ventilation. The following mechanism of acclimatization was proposed by Severinghaus and co-workers in 1963 and has since been confirmed.⁷⁰

Following ascent from sea level to 4000 m, acute exposure to high altitude and low PiO_2 results in arterial hypoxemia. This decrease in PaO_2 activates the peripheral hypoxic ventilatory drive by stimulating the carotid and aortic bodies, and causes increased minute ventilation. As minute ventilation increases, PaCO_2 and CSF PCO_2 decrease, causing concomitant increases in pH and CSF pH . The alkaline shift of the CSF decreases ventilatory drive via medullary chemoreceptors, partially offsetting hypoxic drive. A temporary equilibrium is attained within minutes, with PaCO_2 only 2–5 mm Hg below normal and PaO_2 , approximately 45 mm Hg. This initially profound hypoxemia probably causes the acute respiratory distress and other associated symptoms (headache, diarrhea) associated with rapid ascent. However, the CNS is able to restore CSF pH to normal (7.326) by pumping bicarbonate ions out of the CSF over 2–3 days. In 2–3 days, CSF bicarbonate concentration decreases approximately 5 $\text{mEq} \cdot \text{l}^{-1}$ and restores CSF pH to within 0.01 pH unit of values at sea level. Then, centrally mediated ventilatory drive returns to normal, and hypoxic drive and stimulation of peripheral receptors can proceed unopposed. Thus, after 3 days' exposure to 4000 m altitude, ventilatory adaptation would result in a new equilibrium, with PaCO_2 approximately 30 mm Hg and PaO_2 , approximately 55 mm Hg. Following descent to sea level, the low CSF bicarbonate concentration persists for several days, and the climber “overbreathes” until CSF bicarbonate and pH values return to normal.

Breath-holding

Most adults with normal lungs and gas exchange can hold their breath for ~1 minute when breathing room air without previously hyperventilating. After 1 minute of breath-holding under these circumstances, PaO_2 decreases to ~65–70 mm Hg and PaCO_2 increases by ~12 mm Hg. In the absence of supplemental oxygen and hyperventilation, the “breakpoint” at which normal people feel compelled to breathe is remarkably constant at a PaCO_2 of 50 mm Hg.^{71,72} However, if the individual breathes 100% oxygen prior to breath-holding, he should be able to hold his breath for 2–3 minutes, or until PaCO_2 rises to 60 mm Hg. Hyperventilation sufficient to reduce PaCO_2 to 20 mm Hg can lengthen the period of breath-holding to 3–4 minutes.⁷⁴ Hyperventilation with 100% oxygen prior to breath-holding should extend the apneic period to 6–10 minutes. The PaCO_2 rate of rise in awake, preoxygenated adults with normal lungs who hold their breath without previous hyperventilation is 7 $\text{mm Hg} \cdot \text{min}^{-1}$ in the first 10 seconds, 2 $\text{mm Hg} \cdot \text{min}^{-1}$ in the next 10 seconds, and 6 $\text{mm Hg} \cdot \text{min}^{-1}$ thereafter.⁷²

The duration of voluntary breath-holding is directly proportional to lung volume at onset. This is probably related both to oxygen stores in the alveoli and to the rate at which PaCO_2 rises. With smaller lung volumes, the same amount of carbon dioxide is emptied into a smaller volume during the apneic period, thus increasing the carbon dioxide concentration more rapidly than occurs with larger lung volumes. Of note, apneic patients during general anesthesia actually “breath-hold” at FRC rather than at vital capacity, which would tend to accelerate the rate of rise of carbon dioxide. Despite this difference in lung volume, the rate of rise of PaCO_2 in apneic anesthetized patients is 12 mm Hg during the first minute and 3.5 $\text{mm Hg} \cdot \text{min}^{-1}$ thereafter, significantly lower than in the awake state.^{74,75} During anesthesia, metabolic rate and carbon dioxide production are significantly less than during ambulatory wakefulness, which probably accounts for the different rates of rise in carbon dioxide levels.

Hyperventilation with room air prior to prolonged breath-holding during exercise is inadvisable. During underwater swimming after poolside hyperventilation, the urge to breathe is first stimulated by a rising PaCO_2 . Swimmers who hyperventilate with room air prior to swimming long distances underwater frequently lose consciousness from arterial hypoxemia before the PaCO_2 is sufficiently increased to stimulate the “need” to breathe.

Hyperventilation rarely is followed by an apneic period in awake humans, despite a markedly depressed PaCO_2 . However, minute ventilation may decrease significantly.

Aggressive intermittent positive pressure breathing treatments for patients with COPD can depress minute ventilation sufficiently to create arterial hypoxemia if they breathe room air after cessation of therapy.⁷⁶ In contrast, even mild hyperventilation during general anesthesia will produce prolonged apneic periods.⁷⁷

Quantitative Aspects of Chemical Control of Breathing

The ventilatory responses to oxygen and carbon dioxide can be assessed quantitatively. Unfortunately, the quantitative indices of hypoxemic sensitivity are not clinically useful because the normal range is wide. The reader is referred to more comprehensive sources for a discussion of the quantitative indices of hypoxemic sensitivity.⁷⁸

Ventilatory responses to PaCO₂ changes are measured in several ways, provided that carbon dioxide production remains constant. When subjects voluntarily increase minute ventilation to a prescribed level, the PaCO₂ decreases hyperbolically. The plot of minute ventilation (independent variable) and PaCO₂ (dependent variable) is the metabolic hyperbola (Fig. 29-4). The metabolic hyperbola is cumbersome to evaluate and difficult to use clinically.

Figure 29-4. Carbon dioxide–ventilatory response curve. The metabolic hyperbola, curve A, is generated by varying VE and measuring changes in carbon dioxide concentration. The hyperbolic configuration makes it cumbersome for clinical use. The carbon dioxide–ventilatory response curve, B, is linear between approximately 20 and 80 mm Hg. It is generated by varying PaCO₂ (usually by controlling inspired carbon dioxide concentration) and measuring the resultant VE. This is the most commonly used test of ventilatory response. The slope defines “sensitivity”; the setpoint, or resting PaCO₂, occurs at the intersection of the metabolic hyperbola and the carbon dioxide–ventilatory response curve; and the apneic threshold can be obtained by extrapolating the carbon dioxide–ventilatory response curve to the x-intercept. In the absence of surgical stimulation, increasing doses of potent inhaled anesthesia or opioids will shift the curve to the right and eventually depress the slope (*dashed lines*). Painful stimulation will reverse these changes to varying and unpredictable degrees.

The curve more commonly used is the PaCO₂ ventilatory response curve (see Fig. 29-4). It describes the effect of changing PaCO₂ on the resultant minute ventilation. Usually, subjects inspire carbon dioxide to raise PaCO₂, and the effect on minute ventilation is measured. Creating these curves and observing how they change in a variety of circumstances allows quantitative study of factors that affect the chemical carbon dioxide control of ventilation. The carbon dioxide response curve approaches linearity in the range most often encountered in life: at PaCO₂ values between 20 and 80 mm Hg. Once the PaCO₂ exceeds 80 mm Hg, the curve becomes parabolic, with its peak ventilatory response at a PaCO₂ between 100 and 120 mm Hg. Increasing the PaCO₂ above 100 mm Hg allows carbon dioxide to act as a ventilatory and CNS depressant, the origin of the term “carbon dioxide narcosis,” with 1 MAC being approximately 200 mm Hg.

The slope of the carbon dioxide response curve is considered to represent carbon dioxide sensitivity. Normal carbon dioxide sensitivity ranges from 0.5–0.7 l · min⁻¹ · mm Hg⁻¹ CO₂. When PaCO₂ reaches 100 mm Hg, carbon dioxide sensitivity is at its peak and normally reaches as high as 2.0 l · min⁻¹ · mm Hg⁻¹ CO₂. The *setpoint*, the point of intersection of the carbon dioxide response curve and the metabolic hyperbola, defines normal resting PaCO₂. Extrapolation of the carbon dioxide response curve to the x-intercept (where minute ventilation is 0) defines the apneic threshold. In awake, normal adults, the apneic threshold normally occurs at a PaCO₂ of ~32 mm Hg, although adults usually continue to breathe when they achieve the apneic threshold because the sensation of apnea is disturbing to awake adults. The slope of the curve is a measure of the response of the entire ventilatory mechanism to carbon dioxide stimulation.

Once PaO₂ exceeds 100 mm Hg, it no longer influences the carbon dioxide response curve. When the PaO₂ is between 65 and 100 mm Hg, its effect on the carbon dioxide response curve is small. However, when PaO₂ falls below 65 mm Hg, the carbon dioxide response curve shifts to the left and its slope increases, probably as a result of increased ventilatory drive stimulated by the peripheral chemoreceptors. Thus, during measurements of carbon dioxide ventilatory response, the subject should breathe supplemental oxygen.

The carbon dioxide response curve can be generated rapidly by increasing the fraction of inspired carbon dioxide (FICO₂) by requiring the subject to rebreathe exhaled gas. The results obtained with this technique are less pure because the FICO₂ is not controlled.

Three clinical states result in a left shift and/or a steepened slope of the carbon dioxide response curve. These same three situations are the only causes of true hyperventilation, *i.e.*, an increase in minute ventilation such that the decreased PaCO₂ creates respiratory alkalemia (either primary or compensatory). The three causes of hyperventilation (enhanced carbon dioxide response) are arterial hypoxemia, metabolic acidemia, and central etiologies. Examples of central etiologies that cause hyperventilation include drug administration, intracranial hypertension, hepatic cirrhosis, and nonspecific arousal states such as anxiety and fear. Aminophylline, salicylates, and norepinephrine stimulate ventilation independent of peripheral chemoreceptors. Opioid antagonists, given in the absence of opioids to presumably normal people, do not stimulate ventilation. However, when given after opiate administration, they do reverse the effects of opioids on the carbon dioxide response curve.

Ventilatory depressants displace the carbon dioxide response curve to the right or decrease its slope or both. Changes in physiology that depress ventilation include metabolic alkalemia, denervation of peripheral chemoreceptors, normal sleep, and drugs. During normal sleep, the carbon dioxide response curve is displaced to the right, with the degree of displacement depending on the depth of sleep. Usually, PaCO₂ increases up to 10 mm Hg during deep sleep. Hypoxemic responses are not impaired by sleep, which is convenient for continued survival at high altitude.

Opioids displace the carbon dioxide response curve to the right with little change in slope at sedative doses. With higher, “anesthetic” doses, the curve shifts farther to the right and its slope is depressed, simulating the effect of potent inhalation agents on the carbon dioxide response curve (see Fig. 29-4). Opioids induce pathognomonic changes in ventilatory patterns: a decreased ventilatory rate with an increased tidal volume. Not until opioids nearly induce apnea is tidal volume decreased. Large narcotic doses usually result in apnea before consciousness is lost. Like sex, breathing requires both ability and desire.

Barbiturates in sedative or light hypnotic doses have little effect on the carbon dioxide response curve. In doses adequate to allow skin incision, barbiturates shift the carbon dioxide response curve to the right. The ventilatory pattern resulting from barbiturate administration is characterized by decreased tidal volume and increased ventilatory rate. Potent inhaled anesthetics displace the carbon dioxide response curve to the right and decrease the slope, the degree depending on the anesthetic dose and the level of surgical stimulation. As the inhaled anesthetic dose increases, the carbon dioxide response curve eventually becomes horizontal (slope = 0), resulting in essentially no ventilatory response to PaCO₂ changes.

Potent inhaled anesthetics and opioids displace the setpoint to the right, implying that the resting, steady-state PaCO₂ is higher and minute ventilation lower.

Furthermore, when the carbon dioxide response curve shifts to the right, the apneic threshold also increases (see Fig. 29-4). Surgical stimulation reverses the ventilatory response changes induced by inhaled anesthetics and opioids, but the degree of reversal is not predictable. Enflurane, halothane, and isoflurane all produce qualitatively similar carbon dioxide ventilatory responses. At equipotent doses, when administered with oxygen, the greatest to least ventilatory depression occurs with enflurane, halothane, and isoflurane.

OXYGEN AND CARBON DIOXIDE TRANSPORT

This chapter discusses only external respiration, in which oxygen moves from the ambient environment into the pulmonary capillaries and carbon dioxide leaves the

pulmonary capillaries to enter the atmosphere. The movement of gas across the alveolar–capillary membrane depends on the integrity of the pulmonary and cardiac systems. Unless it is otherwise stated, the reader should assume that the ventilation and perfusion of alveolar–capillary units are normal. Abnormal distribution of ventilation or perfusion of the lungs is discussed later (see [Ventilation–Perfusion Relationships](#)).

Bulk Flow of Gas (Convection)

Convection, in which all gas molecules move in the same direction, is the primary mechanism responsible for gas flow in large and most small airways, down to the bronchi and bronchiolar airways of the 14th or 15th generation. Because the cross-sectional area of the airways progressively increases as gas moves toward the lung periphery, the average velocity of gas particles decreases as they travel toward the alveoli. As a result, the greatest part of airway resistance occurs in the larger airways, where gas molecules travel more quickly. During normal quiet ventilation, gas flow within convective airways is mainly laminar, thus reducing resistance to gas flow (see [Resistance to Gas Flow](#)).

Gas Diffusion

Diffusion within a gas-filled space is random molecular motion that results in complete mixing of all gases. In the lung, diffusion gradually becomes the predominant mode of gas transport, beginning with the terminal bronchioles (16th airway generation). Once gas reaches the small alveolar ducts, alveolar sacs, and alveoli, both diffusion and regional \dot{V}/\dot{Q} relationships influence gas transport. Historically, clinicians assumed that defects in gas diffusion were responsible for arterial hypoxemia. However, the most frequent cause of arterial hypoxemia is physiologic shunt (see [Ventilation–Perfusion Relationships](#)).⁸⁰

The other usage of “diffusion” refers to the passive movement of molecules across a membrane that is governed primarily by concentration gradient. In this sense, carbon dioxide is 20 times more diffusible across human membranes than is oxygen; therefore, carbon dioxide crosses membranes easily. As a result, hypercarbia is never the result of defective diffusion; rather, it is the result of inadequate alveolar ventilation with respect to carbon dioxide production.

True diffusion defects that create arterial hypoxemia are rare. The most common reason for a measured decrease in diffusing capacity (see [Pulmonary Function Testing](#)) is mismatched ventilation and perfusion, which functionally results in a decreased surface area available for diffusion.

Distribution of Ventilation and Perfusion

The efficiency with which oxygen and carbon dioxide exchange at the alveolar–capillary level highly depends on the matching of capillary perfusion and alveolar ventilation. At this level, the marriage between the lung and the circulatory system must be well-matched and intimate.

Distribution of Blood Flow

Blood flow within the lung is mainly gravity-dependent. Because the alveolar–capillary beds are not composed of rigid vessels, the pressure of the surrounding tissues can influence the resistance to flow through the individual capillaries. Thus, blood flow depends on the relationship between pulmonary artery pressure (P_{pa}), alveolar pressure (P_A), and pulmonary venous pressure (P_{pv}) (Fig. 29-5). West created a lung model that divides the lung into three zones.^{80,81} Zone 1 conditions occur in the most gravity-independent part of the lung above the level where pulmonary artery pressure is equal to alveolar pressure. Because alveolar pressure is approximately equal to atmospheric pressure, pulmonary artery pressure in Zone 1 is subatmospheric but necessarily greater than pulmonary venous pressure ($P_A > P_{pa} > P_{pv}$). Alveolar pressure that is transmitted to the pulmonary capillaries promotes their collapse, with a consequent theoretical blood flow of zero to this lung region. Thus, Zone 1 receives ventilation in the absence of perfusion and creates alveolar dead space ventilation. Normally, Zone 1 areas exist only to a limited extent. However, in conditions of decreased pulmonary artery pressure, such as hypovolemic shock, Zone 1 enlarges.

Figure 29-5. Distribution of blood flow in the isolated lung. In Zone 1, alveolar pressure (P_A) exceeds pulmonary artery pressure (P_{pa}), and no flow occurs because the vessels are collapsed. In Zone 2, arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds pulmonary venous pressure (P_{pv}). Flow in Zone 2 is determined by the arterial–alveolar pressure difference ($P_{pa} - P_A$), which steadily increases down the zone. In Zone 3, pulmonary venous pressure exceeds alveolar pressure, and flow is determined by the arterial–venous pressure difference ($P_{pa} - P_{pv}$), which is constant down this pulmonary zone. However, the pressure across the vessel walls increases down the zone, so that their caliber increases, as does flow. (Reproduced with permission from West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: Relation to vascular and alveolar pressures. *J Appl Physiol* 19:713, 1964.)

Zone 3 occurs in the most gravity-dependent areas of the lung where $P_{pa} > P_{pv} > P_A$ and blood flow is primarily governed by the pulmonary arterial to venous pressure difference. Because gravity also increases pulmonary venous pressure, the pulmonary capillaries become distended. Thus, perfusion in Zone 3 is lush, resulting in capillary perfusion in excess of ventilation, or physiologic shunt.

Finally, Zone 2 occurs from the lower limit of Zone 1 to the upper limit of Zone 3, where $P_{pa} > P_A > P_{pv}$. The pressure difference between pulmonary artery and alveolar pressure determines blood flow in Zone 2. Pulmonary venous pressure has little influence. Well-matched ventilation and perfusion occur in Zone 2, which contains the majority of alveoli.

Distribution of Ventilation

Alveolar pressure is the same throughout the lung; therefore, the more negative intrapleural pressure at the apex (or the least gravity-dependent area) results in larger, more distended apical alveoli than in other areas of the lung. The transpulmonary pressure ($P_{aw} - P_{pl}$), or distending pressure of the lung, is greater at the top and lower at the bottom, where intrapleural pressure is less negative. Despite the smaller alveolar size, more ventilation is delivered to dependent pulmonary areas. The decrease in intrapleural pressure at the base of the lungs during inspiration is greater than at the apex because of diaphragmatic proximity. Thus, more gas is sucked into dependent areas of the lung.

Ventilation–Perfusion Relationships

As discussed above, the majority of blood flow is distributed to the gravity-dependent part of the lung. During a spontaneous breath, the largest portion of the tidal volume also reaches gravity-dependent lung. Thus, the nondependent area of the lung receives a lower proportion of both ventilation and perfusion, and dependent lung receives greater proportions of ventilation and perfusion. Nevertheless, ventilation and perfusion are not matched perfectly, and a variety of \dot{V}_A/\dot{Q} ratios result throughout the lung. The ideal \dot{V}_A/\dot{Q} ratio of 1 is believed to occur at approximately the level of the third rib. Above this level, ventilation occurs slightly in excess of perfusion, whereas below the third rib the \dot{V}_A/\dot{Q} ratio becomes less than 1 (Fig. 29-6).

Figure 29-6. Distribution of ventilation, blood flow, and ventilation–perfusion ratio in the normal, upright lung. Straight lines have been drawn through the ventilation and blood flow data. Because blood flow falls more rapidly than ventilation with distance up the lung, ventilation–perfusion ratio rises, slowly at first, then rapidly. (Reproduced with permission from West JB: *Ventilation/Blood Flow and Gas Exchange*, 4th ed. Oxford, England, Blackwell Scientific Publications, 1985.)

In a simplified model, gas exchange units can be divided into normal ($\dot{V}_A/\dot{Q} = 1:1$), dead space ($\dot{V}_A/\dot{Q} = 1:0$), shunt ($\dot{V}_A/\dot{Q} = 0:1$), or a silent unit ($\dot{V}_A/\dot{Q} = 0:0$) (Fig. 29-7). Although this model is helpful in understanding \dot{V}_A/\dot{Q} relationships and their influences on gas exchange,⁸² \dot{V}_A/\dot{Q} really occurs as a continuum. In the lungs of a healthy, upright, spontaneously breathing individual, the majority of alveolar–capillary units are normal gas exchange units. The \dot{V}_A/\dot{Q} ratio varies between absolute shunt (in which $\dot{V}_A/\dot{Q} = 0$) to absolute dead space (in which $\dot{V}_A/\dot{Q} = \infty$). Rather than absolute shunt, most units with low \dot{V}_A/\dot{Q} mismatch receive a small amount of ventilation relative to blood flow. Similarly, most dead space units are not absolute, but rather are characterized by low blood flow relative to ventilation.

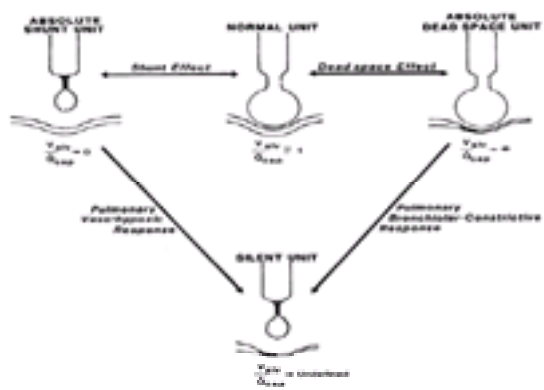

Figure 29-7. Continuum of ventilation–perfusion relationships. Gas exchange is maximally effective in normal lung units and only partially effective in shunt and dead space effect units. It is totally absent in silent units, absolute shunt, and deadspace units.

Hypoxic pulmonary vasoconstriction, stimulated by alveolar hypoxia, severely decreases blood flow. Thus, poorly ventilated alveoli also receive minuscule blood flow. Furthermore, decreased regional pulmonary blood flow results in bronchiolar constriction and diminishes the degree of dead space ventilation.^{83,84} When either of these phenomena occurs, the shunt or dead space units effectively become silent units in which little ventilation or perfusion occurs.

Many pulmonary diseases result in both physiologic shunt and dead space abnormalities. However, most disease processes can be characterized as producing either primarily shunt or dead space in their early stages. Increases in dead space ventilation primarily affect carbon dioxide elimination and have little influence on arterial oxygenation until dead space ventilation exceeds 80–90% of minute ventilation (\dot{V}_E). Similarly, physiologic shunt primarily affects arterial oxygenation with little effect on carbon dioxide elimination until the physiologic shunt fraction exceeds 75–80% of the cardiac output. Defective to absent gas exchange can be the net effect of either abnormality in the extreme.⁸⁵

Physiologic Dead Space

Each inspired breath is composed of gas that contributes to alveolar ventilation (V_A) and gas that becomes dead space ventilation (V_D). Thus, tidal volume (V_t) = V_A + V_D . In the normal, spontaneously breathing person, the ratio of alveolar to dead space ventilation for each breath is 2:1. Conveniently, the rule of “1, 2, 3” applies to normal, spontaneously breathing persons. For each breath, 1 ml · lb⁻¹ (lean body weight) becomes V_D , 2 ml · lb⁻¹ becomes V_A , and 3 ml · lb⁻¹ constitutes the V_t .

Physiologic dead space consists of anatomic and alveolar dead space. Anatomic dead space ventilation, approximately 2 ml · kg⁻¹ ideal body weight, accounts for the majority of physiologic dead space.⁸⁶ It arises from ventilation of structures that do not exchange respiratory gases: the oronasopharynx to the terminal and respiratory bronchioles. Clinical conditions that modify anatomic dead space include tracheal intubation, tracheostomy, and large lengths of ventilator tubing between the tracheal tube and the ventilator Y-piece.

Alveolar dead space ventilation arises from ventilation of alveoli where there is little or no perfusion. Because disease changes anatomic dead space little, physiologic dead space is primarily influenced by changes in alveolar dead space. Rapid changes in physiologic dead space ventilation most often arise from changes in pulmonary blood flow, resulting in decreased perfusion to ventilated alveoli. The most common etiology of acutely increased physiologic dead space is an abrupt decrease in cardiac output.⁸⁷ Another pathologic condition that interferes with pulmonary blood flow is pulmonary embolism, whether due to thrombus or to fat, air, or amniotic fluid.

Chronic pulmonary diseases create dead space ventilation by irreversibly changing the relationship between alveolar ventilation and blood flow; this alteration is especially prominent in patients with COPD. Furthermore, acute diseases such as adult respiratory distress syndrome can cause an increase in dead space ventilation owing to intense pulmonary vasoconstriction. Finally, therapeutic or supportive manipulations such as positive-pressure ventilation or positive airway pressure therapy can increase alveolar dead space because depressed venous return to the right heart will decrease cardiac output.⁸⁸ Intravenous fluid administration will usually overcome this problem.

Assessment of Physiologic Dead Space

Because the lung receives nearly 100% of the cardiac output, assessment of physiologic dead space ventilation in the acute setting yields valuable information about pulmonary blood flow and, ultimately, about cardiac output. If pulmonary blood flow decreases, the most likely cause is a decreased cardiac output. Thus, it is clinically useful to be able to readily assess the degree of physiologic dead space ventilation.

There are two easy and several difficult ways to assess dead space ventilation. A comparison of minute ventilation and P_{aCO_2} allows a gross qualitative assessment of physiologic dead space ventilation. The P_{aCO_2} is determined only by alveolar ventilation and \dot{V}_{CO_2} . If \dot{V}_{CO_2} remains constant, P_{aCO_2} also will remain constant as long as minute ventilation supplies the same degree of alveolar ventilation. If the spontaneously breathing individual must increase minute ventilation to maintain the same P_{aCO_2} he or she has experienced an increase in dead space ventilation because less of the minute ventilation is contributing to alveolar ventilation. Alternatively, a mechanically ventilated patient with a fixed minute ventilation and no increase in \dot{V}_{CO_2} also experiences an increased dead space ventilation if the P_{aCO_2} rises. Hence, when P_{aCO_2} in a mechanically ventilated patient increases, it is necessary to determine if the cause is increased dead space ventilation or an increased \dot{V}_{CO_2} .

The mechanically ventilated patient with normal lungs has a dead space to alveolar ventilation ratio (V_D/V_A) of 1:1 rather than 1:2, as during spontaneous ventilation. If mechanical V_t is 1000 ml, 500 ml contributes to V_A and 500 ml contributes to V_D . At rest, the required \dot{V}_A with normal \dot{V}_{CO_2} is approximately 60 ml · kg⁻¹ · min⁻¹. A

70-kg man would then require a \dot{V}_A of $4200 \text{ ml} \cdot \text{min}^{-1}$. During spontaneous breathing, the required \dot{V}_E would be $6300 \text{ ml} \cdot \text{min}^{-1}$, but during mechanical ventilation \dot{V}_E would have to be $8400 \text{ ml} \cdot \text{min}^{-1}$. Using this calculation, if a 70-kg resting patient requires \dot{V}_E much in excess of $8400 \text{ ml} \cdot \text{min}^{-1}$, either \dot{V}_D or \dot{V}_{CO_2} is increased. A rule of thumb for mechanically ventilated patients is that doubling baseline minute ventilation decreases PaCO_2 from 40 to 30 mm Hg, and quadrupling minute ventilation decreases PaCO_2 from 40 to 20 mm Hg.

The PaCO_2 will be greater than or equal to end-tidal PaCO_2 (PETCO_2) unless the patient inspires carbon dioxide. The difference between PETCO_2 and PaCO_2 is due to dead space ventilation. Measurement of this difference—which is simple, readily obtainable, and fairly inexpensive—yields reliable information relative to the degree of dead space ventilation. Clinical situations that change pulmonary blood flow sufficiently to increase dead space ventilation can be detected by comparing PETCO_2 with temperature-corrected PaCO_2 . Yamanaka and Sue⁸⁹ found that the PETCO_2 in ventilated patients varied linearly with the dead space to tidal volume ratio (VD/Vt), and that PETCO_2 correlated poorly with PaCO_2 . Thus, in the critically ill, mechanically ventilated patient and in anesthetized patients, monitoring PETCO_2 gives far more information about ventilatory efficiency or dead space ventilation than it does about the absolute value of PaCO_2 .

Anesthesiologists commonly measure PETCO_2 to detect venous air embolism during anesthesia. A lowered cardiac output alone, in the absence of venous air embolism, may sufficiently decrease pulmonary perfusion so that dead space ventilation increases and PETCO_2 falls. Thus, a depressed PETCO_2 is a sensitive but nonspecific monitor. Air in the pulmonary arteries mechanically interferes with blood flow and also causes pulmonary arterial constriction, further decreasing pulmonary blood flow. A decreased PETCO_2 suggests that a physiologically significant air embolism has occurred. The same physiologic considerations apply to detecting pulmonary thromboembolism.

Depressed cardiac output is the most common cause of acutely decreased pulmonary blood flow and increased physiologic dead space ventilation in the operating room and intensive care unit. Weil *et al*⁹⁰ observed a correlation between PETCO_2 and cardiac output during resuscitation in pigs when PaCO_2 was kept constant ($r = 0.79$). They concluded that the increase in $\text{P}\bar{\text{V}}\text{CO}_2$ and the concurrent decrease in PETCO_2 reflected a critical reduction in cardiac output, which diminished alveolar blood flow to the extent that carbon dioxide clearance by the lung failed to keep pace with systemic carbon dioxide production.

Some clinicians use the divergence of PETCO_2 from PaCO_2 as a reflection of pulmonary blood flow for other applications. During intentional pharmacologic or surgical manipulation of pulmonary blood flow, the difference between PaCO_2 and PETCO_2 serves as a useful physiologic monitor of the effectiveness of these interventions. Furthermore, regarding PETCO_2 as a reflection of pulmonary perfusion is a useful tool for studying and monitoring the effectiveness of closed-heart massage during resuscitation efforts. Murray and Modell⁹¹ suggested that an appropriate positive end-expiratory pressure (PEEP) level could be chosen based on the difference between PaCO_2 and PETCO_2 . However, extrapolating their canine findings to humans has been unsuccessful.

The most quantitative technique used to measure physiologic dead space utilizes a modification of the Bohr equation:

$$\frac{\text{V}_D}{\text{V}_t} = \frac{\text{PaCO}_2 - \text{P}\bar{\text{E}}\text{CO}_2}{\text{PaCO}_2} \quad (4)$$

where $\text{P}\bar{\text{E}}\text{CO}_2$ is the PCO_2 from the mixture of all expired gases over the period of time during which measurements are made. This calculation estimates the fraction of each breath that does not contribute to gas exchange. In spontaneously breathing patients, normal VD/Vt is between 0.2 and 0.4, or ~ 0.33 . In patients receiving positive-pressure ventilation, VD/Vt becomes ~ 0.5 . The major limitation of performing this calculation is the difficulty in collecting exhaled gas for $\text{P}\bar{\text{E}}\text{CO}_2$ measurement. Exhaled gases, collected in cumbersome 8-l bags, can easily be contaminated with inspired air or supplemental oxygen. The measurement also will be inaccurate if the patient does not maintain a steady ventilatory pattern. Therefore, extreme care must be taken to ensure that all measurements are performed accurately. In practice, this measurement is rarely performed.

Physiologic Shunt

Whereas physiologic dead space ventilation applies to areas of the lung that are ventilated but poorly perfused, physiologic shunt occurs in lung that is perfused but poorly ventilated. The physiologic shunt (\dot{Q}_{SP}) is that portion of the total cardiac output (\dot{Q}_{T}) that returns to the left heart and systemic circulation without receiving oxygen in the lung. When pulmonary blood is not exposed to alveoli or when those alveoli are devoid of ventilation, the result is *absolute shunt*, in which $\dot{V}_A/\dot{Q} = 0$. *Shunt effect*, or *venous admixture*, is the more common clinical phenomenon and occurs in areas where alveolar ventilation is deficient compared to the degree of perfusion: $0 < \dot{V}_A/\dot{Q} < 1$.

Because blood passing through areas of absolute shunt receives no oxygen, arterial hypoxemia resulting from absolute shunt is not reversed with supplemental oxygen. Alternatively, supplemental oxygen supplied to patients with arterial hypoxemia due to venous admixture will increase the PaO_2 . Although ventilation to these alveoli is deficient, they do carry a small amount of oxygen to the capillary bed.

A small percentage of venous blood normally bypasses the right ventricle and empties directly into the left atrium. This anatomic, absolute shunt arises from the venous return from the pleural, bronchiolar, and thebesian veins. This venous drainage accounts for 2–5% of total cardiac output and explains the small shunt that normally occurs. Anatomic shunts of greatest magnitude usually are associated with congenital heart disease that causes right-to-left shunt. Intrapulmonary anatomic shunts can also cause anatomic shunt. For example, the arterial hypoxemia associated with advanced hepatic failure is due to arteriovenous malformations.⁹² Diseases that may cause absolute shunt include acute lobar atelectasis, extensive acute lung injury, advanced pulmonary edema, and consolidated pneumonia. Disease entities that tend to produce venous admixture include mild pulmonary edema, postoperative atelectasis, and chronic obstructive pulmonary disease.

Assessment of Arterial Oxygenation and Physiologic Shunt

The simplest assessment of oxygenation is qualitative comparison of the patient's FIO_2 and PaO_2 . The highest possible PaO_2 for any given FIO_2 (and PaCO_2) can be calculated from the alveolar gas equation:

$$\text{PAO}_2 = \text{FIO}_2(\text{P}_B - \text{PH}_2\text{O}) - \frac{\text{PaCO}_2}{\text{R}} \quad (5)$$

where PAO_2 and PaCO_2 are alveolar PO_2 and PaCO_2 , PH_2O is water vapor pressure at 100% saturation and 37°C , and R is respiratory quotient. Assuming that one makes the calculation for a well-perfused alveolus, the alveolar and arterial PCO_2 are equal. Therefore, PaCO_2 can be substituted for PaCO_2 . Respiratory quotient (R) is the ratio of O_2 consumed (\dot{V}_{O_2}) to CO_2 produced (\dot{V}_{CO_2}):

$$\frac{\dot{V}_{\text{O}_2}}{\dot{V}_{\text{CO}_2}} = \frac{200 \text{ ml} \cdot \text{min}^{-1}}{250 \text{ ml} \cdot \text{min}^{-1}} = 0.8 \quad (6)$$

Oxygen tension–based indices do not reflect mixed venous contribution to arterial oxygenation and can be misleading.⁹³ Even if venous admixture is small, mixed venous blood with very low oxygen content will magnify the effect of a small shunt. Oxygen tension–based indices, for example, $\text{PaO}_2/\text{FIO}_2$, alveolar to arterial PO_2 difference (DA-aO_2), and ratio $\text{PaO}_2/\text{PaO}_2$, do not take into account the influence of $\text{C}\bar{\text{V}}\text{O}_2$ on the arterial oxygenation process. Therefore, in critically ill patients who are hypoxemic, the insertion of a pulmonary artery catheter to assess shunt and to measure cardiac output may be essential to understanding the influence of cardiac function on arterial oxygenation.

DA-aO_2 is a useful quantitative assessment of arterial oxygenation mainly when arterial hemoglobin is well saturated. When PaO_2 is below 150 mm Hg (and certainly when it is below 100 mm Hg), the relationship between oxygen content and oxygen tension is nonlinear. Normal DA-aO_2 is < 5 mm Hg when hemoglobin is well

saturated with oxygen.

The assessment of arterial oxygenation requires knowledge, at least, of FIO_2 and either PaO_2 or SaO_2 . Oxygen tension–based indices of oxygenation are useful, but they do not take into account the contribution of mixed venous blood to arterial oxygenation. Mixed venous blood can become extremely desaturated in the critically ill patient owing to inadequate cardiac output, anemia, arterial hypoxemia, or increased VO_2 . The best knowledge of the efficiency with which the lungs oxygenate the arterial blood can be obtained only by calculating shunt fraction or ventilation–perfusion ratio (VQI) (see below).

Physiologic Shunt Calculation

The clinical reference standard for the calculation of physiologic shunt fraction is derived from a two-compartment pulmonary blood flow model where one compartment performs ideal gas exchange and contains perfectly married alveolar–capillary units. The other compartment is the shunt compartment and contains pulmonary capillaries that enjoy no exposure to ventilated alveoli. Using the Fick relationship, the following equation can be derived:

$$\frac{\dot{Q}_{SP}}{\dot{Q}_T} = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - \bar{C}\bar{V}O_2} \quad (7)$$

where $Cc'O_2$ and $\bar{C}\bar{V}O_2$ are end-capillary and mixed-venous oxygen contents, respectively. Normal intrapulmonary shunt is approximately 5%. Because this equation is based on an artificial two-compartment model, the absolute value is physically meaningless. A calculated \dot{Q}_{SP}/\dot{Q}_T of 25% means that if the lung existed in two compartments, 25% of the cardiac output would travel through the shunt compartment. Because the lung does not exist in two compartments, this equation only grossly estimates pulmonary oxygen exchange defects. Nevertheless, it remains our best tool for clinically evaluating the efficiency with which the lungs oxygenate arterial blood. Observing shunt fraction change with therapeutic intervention or with the progress of disease is more valuable than knowing the absolute value *per se*.

Because hemoglobin concentration is uniform throughout the vascular system, the oxygen contents in the shunt equation are determined primarily by oxyhemoglobin saturation. Thus, the shunt equation can be approximated by substituting saturation values for each term; the new value, called *ventilation–perfusion ratio* (VQI),⁹³ is determined as follows:

$$VQI = \frac{Sc'O_2 - SaO_2}{Sc'O_2 - S\bar{V}O_2} \cong \frac{1 - SaO_2}{1 - S\bar{V}O_2} \quad (8)$$

If the patient is neither breathing a hypoxic gas mixture nor has a methemoglobin or carboxyhemoglobin value in excess of 5–6%, $Sc'O_2$ must equal 1 because the model requires a perfect alveolar–capillary interface. This substitution results in the final expression in the equation above. The absolute values of VQI are meaningless, although “normal” should be 0–4%. Like \dot{Q}_{SP}/\dot{Q}_T , the importance of these values lie in their trend as disease and treatment progress.

SaO_2 and $S\bar{V}O_2$ can be estimated continuously with pulse oximetry and by using a pulmonary artery catheter with oximetry capability. By interfacing the outputs of these two devices with a computer, VQI can be calculated continuously. The greatest advantage of calculating \dot{Q}_{SP}/\dot{Q}_T or VQI to assess arterial oxygenation is that these values include the contribution of mixed venous blood.

PULMONARY FUNCTION TESTING

Anesthesiologists frequently care for patients with significant pulmonary dysfunction. It is important for the anesthesiologist to be able to interpret tests of pulmonary function intelligently and to know which tests will help to define dysfunction if the patient's history and physical are suggestive of disease. This section discusses lung volumes, tests of pulmonary mechanics, and diffusing capacity.

Lung Volumes and Capacities

Known, reproducible pulmonary gas volumes and capacities provide a reliable basis for comparison between normal and abnormal measurements.⁹⁴ Because normal measurements vary with size, height is most frequently used to define “normal.” Lung capacities are composed of two or more lung volumes. Lung volumes and capacities are schematically illustrated in [Figure 29-8](#).

Figure 29-8. Lung volumes and capacities. The darkest bar on the far right depicts the four basic lung volumes that sum to create TLC. Other lung capacities are composed of two or more lung volumes. The overlying spirometric tracing orients the reader to the relationship between the lung volumes and capacities and the spirogram. ERV = expiratory reserve volume; FRC = functional residual capacity; IC = inspiratory capacity; IRV = inspiratory reserve volume; RV = residual volume; VT = tidal volume; TLC = total lung capacity; VC = vital capacity. ERV = expiratory reserve volume; FRC = functional residual capacity; IC = inspiratory capacity; IRV = inspiratory reserve volume; RV = residual volume; VT = tidal volume; TLC = total lung capacity; VC = vital capacity.

Tidal volume is the volume of gas that moves in and out of the lungs during quiet breathing and is $\sim 6\text{--}8 \text{ ml} \cdot \text{kg}^{-1}$. Tidal volume falls with decreased lung compliance or when the patient has reduced ventilatory muscle strength.

Vital capacity is usually $\sim 60 \text{ ml} \cdot \text{kg}^{-1}$, but may vary as much as 20% from normal in healthy individuals. Vital capacity correlates well with the capability for deep breathing and effective coughing. It usually is decreased by restrictive pulmonary disease such as pulmonary edema or atelectasis. Vital capacity also may be reduced by the mechanically induced restriction that occurs with problems such as pleural effusion, pneumothorax, pregnancy, large ascites, or ventilatory muscle weakness.

The *inspiratory capacity* is the largest volume of gas that can be inspired from the resting expiratory level and frequently is decreased in the presence of significant extrathoracic airway obstruction. This measurement is one of the few simple tests that can detect extrathoracic airway obstruction. Most routine pulmonary function tests measure only exhaled flows and volumes, which may be relatively unaffected by extrathoracic obstruction until it is severe. Changes in the absolute volume of

inspiratory capacity usually parallel changes in vital capacity. *Expiratory reserve volume* is not of great diagnostic value.

Functional residual capacity (FRC) is the volume of gas remaining in the lungs at passive end-expiration. *Residual volume* is that gas remaining within the lungs at the end of forced maximal expiration. The FRC serves two primary physiologic functions. It determines the point on the pulmonary volume–pressure curve for resting ventilation (see Fig. 29-2). The tangent defined by the midportion pulmonary volume–pressure curve at FRC defines lung compliance. Thus, FRC determines the elastic pressure–volume relationships within the lung. Furthermore, FRC is the resting expiratory volume of the lung. As such, it greatly influences ventilation–perfusion relationships within the lung. When FRC is reduced, venous admixture (low $\dot{V}A/Q$) increases and results in arterial hypoxemia (see sections [Oxygen and Carbon Dioxide Transport](#) and [Lung Mechanics](#).)

The FRC also may be used to quantify the degree of pulmonary restriction. Disease processes that reduce FRC and lung compliance include acute lung injury, pulmonary edema, pulmonary fibrotic processes, and atelectasis. Mechanical factors also reduce FRC, for example, pregnancy, obesity, pleural effusion, and posture. The FRC decreases 10% when a healthy subject lies down. Ventilatory muscle weakness or paralysis also will decrease FRC. In contrast, patients with chronic obstructive pulmonary disease have excessively compliant lungs that recoil less forcibly. Their lungs retain an abnormally large volume at the end of passive expiration, a phenomenon called *gas trapping*.

FRC Measurement

The FRC and residual volume must be measured indirectly because residual volume cannot be removed from the lung. The multiple-breath nitrogen washout test is performed by having the subject breathe 100% oxygen for several minutes so that alveolar nitrogen is gradually “washed out.” With each breath, the volume of gas and the concentration of nitrogen in the exhaled gas are measured. A rapid nitrogen analyzer coupled to a spirometer or pneumotachometer provides a breath-by-breath analysis of nitrogen washout. Electronic signals proportional to nitrogen concentrations and exhaled volumes (or flow, if a pneumotachometer is used) are integrated to derive the exhaled volume of nitrogen for each breath. Then, the values for all breaths are summed to provide a total volume of nitrogen washed out of the lungs. The test proceeds until the alveolar nitrogen concentration is reduced to less than 7%, usually requiring 7–10 minutes. FRC is calculated using the equation:

$$\text{FRC} = \text{N}_2 \text{ volume} \times \frac{[\text{N}_2]_f}{[\text{N}_2]_i} \quad (9)$$

where $[\text{N}_2]_i$ and $[\text{N}_2]_f$ are the fractional concentrations of alveolar nitrogen at the beginning and end of the test, respectively.

Pulmonary Function Tests

Forced Vital Capacity (FVC)

The FVC is the volume of gas that can be expired as forcefully and rapidly as possible after maximal inspiration. Normally, FVC is equal to vital capacity. Because forced expiration significantly increases intrapleural pressures but changes airway pressure little, bronchiolar collapse, obstructive lesions, and gas trapping are exaggerated. Thus, FVC may be reduced in chronic obstructive diseases even when the vital capacity appears near normal. FVC is nearly always decreased by restrictive diseases. FVC values $<15 \text{ ml} \cdot \text{kg}^{-1}$ are associated with an increased incidence of postoperative pulmonary complications, probably because these patients cough ineffectively.⁹⁵ FVC reduced to this level represents a profound defect, most commonly seen in quadriplegics or severe neuromuscular disease. Finally, FVC is largely dependent on patient effort and cooperation.

Forced Expiratory Volume (FEV)

FEV_T is the volume of gas expired over a given time interval during the FVC maneuver. The interval, described by the subscript T, is the time elapsed in seconds from the onset of expiration. Because FEV_T records a volume of gas expired over time, it is actually a measure of flow. By measuring expiratory flow at specific intervals, the severity of airway obstruction can be ascertained. Decreased FEV_T values are common in both obstructive and restrictive disease patterns. The most important application of FEV_T is its comparison with the patient's FVC. Normal subjects can expire at least three quarters of FVC within the first second of the forced expiratory maneuver. The FEV_1 , the most frequently employed value, is normally greater than or equal to 75% of the FVC, or $\text{FEV}_1/\text{FVC} \geq 0.75$.

Normally, an individual can expire 50–60% of FVC in 0.5 sec, 75–85% in 1 sec, 94% in 2 sec, and 97% in 3 sec. Cooperative patients with obstructive disease will exhibit a reduced FEV_1/FVC in most cases. However, patients with restrictive disease usually have normal FEV_1/FVC ratios. The validity of the evaluation of the FEV_1/FVC is highly dependent on patient cooperation and effort. It is possible to deliberately produce an artificially low FEV_1/FVC .

Forced Expiratory Flow (FEF)

$\text{FEF}_{25-75\%}$ is the average flow during the middle half of the FEV maneuver. This test is also called maximum midexpiratory flow rate (MMFR). The length of time required for a subject to expire the middle half of the FVC is divided into 50% of the FVC. The spirogram in [Figure 29-9](#) marks the place from 25% to 75% of FVC, constituting the middle 50% of FVC. The straight line connecting the 25% and 75% volumes has a slope approximately equal to average flow. A normal value for a healthy 70-kg man is approximately $4.7 \text{ l} \cdot \text{sec}^{-1}$ (or $280 \text{ ml} \cdot \text{min}^{-1}$). Normally, both the absolute value and the percentage of predicted value for the individual being studied are recorded. A normal value is $100 \pm 25\%$ of predicted. Decreased flow rates indicate medium-sized airway obstruction. This value is typically normal in restrictive diseases. This test is fairly sensitive in the early stages of obstructive airway disease. Decreased $\text{FEV}_{25-75\%}$ frequently will be observed before other obstructive manifestations occur. Although somewhat effort-dependent, the test is much more reliable and reproducible than FEV_1/FVC .

Figure 29-9. $\text{FEF}_{25-75\%}$. The spirogram depicts a 4 l FVC on which the points representing 25% and 75% FVC are marked. The slope of the line connecting these points is the $\text{FEF}_{25-75\%}$.

Maximum Voluntary Ventilation

Maximum voluntary ventilation (MVV) is the largest volume of gas that can be breathed in 1 minute by voluntary effort. The MVV is measured by having the subject breathe as deeply and as rapidly as possible for 10, 12, or 15 seconds. The results are extrapolated to 1 minute. The subject is instructed to set his or her own ventilatory rate and move more than tidal volume but less than vital capacity in each breath.

MVV measures the endurance of the ventilatory muscles and indirectly reflects lung–thorax compliance and airway resistance. MVV is the best ventilatory endurance test that can be performed in the laboratory. Values that vary by as much as 30% from predicted values may be normal, so that only large reductions in MVV are significant. Healthy, young adults average $\sim 170 \text{ l} \cdot \text{min}^{-1}$. Values are lower in women and decrease with age in both sexes. Because this maneuver exaggerates air trapping and exerts the ventilatory muscles, MVV is decreased greatly in patients with moderate to severe obstructive disease. MVV is usually normal in patients with

restrictive disease.

Flow–Volume Loops

The flow–volume loop graphically demonstrates the flow generated during a forced expiratory maneuver followed by a forced inspiratory maneuver, plotted against the volume of gas expired (Fig. 29-10). The subject forcefully exhales completely, then immediately and forcefully inhales to vital capacity. The expired and inspired volumes are plotted on the abscissa and flow is plotted on the ordinate. Although a variety of numbers can be generated from the flow–volume loop, the configuration of the loop itself is probably the most informative part of the test.

Figure 29-10. Flow–volume loops. Curve A is a normally configured adult flow–volume loop. The slope of the loop after the subject reaches peak expiratory flow is nearly linear. Obstructive pulmonary disease, caused by increased air resistance in the bronchial tree, results in curve B, with markedly decreased peak expiratory flow and a “scooped-out” appearance for the remainder of expiration. Residual volume is larger and vital capacity is smaller than normal. Curve C results from upper airway (extrathoracic) airway obstruction. A flattened expiratory curve with decreased peak expiratory flow is pathognomonic of upper airway obstruction. Curve D is found in restrictive lung disease that results in a miniature flow–volume loop with normal peak expiratory flows and a normally shaped curve. However, residual volume, total lung capacity, and vital capacity are all proportionally reduced.

Significant decreases in flow or volume are evident in a single graphical display. Obstructive diseases are accompanied by decreased flows and restrictive processes by decreased volumes. The shape of the expiratory curve is largely independent of patient effort, with flow determined mainly by the elastic recoil properties of the lungs (from 75% of TLC down to residual volume). Normally, the flow decreases linearly with volume over most of the vital capacity range, so that the expiratory curve is linear (Fig. 29-10A). In those with obstructive lung disease, flow decreases particularly at lower lung volumes, and the flow–volume loop takes on a scooped-out appearance (Fig. 29-10B). Obstruction of the upper airway and trachea is accompanied by characteristic limitations to expiratory and inspiratory flow that result in a flat, ovoid loop. Thus, the flow–volume loop is useful in the diagnosis of large airway and extrathoracic airway obstruction (Fig. 29-10C).

Restrictive disease usually results in relatively normal peak expiratory flows and a linear decrease in flow, but the lung volume itself is decreased (Fig. 29-10D). Moderate to severe restriction results in equal flows at all lung volumes and appears as a miniature flow–volume loop.

Carbon Monoxide Diffusing Capacity

Because PO_2 collectively measures all the factors that affect the diffusion of gas across the alveolar–capillary membrane. The DLCO is recorded in $\text{mL CO} \cdot \text{min}^{-1} \cdot \text{mm Hg}^{-1}$ at STPD.

In persons with normal hemoglobin concentrations and normal \dot{V}_A/\dot{Q} matching, the main factor limiting diffusion is the alveolar–capillary membrane. Small amounts of carbon dioxide and inspired gas can produce measurable changes in the concentration of inspired gas compared to expired gas. There are several methods for determining DLCO, but all methods measure diffusing capacity according to the equation

$$\text{DLCO} = \frac{\text{ml CO transferred} \cdot \text{min}^{-1}}{\text{mean } P_{\text{ACO}_2} - \text{mean capillary } P_{\text{CO}_2}} \quad (10)$$

The average value for resting subjects when the single-breath method is used is $25 \text{ mL CO} \cdot \text{min}^{-1} \cdot \text{mm Hg}^{-1}$. DLCO values can increase to two or three times normal during exercise.

The DLO_2 may be estimated from the DLCO by multiplying DLCO by 1.23, although the DLCO is usually the reported value. DLCO can be divided by the lung volume at which the measurement was made to obtain an expression of diffusing capacity per unit lung volume.

Some of the other factors that can influence DLCO are as follows:

1. hemoglobin concentration: decreased hemoglobin concentration decreases the DLCO;
2. alveolar PCO_2 : an increased $PaCO_2$ raises DLCO;
3. body position: the supine position increases DLCO;
4. pulmonary capillary blood volume.

Diffusing capacity is decreased in alveolar fibrosis associated with sarcoidosis, asbestosis, berylliosis, oxygen toxicity, and pulmonary edema. These states are frequently categorized as diffusion defects, but low DLCO is probably more closely related to loss of lung volume or capillary bed perfusion. DLCO is decreased in obstructive disease because of the decreased alveolar surface area, loss of capillary bed, the increased distance from the terminal bronchiole to the alveolar–capillary membrane, and \dot{V}_A/\dot{Q} mismatching. Space-occupying lesions and lung resection also decrease diffusing capacity. In short, the decrease in measured DLCO actually is caused by abnormal \dot{V}_A/\dot{Q} matching in most cases. Very few disease states truly inhibit oxygen diffusion across the alveolar–capillary membrane.

Pulmonary Function Tests Summary

Although we have a host of pulmonary function tests from which to choose, spirometry is the most useful, cost-effective, and commonly used test.⁹⁷ Screening spirometry yields VC, FVC, and FEV_1 . From these values, two basic types of pulmonary dysfunction can be identified and quantitated: obstructive defects and restrictive defects. The primary criterion for airflow obstruction is decreased FEV_1/FVC ratio. Other measurements, such as $FEF_{25-75\%}$, can be used to support the diagnosis of an obstructive defect, or assist in making decisions (e.g., whether to institute bronchodilation). A restrictive defect is a proportional decrease in all lung volumes; thus, VC, FVC, and FEV_1 all are reduced, but FEV_1/FVC remains normal. When there is a question about whether a decreased VC is due to restriction, TLC should be measured. Reduced TLC defines a restrictive defect, but is not necessary to perform unless VC on screening spirometry is reduced. The American Thoracic Society published an experts' consensus concerning interpretations of lung function tests.⁹⁸ Table 29-5 summarizes the distinction between pulmonary function results obtained from those with restrictive and obstructive defects.

| Value | Restrictive Disease | Obstructive Disease |
|-----------------------|---|---|
| Definition | Proportional decrease in all lung volumes | Small airway obstruction to expiratory flow |
| FVC | ↓↓↓ | Normal or slightly ↓ |
| FEV ₁ | ↓↓↓ | Normal or slightly ↓ |
| FEV ₁ /FVC | Normal | ↓↓↓ |
| FEV ₂₅₋₇₅ | Normal | ↓↓↓ |
| FRC | ↓↓↓ | Normal or ↑ if gas trapping |
| TLC | ↓↓↓ | Normal or ↑ if gas trapping |

↓↓↓, ↓↓↓ = large decrease or increase, respectively; ↓, ↑ = small/moderate decrease or increase, respectively.

Table 29-5. PULMONARY FUNCTION TESTS IN RESTRICTIVE AND OBSTRUCTIVE LUNG DISEASE

ANESTHESIA AND OBSTRUCTIVE PULMONARY DISEASE

Patients with marked obstructive pulmonary disease are at increased risk for both intraoperative and postoperative pulmonary complications. For example, patients with reduced FEV₁/FVC or reduced midexpiratory flow not only suffer airway obstruction but usually exhibit increased airway reactivity. Because of the hazard of provoking reflex bronchoconstriction during laryngoscopy and tracheal intubation, patients with COPD or asthma should receive aggressive bronchodilator therapy preoperatively. High alveolar concentrations of potent inhalational anesthetics will blunt airway reflexes and reflex bronchoconstriction⁹⁹ but require a fairly robust cardiovascular system. Adjunctive iv administration of opioids and lidocaine prior to airway instrumentation will decrease airway reactivity. Furthermore, a single dose of corticosteroids may help to prevent postoperative increases in airway resistance.

Spontaneous ventilation during general anesthesia in patients with severe obstructive disease is more likely to result in hypercarbia than in patients with normal pulmonary function.¹⁰⁰ Preoperative FEV₁ reduction is related to the PaCO₂ increase. Therefore, controlled mechanical ventilation with ventilatory rates <10 breaths · min⁻¹ should prevent hypercarbia, minimize V̇A/Q mismatch, and allow time for exhalation. Low ventilatory rates necessitate larger tidal volumes, which may predispose the patient to pulmonary barotrauma because of high peak airway pressures. Tidal volume and inspiratory flows should be adjusted to keep peak airway pressure below 40 cm H₂O^{101,102} if possible. Higher inspiratory flows produce a shorter inspiratory time and, fusually, a high peak airway pressure. Thus, a balance that avoids high peak airway pressure yet allows the longest possible expiratory time should be sought.

Ideally, depending on the procedure and the duration of anesthesia, one would extubate the patient's trachea at the end of the operation. The irritating tracheal tube increases both airway resistance and reflex bronchoconstriction, limits the ability of the patient to clear secretions effectively, and increases the risk of iatrogenic infection. For some patients with obstructive disease (for example, the young asthmatic), many advocate tracheal extubation during deep anesthesia at the conclusion of the operation.

ANESTHESIA AND RESTRICTIVE PULMONARY DISEASE

Restrictive disease is characterized by proportional decreases in all lung volumes. The decreased FRC produces low lung compliance, and also results in arterial hypoxemia because of low V̇A/Q mismatching. These patients typically breathe rapidly and shallowly.

Positive-pressure ventilation of patients with restrictive disease is fraught with high peak airway pressures because more pressure is required to expand stiff lungs. Lower mechanical tidal volumes at more rapid rates reduce the risk of barotrauma but augment ventilation-induced cardiovascular depression and increase the chances of developing atelectasis. Larger tidal volumes and lower rates result in less cardiovascular compromise, but the higher peak airway pressure increases the risk of barotrauma.¹⁰³ A variety of ventilatory schemes have been developed to ventilate patients with profound restrictive lung disease (see Chapter 56). The use of PEEP will increase FRC and reverse arterial hypoxemia and will not, by itself, cause barotrauma.¹⁰⁴ During controlled mechanical ventilation, the cardiovascular effects of PEEP can be profound, although most cardiovascular changes can be reversed by allowing spontaneous ventilation or by iv fluid administration. Inotropes or pressors are rarely required when cardiovascular function is depressed as a consequence of increased mean airway pressure.

Because the FRC is small, a lower oxygen store is available during apneic periods. Even preoxygenation with an FIO₂ of 1.0 can result in arterial hypoxemia seconds after the cessation of breathing. Patients with severe restrictive diseases tolerate apnea poorly. Because arterial hypoxemia develops so rapidly, transportation of these patients within the hospital should be performed with a pulse oximeter.

FRC decreases 10–15% when healthy, spontaneously breathing individuals lie supine. Controlled ventilation further reduces FRC only slightly.¹⁰⁵ General anesthesia consistently decreases FRC by a further 5–10%,¹⁰⁶ which usually results in decreased lung compliance.¹⁰⁷ The FRC reaches its nadir within the first 10 minutes of anesthesia^{108,109,109} and is independent of whether ventilation is spontaneous or controlled. The diminished FRC persists in the postoperative period¹¹⁰ but may be restored postoperatively by the use of PEEP or CPAP.^{106,111,112} However, once positive airway pressure is removed, FRC plummets to previously diminished levels, which reach a new postoperative nadir 12 hours after operation.¹¹³

EFFECTS OF CIGARETTE SMOKING ON PULMONARY FUNCTION

Smoking affects pulmonary function in many ways. The irritant smoke decreases ciliary motility and increases sputum production. Thus, these patients have a high volume of sputum and decreased ability to clear it effectively. As smoking habits persist, airway reactivity and the development of obstructive disease become problematic. Studies of the pathogenesis of COPD suggest that smoking results in an excess of pulmonary proteolytic enzymes which directly cause damage to the lung parenchyma.¹¹⁴ Exposure to smoke increases synthesis and release of elastolytic enzymes from alveolar macrophages—cells instrumental in the genesis of COPD due to smoking.^{115,116} Further damage to the lung tissue is probably caused by reactive metabolites of oxygen, such as hydroxyl radicals and hydrogen peroxide, which are usually used by the macrophages to kill microorganisms. The immunoregulatory function of the macrophages is also changed by cigarette smoking, with changes occurring in the presentation of antigens and interaction with T lymphocytes.¹¹⁷ Other direct effects on lung tissue caused by smoking include increased epithelial permeability¹¹⁸ and changed pulmonary surfactant.¹¹⁹ The airway irritation or small airway reactivity evoked by inhaling cigarette smoke is the result of activation of sensory endings located in the central airways, which is primarily caused by nicotine.¹²⁰

Early in the disease, mild V̇A/Q mismatch, bronchitic disease, and airway hyper-reactivity are primary problems. Later, these problems are accompanied by gas trapping, flattened diaphragmatic configuration (which decreases the efficiency with which the diaphragm functions), and barrel chest deformity. Lung compliance increases significantly, so that limited elastic recoil prevents complete passive emptying. As a result, many patients exhale forcibly to reduce gas trapping.

Smoking also affects gas exchange. With gas trapping, ventilation and perfusion become increasingly mismatched. Large areas of dead space ventilation and venous admixture occur. Carbon dioxide elimination is inefficient because of dead space ventilation. The typical minute ventilation for patients with advanced obstructive lung disease can be 1.5–2 times normal. In addition, venous admixture produces arterial hypoxemia that is exquisitely sensitive to low concentrations of supplemental oxygen. Gas exchange is further impaired by the increased carboxyhemoglobin concentration that results from inspiring smoke. Normal carboxyhemoglobin concentration in nonsmokers is approximately 1%; in smokers, however, it can be as high as 8–10%. Cessation of smoking, even for 12–24 hours preoperatively, can decrease CO concentration to near normal. Although normalization of mucociliary function requires 2–3 weeks of abstinence from smoking, several months of smoking abstinence is required to return sputum clearance to normal.¹²¹ Smokers are at increased risk for developing head and neck cancers, which may influence airway management.

Smoking is one of the main and most prevalent risk factors associated with postoperative morbidity.¹²² COPD patients who smoke have a two-¹²³ to sixfold¹²⁴ risk of developing postoperative pneumonia compared to nonsmokers.^{125,126} Further, smokers' relative risk of PPC is doubled, even if they do not have evidence of clinical pulmonary disease or abnormal pulmonary function.¹²⁷ The incidence of PPC in smokers can be reduced by abstinence from smoking, although there is no consensus on the minimal or optimal duration of preoperative abstinence.^{128,129} and ¹³⁰ Smokers who decrease, but do not stop, cigarette consumption without the aid of nicotine replacement therapy, continue to acquire equal amounts of nicotine from fewer cigarettes by changing their technique of smoking to maximize nicotine intake.¹³¹ Levels of serum nicotine and cotinine and urinary mutagenesis levels remain unchanged. Thus, “cold turkey” reduction in the number of cigarettes smoked has much less effect than expected on all aspects of pulmonary function, including PPCs. Use of properly dosed nicotine supplements and antidepressants (e.g., sustained-released

bupropion [Zyban®]) can safely achieve abstinence in as many as 40–50% of subjects during the medication administration. These patients may be converted from “partial quitters,” who are at high risk for PPC,¹²⁴ to “former smokers,” whose risk is reduced after 4 weeks.¹³² Smoking patients should be advised to stop smoking 2 months prior to elective operations to maximize the effect of smoking cessation,¹³⁰ or for at least 4 weeks to gain some benefit from improved mucociliary function, and some reduction in PPC rate. If patients cannot stop smoking for these periods of time, they should be advised to stop smoking for at least 24 hours prior to the operation so that carboxyhemoglobin levels will approach normal.

PULMONARY FUNCTION POSTOPERATIVELY

Risk of Postoperative Pulmonary Complications

Preoperative Pulmonary Assessment

Markedly impaired pulmonary function is likely in patients who have the following:

1. Any chronic disease that involves the lung
2. Smoking history, persistent cough, and/or wheezing
3. Chest wall and spinal deformities
4. Morbid obesity
5. Requirement for single lung anesthesia or lung resection
6. Severe neuromuscular disease

Preoperative pulmonary evaluation must include history and physical examination, and may include chest radiograph, arterial blood gas analysis, and screening spirometry, depending on the patient's history. A history of sputum production, wheezing or dyspnea, exercise intolerance, or limited daily activities may yield more practical information than does formal testing. Arterial blood analysis, which should be sampled while the patient breathes room air, adds information regarding gas exchange and acid–base balance. Arterial blood gas sampling is primarily useful if the patient's history suggests that s/he may be chronically hypoxemic or may “retain” CO₂—*i.e.*, a patient with a chronic, compensated arterial acidemia.

Preoperative assessment of pulmonary function may alert the anesthesiologist to the special needs of a patient with respiratory disease and may allow improvement of pulmonary function before an elective operation. There are published data¹³³ and published opinions^{134,135} concerning guidelines that select patients who should undergo pulmonary function testing preoperatively and whether the tests have any predictive value.¹³⁶ The goals one might *hope* to achieve through preoperative pulmonary function would be to predict the likelihood of pulmonary complications, to obtain quantitative baseline information concerning pulmonary function, and to identify patients who may benefit from therapy to improve pulmonary function preoperatively. For patients who will have lung resections, pulmonary function testing does provide some predictive benefit.¹³⁷ For all other patients, however, overwhelming evidence suggests that preoperative pulmonary function testing does *not* predict or assign risk for PPCs.^{138,139}

The need to obtain baseline pulmonary function data should be reserved for those patients with severely impaired preoperative pulmonary function, such as quadriplegics or myasthenics, so that assessment for weaning from mechanical ventilation and/or tracheal extubation might be based on the patient's baseline pulmonary function. Ideally, tests should be chosen to quantify specific pulmonary problems.

Postoperative Pulmonary Function

The changes in pulmonary function that occur postoperatively are primarily restrictive, with proportional decreases in all lung volumes and no change in airway resistance. The decrease in FRC, however, is the yardstick by which the severity of the restrictive defect is gauged. This defect is generated by abdominal contents that impinge on and prevent normal movement of the diaphragm, and by an abnormal respiratory pattern devoid of sighs and characterized by shallow, rapid respirations. The normal resting respiratory rate for adults is 12 breaths per minute, whereas the postoperative patient in the ward usually breathes approximately 20 breaths per minute. Furthermore, most (but not all) of the factors that tend to make the restrictive defect worse are also those factors associated with a higher risk of postoperative pulmonary complications.

The operative site is the single most important determinant of both the degree of pulmonary restriction and the risk of postoperative pulmonary complications.¹³⁸ Nonlaparoscopic upper abdominal operations cause the most profound restrictive defect, precipitating a 40–50% decrease in FRC compared to preoperative levels, when conventional postoperative analgesia is employed. Lower abdominal and thoracic operations cause the next most severe change in pulmonary function, with decreases in FRC to 30% of preoperative levels. Most other operative sites—intracranial, peripheral vascular, otolaryngologic—have approximately the same effect on FRC, with reductions to 15–20% of preoperative levels.¹⁴⁰

Postoperative Pulmonary Complications

Two problems confound interpretation of the literature examining postoperative pulmonary complications. First, there is no clear definition of what constitutes a postoperative pulmonary complication. For example, some series include only pneumonia, while others add atelectasis and/or ventilatory failure. Thus, to interpret data concerning rates of postoperative pulmonary complications, it is important to discern what complications are specifically being addressed. Second, the criteria by which to make the diagnosis of postoperative pneumonia or atelectasis vary from study to study. For the purposes of this discussion, postoperative pulmonary complications include atelectasis and pneumonia only. Reasonable, well-accepted diagnostic criteria for these diagnoses include: change in the color and quantity of sputum, oral temperature exceeding 38.5°C, and a new infiltrate on chest X-ray.

The operative site is the single most important determinant of both the degree of pulmonary restriction and postoperative pulmonary complications.¹³⁸ Nonlaparoscopic upper abdominal operations increase risk for PPC at least twofold,¹³⁸ with rates of occurrence varying from 20–70%.¹⁴¹ Lower abdominal and intrathoracic operations are associated with slightly less risk, but still higher risk than extremity, intracranial, and head/neck operations.

Other patients at risk for PPC are those with COPD. These patients' risk can be minimized by ensuring that they do not have an active pulmonary infection and that any increased resistance associated with reactive airways disease is minimized by the use of therapeutic bronchodilation. Interestingly, those with asthma are not at increased risk for atelectasis or pneumonia. However, exacerbation of asthma in the postoperative period can be problematic. Careful attention must be given to assuring bronchodilating regimens and steroid administration in the perioperative period.

There are several strategies by which it is possible to reduce risk of PPC: the use of lung-expanding therapies postoperatively, choice of analgesia,¹⁴² and cessation of smoking. After upper abdominal operations, which are associated with the highest incidence of postoperative pulmonary complications, FRC recovers over 3–7 days. With the use of intermittent CPAP by mask, FRC will recover within 72 hours.¹⁴³ Patients use incentive spirometers correctly only 10% of the time unless therapy is supervised.¹⁴⁴ Stir-up regimens are as effective as incentive spirometry at preventing postoperative pulmonary complications,¹⁴³ and they are less expensive than supervised incentive spirometry; thus, they are preferred over incentive spirometry therapy.

After median sternotomy for cardiac operations, FRC does not return to normal for several weeks, regardless of postoperative pulmonary therapy.¹⁴⁵ The persistently low FRC in this population probably is due to mechanical factors such as a widened mediastinum, intrapleural fluid, and altered chest wall compliance. The single most important aspect of postoperative pulmonary care is getting the patient out of bed, preferably walking.

The choice of anesthetic technique for intraoperative anesthesia does not change the risk for PPC independent of the operative site. However, choice of postoperative analgesia strongly influences the risk of PPC.¹³⁸ The advent of postoperative epidural analgesia, particularly for abdominal and thoracic operations, has markedly decreased the risk of PPC and appears to contribute to decreased length of stay in the hospital postoperatively.

Although obesity is associated with marked restrictive defects, some studies demonstrate that obesity does not independently increase the risk of PPC while others do demonstrate increased independent risk for PPCs in the obese population.¹⁴⁶ Similarly, there are data both to support¹⁴⁶ and refute advanced age as an independent risk factor for PPCs.

Several authors have attempted to assess the influence of overall health on PPC risk. The use of indices that weight and score various aspects of physiology and health shows that all are associated with increased risk of PPC.¹³⁹ That is, patients who are in a poor state of health preoperatively tend to be at higher risk of PPC.

Patients with obstructive airway disease and decreased expiratory flows may benefit from preoperative bronchodilator therapy and formal pulmonary toilet.¹⁴⁷ High-risk

patients with COPD who receive bronchodilation, chest physical therapy, deep breathing, forced oral fluids (>3 l · day⁻¹), and preoperative instruction in postoperative respiratory techniques, and those who stop smoking experience postoperative pulmonary complications at a rate approximately equal to that observed in normal patients.^{148,149} and ¹⁵⁰ Interestingly, although a regimen of this nature significantly reduces the incidence of postoperative pulmonary complications,¹⁵¹ airway obstruction and arterial hypoxemia are not measurably reversed during the 48–72 hours of preoperative therapy.¹⁵² It is possible that the reduced complication rate results from the additional attention that these patients receive rather than from the specific regimen employed.

[Chapter References](#)

The number of noncardiac thoracic surgical operations has dramatically increased in recent years and is expected to increase further in the future. A report using data from the National Center for Health Statistics in the United States showed that in 1979, approximately 53,000 procedures on the lung and bronchus were performed; this number had grown to 73,000 by 1983.¹ Mediastinoscopies increased from 33,000 in 1979 to 44,000 in 1983. Most recently, there has been an increase in the number of video-assisted thoracoscopic procedures. The increase in this type of surgery has been associated with and sometimes has been made possible by advances in anesthesia care. Indeed, thoracic anesthesia is developing into a subspecialty in its own right, with reference texts devoted exclusively to this subject.^{2,3}

The physiologic, pharmacologic, and clinical considerations for the patient undergoing pulmonary surgery are reviewed, followed by sections on anesthesia for diagnostic and therapeutic procedures, high-frequency ventilation, and special situations, including bronchopleural fistula (BPF) and tracheal reconstruction. A discussion of myasthenia gravis is included because of the relationship between the thymus gland and myasthenia and because thymectomy is one of the most commonly performed surgical procedures in these patients. The chapter concludes with a review of the postoperative management of the thoracic surgical patient.

PREOPERATIVE EVALUATION

In addition to the routine assessment for major surgery, the preoperative evaluation of the patient for thoracic surgery should focus on the extent and severity of pulmonary disease and of cardiovascular involvement.

History

Dyspnea. Dyspnea occurs when the requirement for ventilation is greater than the patient's ability to respond appropriately. Dyspnea is quantitated as to the degree of physical activity required to produce it, the level of activity possible (*e.g.*, ability to walk on level ground or climb stairs), and management of daily activities. Severe exertional dyspnea usually implies a significantly diminished ventilatory reserve and a forced expiratory volume in 1 second (FEV₁) of less than 1500 ml, with possible need for postoperative ventilatory support.

Cough. Recurrent productive cough for 3 months of the year for 2 consecutive years is necessary to make the diagnosis of chronic bronchitis. Cough indirectly increases airway irritability. If the cough is productive, the volume, consistency, and color of the sputum should be assessed. Sputum should be cultured to rule out infection and to establish whether there is a need for preoperative antibiotic therapy. Blood-stained sputum or episodes of gross hemoptysis should alert the anesthesiologist to the possibility of a tumor invading the respiratory tract (*e.g.*, the mainstem bronchus), which might interfere with endobronchial intubation.

Cigarette Smoking. Cigarette smoking increases the risk of chronic lung disease and malignancy as well as the incidence of postoperative pulmonary complications. The number of pack-years (packs smoked per day multiplied by the number of years) is directly related to measurable changes in respiratory gas flow and closing capacity, making these patients prone to postoperative atelectasis and arterial hypoxemia.

Physical Examination

The physical examination of the patient should address in particular the following aspects.

Respiratory Pattern

The presence of cyanosis and clubbing, the breathing pattern, and the type of breath sounds should be noted.

Cyanosis. The presence of peripheral cyanosis (in the fingers, toes, or ears) should be distinguished from causes of poor circulation (acrocyanosis). The presence of central cyanosis (in the buccal mucosa) is usually secondary to arterial hypoxemia. If cyanosis is present, the arterial saturation is 80% or less ($P_{aO_2} < 50\text{--}52$ mm Hg), which indicates a limited margin of respiratory reserve.

Clubbing. Clubbing is often seen in patients with chronic lung disease, malignancies, or congenital heart disease associated with right-to-left shunt.

Respiratory Rate and Pattern. A patient's inability to complete a normal sentence without pausing for breath is an indication of severe dyspnea. Inspiratory paradox, the abdomen moving in while the chest moves out, suggests diaphragmatic fatigue and respiratory dysfunction. The patient should be assessed for paroxysmal retraction (Hoover's sign), limited diaphragmatic movement because of hyperinflation, asymmetry of chest movement secondary to phrenic nerve involvement, hemothorax, pleural effusion, and pneumothorax. The pattern and rate of breathing have important roles in distinguishing between obstructive and restrictive lung disease. For a constant minute ventilation, the work done against air flow resistance decreases when breathing is slow and deep. Work done against elastic resistance decreases when breathing is rapid and shallow (e.g., as in pulmonary infarct or pulmonary fibrosis).

Breath Sounds. Wet sounds (crackles) are usually caused by excessive fluid in the airways and indicate sputum retention or edema. Dry sounds (wheezes) are produced by high-velocity gas flow through bronchi and are a sign of airway obstruction. Distant sounds are an indication of emphysema and possibly bullae. The trachea should be in the midline. Displacement of the trachea may be secondary to a number of causes, including mediastinal mass, and should alert the anesthesiologist to a potentially difficult intubation of the trachea or airway obstruction on induction of anesthesia.

Evaluation of the Cardiovascular System

One of the most important factors in the evaluation of a patient scheduled for thoracic surgery is the presence of an increase in pulmonary vascular resistance secondary to a fixed reduction in the cross-sectional area of the pulmonary vascular bed. The pulmonary circulation is a low-pressure, high-compliance system capable of handling an increase in blood flow by recruitment of normally underperfused vessels. This acts as a compensatory mechanism, which normally prevents an increase in pulmonary arterial pressure. In chronic obstructive pulmonary disease (COPD), there is distention of the pulmonary capillary bed with reduced ability to tolerate an increase in blood flow (reduced compliance). Such patients demonstrate an increase in pulmonary vascular resistance when cardiac output increases because of a reduced ability to compensate for an increase in pulmonary blood flow. This results in pulmonary hypertension, signs of which include a narrowly split second heart sound, increased intensity of the pulmonary component of the second heart sound, and right ventricular and atrial hypertrophy.

An increase in pulmonary vascular resistance is of significance in the management of the patient during anesthesia because several factors, such as acidosis, sepsis, hypoxia, and application of positive end-expiratory pressure (PEEP), all further increase the pulmonary vascular resistance and increase the likelihood of right ventricular failure.

In patients with ischemic or valvular heart disease, the function of the left side of the heart should also be carefully evaluated. This is discussed elsewhere in this volume (see [Chapter 32](#)).

Electrocardiogram

A patient with COPD may present with electrocardiographic features of right atrial and ventricular hypertrophy and strain. These include a low-voltage QRS complex due to lung hyperinflation and poor R-wave progression across the precordial leads. An enlarged P wave ("P pulmonale") in standard lead II is diagnostic of right atrial hypertrophy. The electrocardiographic changes of right ventricular hypertrophy are an R/S ratio of greater than 1.0 in lead V_1 (i.e., R-wave voltage exceeds S-wave voltage).

Chest Radiography

Hyperinflation and increased vascular markings are usually present with COPD. Prominent lung markings often occur in bronchitis, whereas they are decreased in emphysema, particularly at the bases, where actual bullae may be present in severe cases. Hyperinflation, with an increased anteroposterior chest diameter, may be present, together with an enlarged retrosternal air space of greater than 2 cm in diameter seen in a lateral chest radiograph.

The location of the lung lesion should be assessed by postero-anterior and lateral projections on chest radiography. In addition to tracheal or carinal shift, a mediastinal mass may indicate a difficult intubation, a difficult and bloody dissection, difficulty in using a double-lumen tube (because of deviation of the mainstem bronchus), or a collapsed lobe owing to bronchial obstruction with possible sepsis. Review of a computed tomographic study is also useful and often provides more information about tumor size and location than the chest radiograph.

Arterial Blood Gases

A common finding in arterial blood gas analysis of patients with COPD is hypoventilation and CO_2 retention. The "blue bloaters" (chronic bronchitics) are cyanotic, hypercarbic, hypoxemic, and usually overweight. They are in a state of chronic respiratory failure and have a reduced ventilatory response to CO_2 . In these patients, the high P_{aCO_2} increases cerebrospinal fluid bicarbonate concentration, the medullary chemoreceptors become reset to a higher level of CO_2 , and sensitivity to CO_2 is decreased. Such patients hypoventilate when given high oxygen concentrations because of a decreased hypoxic drive.

The "pink puffers" (patients with emphysema) typically are thin, dyspneic, and pink, with essentially normal blood gas values. They present with an increase in minute ventilation to maintain their normal P_{aCO_2} , which explains the increase in work of breathing and dyspnea.

Pulmonary Function Testing and Evaluation for Lung Resectability

There are three goals in performing pulmonary function tests in patients scheduled for lung resection. The first is to identify those patients at risk of increased postoperative morbidity and mortality. In thoracic surgery for lung cancer, the specific question is: How much lung tissue may be safely removed without making the patient a pulmonary cripple? This should be weighed against the 1-year mean survival rate of the patient with surgically untreated lung carcinoma. The second goal is to identify those patients who will need short- or long-term postoperative ventilatory support. The third goal is to evaluate the beneficial effect and reversibility of airway obstruction with the use of bronchodilators.

Effects of Anesthesia and Surgery on Lung Volumes

Anesthesia and postoperative medications can cause changes in lung volumes and ventilatory pattern (see [Chapter 29](#)). Total lung capacity (TLC) decreases after abdominal surgery but not after surgery on an extremity. Vital capacity is decreased by 25–50% within 1–2 days after surgery and generally returns to normal after 1–2 weeks. Residual volume (RV) increases by 13%, whereas expiratory reserve volume decreases by 25% after lower abdominal surgery and 60% after upper abdominal and thoracic surgery. Tidal volume (V_T) decreases by 20% within 24 hours after surgery and gradually returns to normal after 2 weeks. Pulmonary compliance decreases by 33% with similar reductions in functional residual capacity (FRC) secondary to small airway closure. Most of the patients who undergo lung resection are smokers with a certain degree of COPD and are prone to postoperative complications in direct relation to the amount of lung to be resected (lobectomy or pneumonectomy) and to the severity of the preoperative lung disease.

Spirometry

Forced vital capacity (FVC), forced expired volume in one second (FEV_1), and peak expiratory flow can be measured at the patient's bedside using a spirometer. The measurement can be recorded as a volume–time trace or as a flow–volume loop.

A vital capacity of at least three times the VT is necessary for an effective cough. A vital capacity of less than 50% of predicted or less than 21 is an indicator of increased risk.⁴ An abnormal preoperative vital capacity can be identified in 30–40% of postoperative deaths. A patient with an abnormal vital capacity has a 33% chance of complications and a 10% risk of postoperative mortality.

FEV_1 is a more direct indication of airway obstruction. An FEV_1 of less than 800 ml in a 70-kg male is probably incompatible with life and is an absolute contraindication to lung resection. Mortality in patients with an FEV_1 greater than 21 is 10%, and in patients below 11 is between 20% and 45%.⁵

The ratio FEV_1/FVC is useful in differentiating between restrictive and obstructive disease. It is normal in restrictive disease because both decrease, whereas in obstructive disease the ratio usually is low because the FEV_1 is markedly decreased.

Maximum voluntary ventilation is a nonspecific test and is an indicator of both restriction and obstruction. Although maximum voluntary ventilation has not been systematically evaluated as a predictor of morbidity, it is generally accepted that a maximum voluntary ventilation below 50% of predicted value is an indication of high risk.

A ratio of RV to TLC (RV/TLC) of greater than 50% is generally indicative of a high-risk patient for pulmonary resection. Mittman⁶ found that an RV/TLC ratio of greater than 40% was associated with a 30% mortality rate, compared with a 7% mortality when RV/TLC was less than 40% (normal range 20–25%).

Flow–Volume Loops

The flow–volume loop displays essentially the same information as a spirometer but is more convenient for measurement of specific flow rates (Fig. 30-1). The shape and peak air flow rates during expiration at high lung volumes are effort dependent but indicate the patency of the larger airways. Effort-independent expiration occurs at low lung volumes and usually reflects small airways resistance, best measured by forced expiratory flow during the middle half of the FVC ($FEF_{25-75\%}$).

Figure 30-1. Flow–volume loop in a normal subject. \dot{V}_{75} , \dot{V}_{50} , and \dot{V}_{25} represent flow at 75, 50, and 25% of vital capacity, respectively. (RV = residual volume). (Reproduced with permission from Goudsouzian N, Karamanian A: *Physiology for the Anesthesiologist*, 2nd ed. Norwalk, Appleton-Century-Crofts, 1984.)

In general, patients with obstructive airways disease (Fig. 30-2), such as asthma, bronchitis, and emphysema, have grossly reduced FEV_1/FVC ratios because of increased airways resistance and a reduction in FEV_1 . Peak expiratory flow rate and maximum voluntary ventilation are usually reduced, whereas total lung capacity increases secondary to increases in RV. In these patients, the effort-independent portion of the flow–volume curve is markedly depressed inward, with reduction of the flow rate at 25–75% of FVC.

Figure 30-2. Flow–volume loops relative to lung volumes (1) in a normal subject, (2) in a patient with chronic obstructive pulmonary disease (COPD), (3) in a patient with fixed obstruction (tracheal stenosis), and (4) in a patient with pulmonary fibrosis (restrictive defect). Note the concave expiratory form in the patient with COPD and the flat inspiratory curve in the patient with a fixed obstruction. (Reproduced with permission from Goudsouzian N, Karamanian A: *Physiology for the Anesthesiologist*, 2nd ed. Norwalk, Appleton-Century-Crofts, 1984.)

In patients with restrictive disease (see Fig. 30-2), such as pulmonary fibrosis and scoliosis, there is a reduction in FVC with a relatively normal FEV_1 . Because the airways resistance is normal, FEV_1/FVC is also normal. TLC is markedly reduced, whereas maximum voluntary ventilation and $FEF_{25-75\%}$ are usually normal. The flow–volume curves of these patients are normal in shape, but the lung volumes and peak flow rates are lower (see Fig. 30-2).

Significance of Bronchodilator Therapy. Pulmonary function tests are usually performed before and after bronchodilator therapy to assess the reversibility of the airways obstruction. This is useful in the assessment of the degree of airways obstruction and the patient's effort ability. After treatment with bronchodilators, increases in peak expiratory flow compared with a baseline indicate reversibility of airways obstruction (often seen in asthmatic patients). A 15% improvement in pulmonary function tests may be considered a positive response to bronchodilator therapy and indicates that this therapy should be initiated before surgery. The overall prognosis of COPD is better related to the level of spirometric function after bronchodilator therapy than to a baseline function.

Split-Lung Function Tests

Regional lung function studies serve to predict the function of the lung tissue that would remain after lung resection. A whole (two)-lung test may fail to estimate whether the amount of postresection lung tissue will allow the patient to function at a reasonable level of activity without disabling dyspnea or cor pulmonale.

Regional Perfusion Test. This involves the intravenous injection of insoluble radioactive xenon (^{133}Xe). The peak radioactivity of each lung is proportional to the degree of perfusion of each lung.

Regional Ventilation Test. Using an inhaled, insoluble radioactive gas, the peak radioactivity over each lung is proportional to the degree of ventilation. Combining radiospirometry with whole lung testing (FEV_1 , FVC, maximal breathing capacity) has resulted in a fair degree of correlation between predicted volumes and pulmonary

function tests measured after pneumonectomy. It is generally held that a FEV₁ of 800 ml is the minimum accepted volume for postresection survival.

Regional Bronchial Balloon Occlusion Test. This test basically simulates the postresection condition preoperatively by using balloon occlusion of the bronchus to the segment of the lung to be resected. Spirometry and arterial blood gas analysis are then performed with the remaining functional lung.

Pulmonary Artery Balloon Occlusion Test

The postoperative stress on the right ventricle and remaining pulmonary vascular bed can be simulated by occluding the pulmonary artery of the lung to be resected using a specially designed balloon-tipped pulmonary artery (PA) catheter that has a pressure-sensing port just proximal to the balloon. This test may be performed with or without exercise. If, on balloon occlusion of the pulmonary artery of the lung to be resected, the mean pulmonary artery pressure increases above 40 mm Hg, PaO₂ is less than 60 mm Hg, or PaCO₂ is greater than 45 mm Hg, it is unlikely that the patient will be able to tolerate pneumonectomy without experiencing postoperative respiratory failure or cor pulmonale.

The preoperative pulmonary evaluation of patients considered for lung resection is summarized as follows. First, a whole-lung test with spirometry and arterial blood gases should be done. If any of the following values—PaCO₂ > 40 mm Hg, FEV₁ < 50%, FVC < 21, maximal breathing capacity < 50%, or RV/TLC > 50%—is found to be outside these limits, a second level of split-lung function testing should be done to estimate the exact contribution of the resected portion of the lung to either ventilation or perfusion. Conventional spirometry should yield a predicted postresection FEV₁ greater than 800 ml. If these criteria cannot be met, surgery is usually contraindicated. A postoperative simulation of ventilation or perfusion by bronchial or pulmonary artery occlusion can produce additional information, and risk–benefit ratio must be considered for each individual patient. The preoperative evaluation of the patient for lung resection is summarized in [Figure 30-3](#).

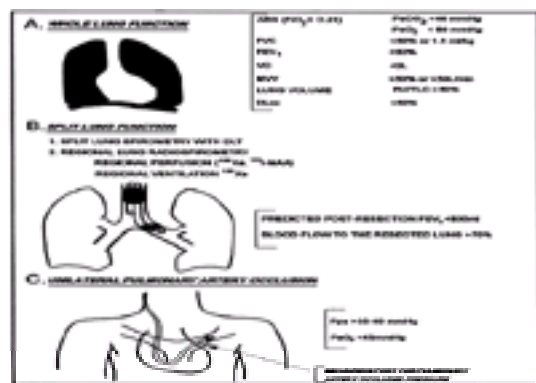

Figure 30-3. The order of tests to determine the cardiopulmonary status of the patient and the extent of lung resection that would be tolerated. (A) The whole-lung function test is a basic screening test. (B) The split-lung function tests are regional tests to determine the involvement of the diseased lung to be removed. (C) Tests that mimic the postoperative cardiopulmonary function are the decisive tests to determine if the patient will be able to tolerate the planned resection. (Adapted with permission from Neustein SM, Cohen E: Preoperative evaluation of thoracic surgical patients. In Cohen E [ed]: *The Practice of Thoracic Anesthesia*, p 187. Philadelphia, JB Lippincott, 1995.)

PREOPERATIVE PREPARATION

The wide spectrum of physiologic changes occurring during thoracic surgery puts patients at great risk of developing postoperative complications. Morbidity and mortality increase when these changes are superimposed on an acutely or chronically compromised patient. Several conditions, including infection, dehydration, electrolyte imbalance, wheezing, obesity, cigarette smoking, cor pulmonale, and malnutrition, show particular correlations with postoperative complications. Proper, vigorous preoperative preparation can improve the patient's ability to face the surgery with a reduced risk of morbidity and mortality. It is important that conditions predisposing to postoperative complications be effectively treated before surgery.

Smoking

Approximately 33% of adult patients presenting for surgery are smokers, and there is extensive evidence that they are at increased risk for development of postoperative respiratory complications.⁷ Smoking increases airway irritability, decreases mucociliary transport, and increases secretions. Smoking also decreases FVC and FEF_{25–75%}, thereby increasing the incidence of postoperative pulmonary complications. On the other hand, cessation of smoking for a period of longer than 4–6 weeks before surgery is associated with a decreased incidence of postoperative complications.⁸ Furthermore, cessation of smoking for 48 hours before surgery has been shown to decrease the level of carboxyhemoglobin, to shift the oxyhemoglobin dissociation curve to the right, and to increase tissue oxygen availability. It should be emphasized that most of the beneficial effects of cessation of smoking, however, such as improvement in ciliary function, improvement in closing volume, increase in FEF_{25–75%}, and reduction in sputum production, usually occur 2–3 months after the cessation of smoking.

Infection

Acute or chronic infection should be vigorously treated before surgery. Broad-spectrum antibiotics are commonly used. Treatment of the acutely ill patient depends on the results of the Gram stain of the sputum and on blood culture findings. In one prospective study, the incidence of mortality was lower (9%) in the group treated with prophylactic antibiotics compared with the untreated patients (17%), and a lower incidence of postoperative pulmonary infection was shown as well.⁹ Although not all surgeons administer antibiotics prophylactically to their patients, infection, when present before surgery, should be vigorously treated.

Hydration and Removal of Bronchial Secretions

Correction of hypovolemia and electrolyte imbalance should be accomplished before surgery because hydrating the patient decreases the viscosity of the bronchial secretions and facilitates their removal from the bronchial tree. Humidification is extremely useful. The use of mucolytic drugs, such as acetylcysteine (Mucomyst), or of oral expectorants (potassium iodide) can be of benefit to patients with viscous secretions. Commonly used methods for removing the secretions from the bronchial tree include postural drainage, vigorous coughing, chest percussion, deep breathing, and the use of an incentive spirometer. These often require patient cooperation and frequent verbal encouragement to maximize the beneficial effect.

Wheezing and Bronchodilation

The presence of acute wheezing represents a medical emergency, and elective surgery should be postponed until effective proper treatment has been instituted. Chronic wheezing is often seen in patients with COPD and is attributable to the presence of gas flow obstruction secondary to smooth muscle contraction, accumulation of secretions, and mucosal edema. Smooth muscle contraction may occur in small airways only (detectable by changes in FEF_{25–75%}) or may be widespread, with a large reduction of FEV₁ and FVC. The efficacy of bronchodilators in reversing the bronchospastic component is extremely important. A trial of bronchodilators and measurement of their effects on pulmonary function should be performed in any patient who shows evidence of air flow obstruction. Several classes of bronchodilators are available.

Sympathomimetic Drugs. Sympathomimetic drugs increase the formation of 3'5'-cyclic adenosine monophosphate (cAMP). The balance between cAMP, which produces bronchodilation, and cyclic guanosine monophosphate, which produces bronchoconstriction, determines the state of contraction of the bronchial smooth muscle. Thus, increasing cAMP production causes relaxation of the bronchial tree. Sympathomimetic drugs, such as epinephrine, isoproterenol, isoetharine, and ephedrine, all have mixed b₁ and b₂ sympathetic agonist effects. The b₁ (cardiac effects) of these drugs are often undesirable in treating patients with COPD. Selective b₂ sympathomimetic drugs, such as albuterol, terbutaline, and metaproterenol, given as inhaled aerosols, are the preferred drugs in the treatment of bronchospasm, particularly in patients with cardiac disease.

Phosphodiesterase Inhibitors. Phosphodiesterase inhibitors inhibit the breakdown of cAMP by cytoplasmic phosphodiesterase. The methylxanthines, such as aminophylline, increase the level of cAMP, resulting in bronchodilation. In addition, aminophylline improves diaphragmatic contractility and increases the patient's

resistance to fatigue. Therapeutic blood levels of aminophylline are 5–20 $\mu\text{g} \cdot \text{mL}^{-1}$ and can be achieved by giving a loading dose of 5–7 $\text{mg} \cdot \text{kg}^{-1}$ infused over 20 minutes, followed by a continuous intravenous (iv) infusion of 0.5–0.7 $\text{mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$. Aminophylline may cause ventricular arrhythmias, and this side-effect should be borne in mind when treating patients who have myocardial ischemia.

Steroids. Although they are not true bronchodilators, steroids are traditionally considered to decrease mucosal edema and may prevent the release of bronchoconstricting substances. They are of questionable benefit in acute bronchospasm. Steroids may be given orally, parenterally, or in aerosol form, such as beclomethasone by inhaler.

Cromolyn Sodium. Cromolyn sodium stabilizes mast cells and inhibits degranulation and histamine release. It is useful in the prevention of bronchospastic attacks but is of little value in the treatment of the acute situation.

Parasympatholytics. Parasympatholytics include atropine and ipratropium. In the past, atropine has been avoided in patients with COPD and bronchitis because of the concern regarding increases in the viscosity of mucus produced by this agent. However, atropine blocks the formation of cyclic guanosine monophosphate and therefore has a bronchodilator effect. Marini *et al*¹⁰ found that inhaled atropine alone improved FEV₁ in 85% of patients with COPD. When atropine was given together with terbutaline, the FEV₁ improved in 93% of patients, whereas terbutaline alone improved FEV₁ in only 56% of patients. Therefore, the antimuscarinic drugs such as atropine potentiate the bronchodilator effect of the sympathomimetic agents.

In conclusion, the preoperative preparation of the patient for thoracic surgery should focus on those conditions that are treatable before surgery so that the patient is in optimal condition at the time of surgery.

INTRAOPERATIVE MONITORING

All patients undergoing thoracic surgical procedures require monitoring with an electrocardiogram (lead II and, if possible, V₅), chest or esophageal stethoscopes for heart and breath sound auscultation, and a temperature probe. A chest stethoscope should be placed over the dependent hemithorax to assess dependent lung ventilation. Pulse oximetry is a standard of care during the administration of anesthesia and is especially valuable during thoracic surgery because hypoxemia may occur during one-lung ventilation.

Dysrhythmias occur commonly both during and after thoracic surgery, making the usual need for continuous electrocardiographic monitoring even more important. Intraoperative supraventricular tachyarrhythmias may be caused by cardiac manipulation. Dysrhythmias occurring during one-lung ventilation may be a sign of inadequate oxygenation or ventilation. Postoperative dysrhythmias may be related to sympathetic nervous system stimulation from pain or to a reduced pulmonary vascular bed from the lung resection. Patients presenting for lung resection often have COPD owing to cigarette smoking, have right-sided heart strain, and are prone to multifocal atrial tachydysrhythmias.

The axis of electrocardiogram lead II parallels that of the P wave, making this lead useful for arrhythmia detection. The simultaneous monitoring of lead V₅ also allows for monitoring of anterolateral wall myocardial ischemia. The use of multiple leads facilitates a greater sensitivity of ischemia detection.¹¹ The following types of invasive monitoring are also indicated and have led to markedly improved patient care.

Direct Arterial Catheterization

Peripheral arterial catheterization has become an essential tool for the anesthesiologist in the management of patients undergoing major thoracic surgical procedures. It allows for continuous beat-to-beat measurement of blood pressure as well as frequent sampling for the determination of arterial blood gases. The risk, when utilizing a 20-gauge Teflon catheter in the radial artery, is extremely low, and any risk can be further decreased by ensuring patency of the ulnar artery. This can be done by the use of a modified Allen test, digital plethysmography, or Doppler ultrasonography. Although the modified Allen test is a commonly performed technique, its usefulness has been challenged. Permanent ischemic complications have been reported in patients with normal Allen test results, and catheterization in patients with abnormal Allen test findings has not resulted in ischemic sequelae. The incidence of ischemic complications after radial artery catheterization has been reported to be 0.01%.

Continuous blood pressure readings are critical during thoracic surgery because surgical manipulations or intravascular volume shifts can cause sudden major changes in the blood pressure. Immediate recognition of the change allows time for proper identification of the etiology and the institution of appropriate treatment.

Serial blood gas determinations are performed as needed in the management of patients undergoing one-lung anesthesia or during cases in which part of the lung may be “packed away” for a period. Arterial hypoxemia may occur because of shunting through the collapsed lung and inadequate hypoxic pulmonary vasoconstriction (HPV). Significant changes in acid–base status as well as hyperventilation or hypoventilation can also be determined.

A radial artery catheter can be placed in either extremity during thoracic surgery. For a mediastinoscopic examination, it is useful to place the catheter in the right arm and to use it to monitor for compression of the innominate artery by the mediastinoscope.¹² This can help to avoid central nervous system complications resulting from inadequate cerebral blood flow through the right carotid artery (see the section on [Mediastinoscopy](#)). During thoracotomy, the radial artery catheter is often placed in the dependent arm to aid in stabilizing the catheter. However, a roll must be placed under the patient to protect the axilla and avoid compression of the axillary artery and brachial plexus in this arm. In rare cases, the arterial catheter can be placed in the brachial, femoral, or dorsalis pedis artery if the ulnar collateral circulation is thought to be inadequate.

Central Venous Pressure Monitoring

Central venous pressure (CVP) is usually measured as an indication of right atrial and right ventricular pressures. It is a useful monitor if the factors affecting it are realized and its limitations are understood. The CVP reflects the patient's blood volume, venous tone, and right ventricular performance; however, it is also affected by central venous obstructions and alterations of intrathoracic pressure (e.g., PEEP). Serial measurements are more useful than an individual number, and the response of the CVP to a volume infusion is a useful test of right ventricular function. The CVP reflects right-sided heart function and not left ventricular performance. The combination of the CVP as a monitor of right atrial pressure and the esophageal stethoscope to “monitor” left atrial pressure (e.g., rales, S₃) is still a useful technique in patients with good left ventricular function. A CVP catheter is often used in patients with good left ventricular function during thoracic surgical procedures for either monitoring or infusion/insertion applications. CVP monitoring is needed when there may be large volume shifts (e.g., pneumonectomy) or the patient is hypovolemic. Uses of CVP catheter or large-bore introducer include: (1) insertion of a transvenous pacemaker where necessary; (2) infusion of vasoactive drugs; and (3) insertion of a PA catheter, which may subsequently be required during surgery or in the postoperative period.

The CVP catheter can be placed centrally from either the external or the internal jugular vein, from the subclavian veins, or from one of the arm veins. The success rate is highest using the right internal jugular vein, and a pacemaker or PA catheter can be inserted most easily from this vein. The major disadvantage of using the external jugular vein during thoracotomy is that the catheter often kinks when the patient is turned to the lateral decubitus position. The subclavian technique leads to a high incidence of pneumothorax, which can be disastrous if it occurs in the dependent lung during one-lung ventilation.

Pulmonary Artery Catheterization

The use of the PA catheter allows measurements of left-sided filling pressures, the determination of cardiac output by thermodilution, calculation of derived hemodynamic and respiratory parameters (e.g., systemic vascular resistance and intrapulmonary shunt, respectively), and clinical use of Starling function curves. In addition, advanced versions of the basic catheter allow measurement of mixed venous oxygen saturation or right ventricular ejection fraction as well as the application of atrial or ventricular pacing. The PA catheter is indicated during thoracic surgery in specific situations ([Table 30-1](#)).

1. Patients with known cardiovascular disease, with or without heart failure
2. Surgery in which cross-clamping of the thoracic aorta is anticipated
3. Patients with respiratory failure
4. Patients with suspected or diagnosed pulmonary emboli
5. Patients who have undergone previous cardiac surgery
6. When a pneumonectomy is anticipated
7. When significant shifts of intravascular volume are anticipated
8. When sepsis is present
9. Patients who receive continuous infusions of inotropes or vasodilators
10. Patients with pulmonary hypertension or elevated pulmonary vascular resistance
11. When cor pulmonale is present
12. Patients treated with bleomycin

Table 30-1. INDICATIONS FOR PULMONARY ARTERY CATHETERIZATION IN THORACIC SURGERY

In the past, CVP catheters were used to monitor patients with left-sided heart disease or pulmonary disease; however, the CVP has been shown to have a poor correlation with the left atrial pressure in these types of patient. Many studies have shown the disparity between left- and right-sided pressures owing to the many factors separating the CVP reading from the true left ventricular preload.

The PA catheter is most reliably inserted through the right internal jugular vein using a modified Seldinger technique. Insertion of the PA catheter through either the external jugular vein or the subclavian vein often leads to obstruction of the catheter when the patient is placed in the lateral decubitus position. Complications of PA catheter insertion and use can be divided into immediate and long term. Immediate complications include the development of supraventricular and ventricular dysrhythmias during insertion, onset of a right bundle-branch block or complete heart block in patients with a pre-existing left bundle-branch block, and all the potential complications of inserting a needle into a central vein (e.g., arterial puncture, hematoma formation, pneumothorax, nerve damage, Horner's syndrome, air embolization, or thoracic duct injury). The incidence of dysrhythmias is decreased by changing the position of the patient from Trendelenburg to a head-up right lateral tilt position before flotation of the PA catheter. Long-term complications of use of the PA catheter include balloon rupture and gas embolization, pulmonary infarction, pulmonary artery rupture, knotting of the catheter in the right ventricle, infection, vascular obstruction, and erroneous diagnosis from misinterpretation of data.¹³

Pulmonary artery rupture is the most serious complication associated with the use of the PA catheter. Risk factors for this complication include hypothermia, pulmonary hypertension, anticoagulation, and being elderly or female. Pulmonary artery perforation most commonly manifests as hemoptysis.

Management of pulmonary artery rupture and massive airway hemorrhage includes protecting the nonbleeding lung by placement of a double-lumen endotracheal tube. This allows suctioning and application of continuous positive airway pressure (CPAP) to the bleeding lung, which is not possible if the single-lumen tube is merely advanced into the bronchus of the nonbleeding lung. If a single-lumen tube is already in place, another alternative is the placement of a bronchial blocker alongside the tracheal tube after the site of bleeding has been identified. The bleeding most often comes from the right side because the PA catheter usually floats to the right side. Bronchoscopy may allow identification of the bleeding site. Other treatment modalities include the use of PEEP, inflation of the PA catheter balloon to tamponade the bleeding, and the administration of protamine, if possible, if the patient has been anticoagulated with heparin. Fluid resuscitation is essential, and if the bleeding continues, surgical exploration and lung resection may be necessary.

Misinterpretation of data from a PA catheter is a real risk in a patient with cardiac and pulmonary disease undergoing thoracic surgery with one-lung ventilation. These errors can be produced by altered ventilatory modes, the location of the PA catheter tip, ventricular compliance changes, or ventricular interdependence.¹³ A major limitation of the PA catheter is the assumption that the pulmonary capillary wedge pressure is a good approximation of left ventricular end-diastolic volume. The use of pulmonary capillary wedge pressure directly to assess preload assumes a linear relationship between ventricular end-diastolic volume and ventricular end-diastolic pressure. However, alterations in ventricular compliance affect this pressure-volume relationship during surgery. Reductions in ventricular compliance can be seen with myocardial ischemia, shock, right ventricular overload, or pericardial effusion. Numerous investigators have demonstrated a poor correlation between pulmonary capillary wedge pressure and left ventricular end-diastolic volume in acutely ill patients.¹⁴ This correlation is further worsened by the application of PEEP. Therefore, whenever pulmonary capillary wedge pressure is used to estimate left ventricular preload, the number must be interpreted in light of the clinical situation. The interdependence of the right and left ventricles must also be remembered when interpreting pulmonary capillary wedge pressure. Ventricular interdependence can cause misdiagnosis when the interventricular septum encroaches on the left ventricular cavity, leading to increased values of pulmonary capillary wedge pressure. An increased pulmonary capillary wedge pressure associated with a decreased cardiac output can be interpreted as left ventricular failure, when, in fact, left ventricular end-diastolic volume may not be increased but decreased because of compression of the left ventricle by a distended right ventricle (Fig. 30-4). This situation can occur with acute respiratory failure and high levels of PEEP. Techniques such as echocardiography, which directly measure ventricular dimensions, are necessary to resolve this complex situation.

Figure 30-4. Comparison of left ventricular failure and ventricular inter-dependence. (PCWP = pulmonary capillary wedge pressure; LVEDV = left ventricle end-diastolic volume.) (Reproduced with permission from Keefer JR, Barash PG: Pulmonary artery catheterization. In Blitt CD [ed]: Monitoring in Anesthesia and Critical Care Medicine, p 213. New York, Churchill Livingstone, 1985.)

Because most of the pulmonary blood flow is to the right lower lobe, the tip of a flow-directed PA catheter is usually located in the right lower lobe. During a left thoracotomy with one-lung ventilation, the catheter tip would then be in the dependent lung and should provide accurate hemodynamic measurements. However, during a right thoracotomy with one-lung ventilation, the catheter tip should be in the nondependent lung. Cohen *et al*¹⁵ reported that during right thoracotomies with the tip of the PA catheter in a West zone 1 or 2 region of the right lung, hemodynamic measurements may be inaccurate. These authors found that cardiac output measurements were lower during right thoracotomies than left thoracotomies, and the derived parameters of stroke volume index and oxygen delivery were also inappropriately low. Therefore, hemodynamic data derived from a PA catheter in the nondependent collapsed lung must be carefully evaluated.

Assessment of right ventricular function is made difficult by the complex geometry and shape of the right ventricle. The thermodilution technique used to measure cardiac output with the PA catheter can also be used to determine right ventricular ejection fraction if a fast-response thermistor is used. There are numerous situations during thoracic surgery when decreased right ventricular function precludes adequate right-sided heart output to a normal left ventricle. Because the right ventricle is very sensitive to increases in afterload, right ventricular function can be evaluated by comparing right ventricular ejection fraction with a measure of right ventricular afterload, such as pulmonary vascular resistance. Right ventricular function curves may be even more useful than left ventricular function curves in patients with chronic pulmonary disease undergoing thoracic surgical procedures.

The multipurpose PA catheter, with five pacing electrodes, is now widely available. This catheter can be used for atrial, ventricular, or atrioventricular sequential pacing in patients who require a PA catheter for hemodynamic monitoring. Another design of PA catheter incorporates a channel through which a pacing wire may be inserted (Paceport Catheter). Indications for a pacing PA catheter are (1) intermittent third-degree heart block, (2) second-degree heart block, (3) left bundle-branch block, (4) digitalis toxicity, and (5) severe bradycardia.

A PA catheter capable of monitoring $\bar{S}\bar{V}_{O_2}$ is also available. Four mechanisms can account for a decreased $\bar{S}\bar{V}_{O_2}$: (1) decreased Sa_{O_2} , (2) decreased cardiac output, (3) increased oxygen consumption, and (4) decreased hemoglobin concentration. $\bar{S}\bar{V}_{O_2}$ represents a measure of global tissue oxygen extraction and consumption and

is in general directly related to cardiac output *via* the Fick formula. The monitoring of $\overline{S\dot{V}}_{O_2}$ has been evaluated in patients undergoing one-lung anesthesia.¹⁶ Changes in $\overline{S\dot{V}}_{O_2}$ were mainly dependent on changes in SaO_2 .

Transesophageal Echocardiography

Transesophageal echocardiography is a useful intraoperative monitor for ventricular function, valvular function, and wall motion changes that might reflect ischemia. Its use in thoracic surgical patients has been limited. In one study, central lung tumors were seen with transesophageal echocardiography in nine of nine patients, peripheral lung tumors in one of three patients, and an anterior mediastinal mass in one of one patient.¹⁷ In this study, transesophageal echocardiography revealed pulmonary artery compression in five patients and pulmonary artery infiltration in two patients.

In another study investigating echocardiographic recognition of mediastinal tumors, transesophageal echocardiography revealed that the tumors were often adjacent to the heart and identified those patients in whom there was compression of the innominate vein or pulmonary artery or infiltration of the heart.¹⁸

Intraoperative transesophageal echocardiography has also revealed tumor invasion of the heart, indicating that a resection by thoracotomy without cardiopulmonary bypass was not feasible.¹⁹ In another case report, transesophageal echocardiography monitoring during an attempted resection of a tumor invading the left atrium showed embolization of the tumor.²⁰ Fragments of the tumor were seen to pass through the aortic valve. This patient subsequently died of disseminated metastases. In an exploratory thoracotomy for hemothorax, intraoperative transesophageal echocardiography revealed the presence of a subacute aortic dissection, which was believed to be the etiology of the hemothorax.²¹

Monitoring of Oxygenation and Ventilation

Oxygenation

During the administration of all thoracic surgical anesthetics, the concentration of oxygen in the breathing system must be measured using an oxygen analyzer with a low oxygen concentration limit alarm. Such analyzers vary in sophistication from fuel cells, polarographic and paramagnetic analyzers, to mass and Raman spectrometers that can monitor all the gases used during anesthesia. Adequacy of blood oxygenation must also be ensured, and adequate illumination and exposure of the patient are necessary to assess the color of shed blood or the presence of cyanosis of the lips, nail beds, or mucous membranes. Most patients undergoing thoracic surgical or diagnostic procedures have an arterial catheter in place for continuous monitoring of blood pressure and sampling of arterial blood for arterial blood gas determinations. In such cases, baseline arterial blood gas values should be obtained with an $F_{IO_2} = 0.21$ (room air) before starting the procedure and repeated regularly and/or whenever indicated during surgery. Arterial blood is usually analyzed for oxygen tension (P_{aO_2}), and saturation is calculated from the oxyhemoglobin dissociation curve, correcting for temperature, pH, and P_{aCO_2} .

The oxygen content of arterial blood can be assessed using a bench co-oximeter, such as the IL482 (Instrumentation Laboratory, Lexington, MA), which uses spectrophotometric principles to measure the total hemoglobin (Hb_{TOT}), which represents 100% ($g \cdot dl^{-1}$), and the percentages of oxyhemoglobin (HbO_2), methemoglobin, and carboxyhemoglobin. Deoxygenated (reduced) hemoglobin (RHb) is the difference between 100% and the sum of carboxyhemoglobin, methemoglobin, and HbO_2 . The oxyhemoglobin percentage* ($HbO_2\%$, previously termed *fractional concentration*) is the more important index for assessing oxygen content. The oxygen saturation of available hemoglobin* (total amount of hemoglobin available to bind oxygen, or $SaO_2\%$, and previously known as functional saturation) differs from $HbO_2\%$ depending on the amount of dyshemoglobins (carboxyhemoglobin, methemoglobin) present. Thus, if the hemoglobin concentration is $15 g \cdot dl^{-1}$, and 1 g of hemoglobin combines with 1.34 ml O_2 when fully saturated, the formula $(15 \times HbO_2\% \times 1.34)$ provides the more accurate estimate of ml $O_2 \cdot dl^{-1}$ of blood than using $(15 \times SaO_2\% \times 1.34)$ or using the calculated saturation from a saturation nomogram based on P_{aO_2} .†

Pulse oximetry is now a standard of care for noninvasive assessment of oxygenation. Pulse oximeters are fairly accurate in estimating hemoglobin saturation with oxygen over the range of 60–100%. Their value has also been demonstrated during one-lung ventilation, when rapid assessment of oxygenation is extremely important, and when blood gas analysis may involve some delay²² (Fig. 30-5). Pulse oximetry does not, however, eliminate the need for arterial blood gas analysis during thoracic surgery. A low SpO_2 reading provides the clinician with an indication for sampling and laboratory analysis of arterial blood, but an erroneously high SpO_2 reading may also occur.²³

Figure 30-5. Changes in hemoglobin oxygen saturation during one-lung ventilation. Early detection of hypoxemia with pulse oximetry facilitates prompt treatment with positive end-expiratory pressure (5 cm H_2O) and incremental continuous positive airway pressure (2.5–5 cm H_2O) until arterial saturation is returned to an acceptable level. (PEEP = positive end-expiratory pressure; CPAP = continuous positive airway pressure.) (Reproduced with permission from Brodsky JB, Shulman MS, Swan M: Pulse oximetry during one-lung ventilation. *Anesthesiology* 65:213, 1985.)

The monitoring of transcutaneous oxygen tension (P_{tCO_2}) has also been used during thoracic surgery and one-lung ventilation. Although these monitors are noninvasive and continuous, a warm-up time is required before use, and the skin underlying the sensor must be heated to 45°C to arterialize the blood. Generally, P_{tCO_2} is approximately 80% of actual arterial oxygen tension (P_{aO_2}) and is accurate only when the patient is hemodynamically stable with a cardiac index in excess of $2.2 l \cdot min^{-1} \cdot m^{-2}$. During periods of hypotension, P_{tCO_2} does not follow P_{aO_2} but decreases. Thus, a low P_{tCO_2} may be misleading in the presence of an adequate P_{aO_2} and poor tissue perfusion. For these reasons, pulse oximetry is usually preferred over transcutaneous oxygen monitoring during thoracic surgery.

Another device that has been reported for continuous monitoring of oxygenation is the *optode*, a fiberoptic probe for continuous intra-arterial measurement of P_{aO_2} . It consists of a single optical fiber with a luminescent dye coating at the tip. It is heparin coated, less than 0.5 mm in diameter, and passes easily through a 20-gauge arterial cannula. It does not appear to interfere with the arterial pressure waveform, and blood samples can easily be withdrawn from the cannula with the optode in place. A flash lamp emits light that excites the molecules of the luminescent dye. The excited electrons of the dye can either decay to a lower energy level by emitting light or react with oxygen without light emission. Thus, the light emitted is inversely proportional to the amount of oxygen. This device has been evaluated, but further improvements in accuracy are required for use at a low P_{aO_2} .²⁴ Once the problems of accuracy and reliability have been adequately addressed, the optode would likely be useful in thoracic surgical patients because it also permits simultaneous arterial pressure monitoring and arterial blood sampling.

Ventilation

All patients must be continually monitored to ensure adequacy of ventilation. Monitoring includes qualitative signs such as chest excursion (visual observation of the lungs when the chest is open), observation of the reservoir bag, and auscultation of breath sounds. An esophageal or precordial stethoscope should be used routinely. In addition, during one-lung ventilation, a stethoscope should be placed on the chest wall under the ventilated dependent lung. During controlled ventilation, circuit low- and high-pressure alarms with an audible signal must be used. The respiratory rate, V_T , minute volume, and inflation pressures should be observed.

Adequacy of ventilation should be confirmed by monitoring arterial blood gases, P_{aCO_2} in particular. This may be estimated continuously and noninvasively by using a capnometer. The end-tidal CO_2 concentration represents alveolar CO_2 (P_{ACO_2}), which approximates P_{aCO_2} . There is normally a small arterial-to-alveolar CO_2 gradient

(4–6 mm Hg), depending on alveolar dead space. The capnogram waveform is also helpful in diagnosing airway obstruction, incomplete relaxation, and even malposition of the double-lumen tube. In the latter application, a capnograph is coupled with each port of the double-lumen tube (one or two capnographs may be used), and the correct position of the double-lumen tube is identified by simultaneous and synchronous CO₂ readings on each of the two analyzers. The waveforms from each lung are examined for shape, height, and rhythm, depending on the correct position of the tube as well as on the ventilation/perfusion (\dot{V}/\dot{Q}) ratio for each lung.²⁵ A decrease in end-tidal CO₂ in the gas from one lumen of the double-lumen tube suggests malposition of the tube. During one-lung ventilation, systemic hypoxemia is usually a greater problem than hypercarbia.²⁶ This is because CO₂ is some 20 times more diffusible than oxygen and PaCO₂ is more dependent on ventilation compared with PaO₂, which is more dependent on perfusion.

Sidestream Spirometry. Using a patented airway sampling adapter that incorporates a Pitot tube flowmeter system (D-Lite; Datex-Ohmeda, Tewksbury, MA), volume–pressure and flow–volume loops may be displayed from patients who are tracheally intubated and whose lungs are being mechanically ventilated.²⁷ This technique of continuous spirometry has been used as a monitor of ventilation as well as a means to detect displacement of a double-lumen tube.²⁸

Physiology of the Lateral Decubitus Position. Ventilation and blood flow in the upright position have been discussed in a previous chapter (see [Chapter 24](#)). These variables will now be considered as they pertain to the lateral decubitus position under six circumstances that are encountered during thoracic surgery.

LATERAL POSITION, AWAKE, BREATHING SPONTANEOUSLY, CHEST CLOSED. In the lateral decubitus position, the distribution of blood flow and ventilation is similar to that in the upright position but turned by 90 degrees ([Fig. 30-6](#)). Blood flow and ventilation to the dependent lung are significantly greater than to the nondependent lung. Good \dot{V}/\dot{Q} matching at the level of the dependent lung results in adequate oxygenation in the awake patient breathing spontaneously. There are two important concepts in this situation. First, because perfusion is gravity dependent, the vertical hydrostatic gradient is smaller in the lateral than in the upright position; therefore, zone 1 is usually less extended. Second, in regard to ventilation, the dependent hemidiaphragm is pushed higher into the chest by the abdominal contents compared with the nondependent lung hemidiaphragm. During spontaneous ventilation, the conserved ability of the dependent diaphragm to contract results in an adequate distribution of \dot{V}_T to the dependent lung. Because most of the perfusion is to the dependent lung, the \dot{V}/\dot{Q} matching in this position is maintained similar to that in the upright position.

Figure 30-6. Schematic representation of the effects of gravity on the distribution of pulmonary blood flow in the lateral decubitus position. Vertical gradients in the lateral decubitus position are similar to those in the upright position and cause the creation of zones 1, 2, and 3. Consequently, pulmonary blood flow increases with lung dependency and is largest in the dependent lung and least in the nondependent lung. (P_a = pulmonary artery pressure; P_A = alveolar pressure; P_v = pulmonary venous pressure.) (Reproduced with permission from Benumof JL: Physiology of the open-chest and one lung ventilation. In Kaplan JA [ed]: Thoracic Anesthesia, p 288. New York, Churchill Livingstone, 1983.)

LATERAL POSITION, AWAKE, BREATHING SPONTANEOUSLY, CHEST OPEN. Controlled positive-pressure ventilation is the most common way to provide adequate ventilation and ensure gas exchange in an open chest situation. Frequently, thoracoscopy is performed using intercostal blocks with the patient breathing spontaneously to allow proper lung examination. The thoracoscope provides an adequate seal of the open chest to prevent a “free” open-chest situation. Two complications can arise from the patient breathing spontaneously with an open chest. The first is mediastinal shift, usually occurring during inspiration ([Fig. 30-7](#)). The negative pressure in the intact hemithorax, compared with the less negative pressure of the open hemithorax, can cause the mediastinum to move vertically downward and push into the dependent hemithorax. The mediastinal shift can create circulatory and reflex changes that may result in a clinical picture similar to that of shock and respiratory distress. Sometimes, depending on the severity of the distress, the patient needs to be tracheally intubated immediately, with initiation of positive-pressure ventilation, and the anesthesiologist must be prepared to intubate in this position without disturbing the surgical field. The second phenomenon is paradoxical breathing ([Fig. 30-8](#)). During inspiration, the relatively negative pressure in the intact hemithorax compared with atmospheric pressure in the open hemithorax can cause movement of air from the nondependent into the dependent lung. The opposite occurs during expiration. This gas movement reversal from one lung to the other represents wasted ventilation and can compromise the adequacy of gas exchange. Paradoxical breathing is increased by a large thoracotomy or by an increase in airways resistance in the dependent lung. Positive-pressure ventilation or adequate sealing of the open chest eliminates paradoxical breathing.

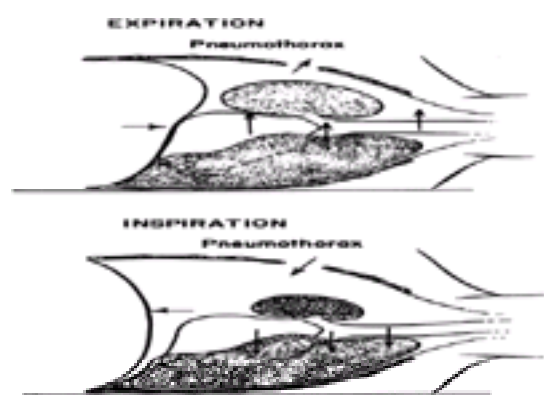

Figure 30-7. Schematic representation of mediastinal shift in the spontaneously breathing, open-chested patient in the lateral decubitus position. During inspiration, negative pressure in the intact hemithorax causes the mediastinum to move downward. During expiration, relative positive pressure in the intact hemithorax causes the mediastinum to move upward. (Reproduced with permission from Tarhan S, Moffitt EA: Principles of thoracic anesthesia. Surg Clin North Am 53:813, 1973.)

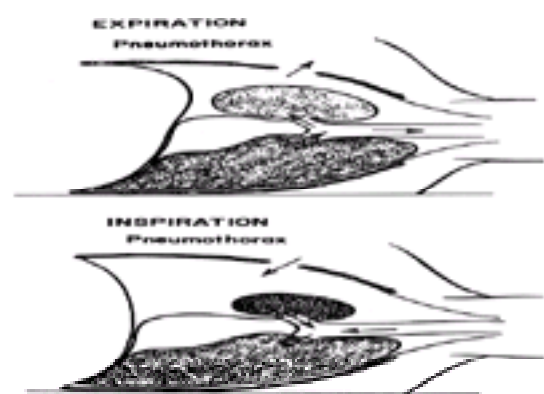

Figure 30-8. Schematic representation of paradoxical respiration in the spontaneously breathing, open-chested patient in the lateral decubitus position. During inspiration, movement of gas from the exposed lung into the intact lung and movement of air from the environment into the open hemithorax cause collapse of the exposed lung. During expiration, the reverse occurs, and the exposed lung expands. (Reproduced with permission from Tarhan S, Moffitt EA: Principles of thoracic anesthesia. Surg Clin North Am 53:813, 1973.)

LATERAL POSITION, ANESTHETIZED, BREATHING SPONTANEOUSLY, CHEST CLOSED. The induction of general anesthesia does not cause significant change in the distribution of blood flow but has an important impact on the distribution of ventilation. Most of the V_T enters the nondependent lung, and this results in a significant \dot{V}/\dot{Q} mismatch. Induction of general anesthesia causes a reduction in the volumes of both lungs secondary to a reduction in FRC. Any reduction in volume in the dependent lung is of a greater magnitude than that in the nondependent lung for several reasons. First, the cephalad displacement of the dependent diaphragm by the abdominal contents is more pronounced and is increased by paralysis. Second, the mediastinal structures pressing on the dependent lung or poor positioning of the dependent side of the operating table prevents the lung from expanding properly. The aforementioned factors will move lungs to a lower volume on the S-shaped volume–pressure curve (Fig. 30-9). The nondependent lung moves to a steeper position on the compliance curve and receives most of the V_T , whereas the dependent lung is on the flat (noncompliant) part of the curve.

Figure 30-9. The left-hand side of the schematic shows the distribution of ventilation in the awake patient (closed chest) in the lateral decubitus position, and the right-hand side shows the distribution of ventilation in the anesthetized patient (closed chest) in the lateral ducubitus position. The induction of anesthesia has caused a loss in lung volume in both lungs, with the nondependent (up) lung moving from a flat, noncompliant portion to a steep, compliant portion of the pressure–volume curve, and the dependent (down) lung moving from a steep, compliant part to a flat, noncompliant part of the pressure–volume curve. Thus, the anesthetized patient in the lateral decubitus position has most tidal ventilation in the nondependent lung (where there is the least perfusion) and less tidal ventilation in the dependent lung (where there is the most perfusion). (V = volume; P = pressure.) (Reproduced with permission from Benumof JL: Physiology of the open-chest and one lung ventilation. In Kaplan JA [ed]: Thoracic Anesthesia, p 294. New York, Churchill Livingstone, 1983.)

LATERAL POSITION, ANESTHETIZED, BREATHING SPONTANEOUSLY, CHEST OPEN. Opening the chest has little impact on the distribution of perfusion. However, the upper lung is now no longer restricted by the chest wall and is free to expand, resulting in a further increase in \dot{V}/\dot{Q} mismatch as the nondependent lung is preferentially ventilated owing to a now increased compliance.

LATERAL POSITION, ANESTHETIZED, PARALYZED, CHEST OPEN. During paralysis and positive-pressure ventilation, diaphragmatic displacement is maximal over the nondependent lung, where there is the least amount of resistance to diaphragmatic movement caused by the abdominal contents (Fig. 30-10). This further compromises the ventilation to the dependent lung and increases the \dot{V}/\dot{Q} mismatch.

Figure 30-10. This schematic of a patient in the lateral decubitus position compares the closed-chested anesthetized condition with the open-chested anesthetized and paralyzed condition. Opening the chest increases nondependent lung compliance and reinforces or maintains the larger part of the tidal ventilation going to the nondependent lung. Paralysis also reinforces or maintains the larger part of tidal ventilation going to the nondependent lung because the pressure of the abdominal contents (P_{AB}) pressing against the upper diaphragm is minimal, and it is therefore easier for positive-pressure ventilation to displace this less resisting dome of the diaphragm. (V = volume; P = pressure.) (Reproduced with permission from Benumof JL: Physiology of the open-chest and one lung ventilation. In Kaplan JA [ed]: Thoracic Anesthesia, p 295. New York, Churchill Livingstone, 1983.)

ONE-LUNG VENTILATION, ANESTHETIZED, PARALYZED, CHEST OPEN. During two-lung ventilation in the lateral position, the mean blood flow to the nondependent lung is assumed to be 40% of cardiac output, and 60% of cardiac output goes to the dependent lung (Fig. 30-11). Normally, venous admixture (shunt) in the lateral position is 10% of cardiac output and is equally divided as 5% in each lung. Therefore, the average percentage of cardiac output participating in gas exchange is 35% in the nondependent lung and 55% in the dependent lung.

Figure 30-11. Schematic representation of two-lung ventilation versus one-lung ventilation. Typical values for fractional blood flow to the nondependent and dependent lungs, as well as P_{aO_2} and \dot{Q}_s/\dot{Q}_t for the two conditions, are shown. The \dot{Q}_s/\dot{Q}_t during two-lung ventilation is assumed to be distributed equally between the two lungs (5% to each lung). The essential difference between two-lung and one-lung ventilation is that, during one-lung ventilation, the nonventilated lung has some blood flow and therefore an obligatory shunt, which is not present during two-lung ventilation. The 35% of total flow perfusing the nondependent lung, which was not shunt flow, was assumed to be able to reduce its blood flow by 50% by hypoxic pulmonary vasoconstriction. The increase in \dot{Q}_s/\dot{Q}_t from two-lung to one-lung ventilation is assumed to be due solely to the increase in blood flow through the nonventilated, nondependent lung during one-lung ventilation. (Reproduced with permission from Benumof JL: Anesthesia for Thoracic Surgery, p 112. Philadelphia, WB Saunders, 1987.)

One-lung ventilation creates an obligatory right-to-left transpulmonary shunt through the nonventilated, nondependent lung because the \dot{V}/\dot{Q} ratio of that lung is zero. In theory, an additional 35% should be added to the total shunt during one-lung ventilation. However, assuming active HPV, blood flow to the nondependent hypoxic lung will be reduced by 50% and therefore is $(35/2) = 17.5\%$. To this must be added 5%, which is the obligatory shunt through the nondependent lung. The shunt through the nondependent lung is therefore 22.5% (see Fig. 30-11). Together with the 5% shunt in the dependent lung, total shunt during one-lung ventilation is $22.5\% + 5 = 27.5\%$. This results in a P_{aO_2} of approximately 150 mm Hg ($F_{iO_2} = 1.0$).²⁹

Because 72.5% of the perfusion is directed to the dependent lung during one-lung ventilation, the matching of ventilation in this lung is important for adequate gas exchange. The dependent lung is no longer on the steep (compliant) portion of the volume–pressure curve because of reduced lung volume and FRC. There are several reasons for this reduction in FRC, including general anesthesia, paralysis, pressure from abdominal contents, compression by the weight of mediastinal structures, and suboptimal positioning on the operating table. Other considerations that impair optimal ventilation to the dependent lung include absorption atelectasis, accumulation of secretions, and the formation of a fluid transudate in the dependent lung. All of these create a low \dot{V}/\dot{Q} ratio and a large $P_{(A-a)}O_2$ gradient.

ONE-LUNG VENTILATION

Absolute Indications for One-Lung Ventilation

Separation of the lungs to prevent spillage of pus or blood from an infected or bleeding source is an absolute indication for one-lung ventilation (Table 30-2). Life-threatening complications, such as massive atelectasis, sepsis, and pneumonia, can result from bilateral contamination. Bronchopleural and bronchocutaneous fistulae both represent low-resistance pathways for the V_T delivered by positive-pressure ventilation, and both prevent adequate alveolar ventilation. Giant cysts or unilateral bullae may rupture under positive-pressure ventilation. This can be avoided by selective lung ventilation. During bronchopulmonary lavage, an effective separation of the lungs is mandatory to avoid accidental spillage of fluid from the lavaged lung to the nondependent ventilated lung. Video assisted thoracoscopic surgery requires lung separation and is becoming the most common indication for one-lung ventilation.

| ABSOLUTE | |
|----------|---|
| 1. | Isolation of each lung to prevent contamination of a healthy lung |
| a. | Infection (abscess, infected cyst) |
| b. | Massive hemorrhage |
| 2. | Control of distribution of ventilation to only one lung |
| a. | Bronchopleural fistula |
| b. | Bronchopleural cutaneous fistula |
| c. | Unilateral cyst or bullae |
| d. | Major bronchial disruption or trauma |
| 3. | Unilateral lung lavage |
| 4. | Video-assisted thoracoscopic surgery |
| RELATIVE | |
| 1. | Surgical exposure—high priority |
| a. | Thoracic aortic aneurysm |
| b. | Pneumorectomy |
| c. | Upper lobectomy |
| 2. | Surgical exposure—low priority |
| a. | Esophageal surgery |
| b. | Middle and lower lobectomy |
| c. | Thoracoscopy under general anesthesia |

Modified from Bernard JL. Physiology of the open-chest and one lung ventilation. In Kaplan JA (ed): *Textbook of Anesthesia*, p 299. New York, Churchill Livingstone, 1983.

Table 30-2. INDICATIONS FOR ONE-LUNG VENTILATION

Relative Indications for One-Lung Ventilation

In clinical practice, a double-lumen tube is commonly used for a lobectomy or pneumonectomy; these represent relative indications for lung separation. Upper lobectomy, pneumonectomy, and thoracic aortic aneurysm repair are relatively high-priority indications. These procedures are technically difficult, and optimal surgical exposure and a quiet operative field are highly desirable. Lower or middle lobectomy and esophageal resection are of lower priority. Nevertheless, many surgeons are accustomed to operating with the lung collapsed, which minimizes lung trauma from retractors and manipulation, improves visualization of lung anatomy, and facilitates identification and separation of anatomic structures and lung fissures. Thoracoscopy, if not performed with an intercostal block in the spontaneously breathing patient, is greatly facilitated by collapse of the lung under examination.

Methods of Lung Separation

Bronchial Blockers

Bronchial Blocker. Lung separation can be achieved with a reusable bronchial blocker. Magill described an endobronchial blocker that is placed using a bronchoscope and directed to the nonventilated lung. Inflation of the cuff at the distal end of the blocker serves to block ventilation to that lung. The lumen of the blocker permits suctioning of the airway distal to the catheter tip. Depending on the clinical circumstance, oxygen can be insufflated through the catheter lumen. A conventional endotracheal tube is then placed in the trachea. This technique can be useful in achieving selective ventilation in children younger than 12 years of age. However, because the blocker balloon requires a high distending pressure, it easily slips out of the bronchus into the trachea, obstructing ventilation and losing the seal between the two lungs. This displacement can be secondary to changes in position or to surgical manipulation. The loss of lung separation can be a life-threatening situation if it was performed to prevent spillage of pus, blood, or fluid from bronchopulmonary lavage. For this reason, bronchial blockers are rarely used in current practice.

Arterial Embolectomy Catheter. Selective airway occlusion can be achieved by the use of a Fogarty catheter designed for embolectomy procedures. Placement of the embolectomy catheter is best performed under direct vision with the aid of a fiberoptic bronchoscope. A conventional endotracheal tube is then placed alongside the catheter after withdrawing the bronchoscope. Alternatively, the bronchial blocker may be inserted through the lumen of a standard tracheal tube if the rubber diaphragm in a swivel connector is first perforated for passage of the blocker. The swivel connector is then placed between the tracheal tube and the Y-piece of the breathing circuit. A fiberoptic catheter can be inserted through the lumen of the tracheal tube to facilitate positioning of the blocker under direct vision.

Univent Tube. The Univent is a single-lumen endotracheal tube with a movable endobronchial blocker. In this tube, the bronchial blocker is housed in a small channel bored in the endotracheal tube wall. After intubation of the trachea, the movable blocker is manipulated into the desired mainstem bronchus with the aid of a fiberoptic bronchoscope.³⁰ Disadvantages of the Univent tube are that correct positioning of the blocker may be difficult to achieve or maintain. The Univent tube may be ideal for cases in which changing tubes (e.g., from single- to double-lumen) may be difficult (e.g., mediastinoscopy followed by thoracotomy), or in cases of bilateral lung transplantation.

Double-Lumen Endobronchial Tubes

These tubes are currently the most widely used means of achieving lung separation and one-lung ventilation. There are several different types of double-lumen tube, but all are essentially similar in design in that two catheters are bonded together. One lumen is long enough to reach a mainstem bronchus, and the second lumen ends with an opening in the distal trachea. Lung separation is achieved by inflation of two cuffs, the proximal tracheal cuff and the distal bronchial cuff located in the mainstem bronchus (see Positioning Double-Lumen Tubes). The endobronchial cuffs of right-sided tubes are slotted or otherwise designed to allow ventilation of the right upper lobe because the right mainstem bronchus is too short to accommodate both the right lumen tip and a right bronchial cuff.

Robertshaw Tube. This double-lumen tube is available in left- and right-sided forms without a carinal hook, which makes insertion easier (Fig. 30-12). This tube has the advantages of having D-shaped, large-diameter lumina that allow easy suctioning and offer low resistance to gas flow and a fixed curvature to facilitate proper positioning and to reduce the possibility of kinking. The original red rubber tubes are available in three sizes: small, medium, and large. Clear, polyvinyl chloride disposable Robertshaw-design double-lumen tubes are now in wide use. These tubes are available in a right or left design and in French sizes 35, 37, 39, and 41. A French size 28 has been made available for use in pediatric cases. The advantages of the disposable tubes include relative ease of insertion, proper positioning, easy recognition of the blue color of the endobronchial cuff when fiberoptic bronchoscopy is used, confirmation of position on a chest radiograph using the radiopaque lines in the wall of the tube, and continuous observation of tidal gas exchange and of respiratory moisture through the clear plastic. The right-sided endobronchial tube is designed to minimize occlusion of the right upper lobe. The right endobronchial cuff is doughnut shaped and allows the right upper lobe ventilation slot to ride over the right upper lobe orifice. The tube is also suitable for use in long-term ventilation in the intensive care unit because it has a high-volume low-pressure cuff. These are

now considered the tubes of choice for achieving lung separation and one-lung ventilation.

Figure 30-12. Left mainstem endobronchial intubation using a Carlens tube. Note carinal “hook” used for correct positioning. (Reproduced with permission from Hillard EK, Thompson PW: Instruments used in thoracic anaesthesia. In Mushin WW [ed]: Thoracic Anaesthesia, p 315. Oxford, Blackwell Scientific, 1963.)

Despite the availability of disposable double-lumen tubes, many centers continue to use the red rubber Robertshaw tubes. There are several reasons for this. First, the cost of reusable tubes is significantly less than that of the disposable tubes. Second, some anesthesiologists believe that although the red rubber tubes may be more difficult to insert, they are less likely to dislocate during patient positioning and surgical manipulation. Third, during insertion of the double-lumen tube, the tracheal cuff often directly rubs against the patient's upper teeth. If these teeth are prominent and sharp, the thin-walled tracheal cuffs of the disposable tubes are much more likely to tear as compared with the thicker-walled cuffs of the red rubber tubes. Fourth, if the wrong size of disposable tube is selected and insertion is attempted, the tube cannot be reused because sterility is compromised. This does not apply to the red rubber tubes, which withstand repeated sterilization.³¹

Positioning Double-Lumen Tubes. This section concentrates on the insertion of Robertshaw-design double-lumen tubes (both disposable and nondisposable), because they are the most widely used. Before insertion, the double-lumen tube should be prepared and checked. The tracheal cuff (high-volume, low-pressure) can accommodate up to 20 ml of air, and the bronchial cuff should be checked using a 3-ml syringe. The tube should be coated liberally with water-soluble lubricant ointment and the stylet should be withdrawn, lubricated, and gently placed back into the bronchial lumen without disturbing the tube's preformed curvature. The Macintosh 3 blade is preferred for intubation of the trachea because it provides the largest area through which to pass the tube. The insertion of the tube is performed with the distal concave curvature facing anteriorly. After the tip of the tube is past the vocal cords, the stylet is removed and the tube is rotated through 90 degrees. A left-sided tube is rotated 90 degrees to the left and a right-sided tube is rotated to the right. Advancement of the tube ceases when moderate resistance to further passage is encountered, indicating that the tube tip has been firmly seated in the mainstem bronchus. It is important to remove the stylet before rotating and advancing the tube to avoid tracheal or bronchial lacerations. Rotation and advancement of the tube should be performed gently and under continuous direct laryngoscopy to prevent hypopharyngeal structures from interfering with proper positioning. Once the tube is thought to be in the proper position, a sequence of steps should be performed to check its location.

First, the tracheal cuff should be inflated and equal ventilation of both lungs established. If breath sounds are not equal, the tube is probably too far down and the tracheal lumen opening is in a mainstem bronchus or is lying at the carina. Withdrawal of the tube by 2–3 cm usually restores equal breath sounds. The second step is to clamp the right side (in the case of the left-sided tube) and remove the right cap from the connector. Then the bronchial cuff is slowly inflated to prevent an air leak from the bronchial lumen around the bronchial cuff into the tracheal lumen. This ensures that excessive pressure is not applied to the bronchus and helps avoid laceration. Inflation of the bronchial cuff rarely requires more than 2 ml of air. The third step is to remove the clamp and check that both lungs are ventilated with both cuffs inflated. This ensures that the bronchial cuff is not obstructing the contralateral hemithorax, either totally or partially. The final step is to clamp each side selectively and watch for absence of movement and breath sounds on the ipsilateral (clamped) side; the ventilated side should have clear breath sounds, chest movement that feels compliant, respiratory gas moisture with each tidal ventilation, and no air leak. If peak airway pressure during two-lung ventilation is 20 cm H₂O, it should not exceed 40 cm H₂O for the same V_T during one-lung ventilation.

Other methods that have been used for ensuring the correct placement of a double-lumen tube include fluoroscopy, chest radiography, selective capnography, and the use of an underwater seal. Determination of the presence of air leaks when positive pressure is applied to one lumen of a double-lumen tube is easily done in the operating room. If the bronchial cuff is not inflated and positive pressure is applied to the bronchial lumen of the double-lumen tube, gas leaks past the bronchial cuff and returns through the tracheal lumen. If the tracheal lumen is connected to an underwater seal system, gas will be seen to bubble up through the water. The bronchial cuff can then be gradually inflated until no gas bubbles are seen and the desired cuff seal pressure can be attained. This test is of extreme importance when absolute lung separation is needed, such as during bronchopulmonary lavage.

The most important advance in checking the proper position of a double-lumen tube is the introduction of the pediatric flexible fiberoptic bronchoscope. Smith *et al*³² showed that when the disposable double-lumen tube was thought to be in correct position by auscultation and physical examination, subsequent fiberoptic bronchoscopy showed that 48% of tubes were, in fact, malpositioned. Such malpositions, however, are usually of no clinical significance.³³ When using a left-sided double-lumen tube, the bronchoscope is usually first introduced through the tracheal lumen. The carina is visualized; no bronchial cuff herniation should be seen. The upper surface of the blue endobronchial cuff should be just below the tracheal carina. The bronchial cuff of the disposable double-lumen tube is easily visualized because of its blue color. The bronchoscope should then be passed through the bronchial lumen and the left upper lobe orifice should be identified. When a right-sided double-lumen tube is used, the carina should be visualized through the tracheal lumen but, more important, the orifice of the right upper lobe bronchus should be identified when the bronchoscope is passed through the right upper lobe ventilating slot of the double-lumen tube. Pediatric fiberoptic bronchoscopes are available in several sizes: 5.6, 4.9, and 3.6 mm in external diameter. The 4.9-mm diameter bronchoscopes can be passed through double-lumen tubes of French sizes 37 and larger. The 3.6-mm diameter bronchoscope is easily passed through all sizes of double-lumen tube. In general, it is recommended that the largest size that can pass through the lumen of a double-lumen tube be used because it provides better visualization and facilitates identification of the bronchial anatomy.

Problems of Malposition of the Double-Lumen Tube. The use of a double-lumen tube is associated with a number of potential problems, the most important of which is malposition. There are several possibilities for tube malposition. The double-lumen tube may be accidentally directed to the side opposite the desired mainstem bronchus. In this case, the lung opposite the side of the connector clamped will collapse. Inadequate separation, increased airway pressures, and instability of the double-lumen tube usually occur. In addition, because of the morphology of the double-lumen tube curvatures, tracheal or bronchial lacerations may result. If a left-sided double-lumen tube is inserted into the right mainstem bronchus, it obstructs ventilation to the right upper lobe. It is therefore essential to recognize and correct such a malposition as soon as possible.

Second, the double-lumen tube may be passed too far down into either the right or the left mainstem bronchus. In this case, breath sounds are very diminished or not audible at all over the contralateral side. This situation is corrected when the tube is withdrawn until the opening of the tracheal lumen is above the carina.

Third, the double-lumen tube may not be inserted far enough, leaving the bronchial lumen opening above the carina. In this position, good breath sounds are heard bilaterally when ventilating through the bronchial lumen, but no breath sounds are audible when ventilating through the tracheal lumen because the inflated bronchial cuff obstructs gas flow arising from the tracheal lumen. The cuff should be deflated and the double-lumen tube rotated and advanced into the desired mainstem bronchus.

Fourth, a right-sided double-lumen tube may occlude the right upper lobe orifice. The mean distance from the carina to the right upper lobe orifice is 2.3 ± 0.7 cm in men and 2.1 ± 0.7 cm in women.³⁴ With right-sided double-lumen tubes, the ventilatory slot in the side of the bronchial catheter must overlie the right upper lobe orifice to permit ventilation of this lobe. The margin of safety, however, is extremely small, and varies from 1 to 8 mm.³⁴ It is, therefore, difficult to ensure proper ventilation to the right upper lobe and to avoid dislocation of the double-lumen tube during surgical manipulation. When right endobronchial intubation is required, a disposable right-sided double-lumen tube is perhaps the best choice because of the slanted doughnut shape of the bronchial cuff, which allows the ventilation slot to ride off the right upper lobe ventilation orifice and increases the margin of safety.

Fifth, the left upper lobe orifice may be obstructed by a left-sided double-lumen tube. Traditionally, it was believed that the take-off of the left upper lobe bronchus was at a safe distance from the carina and that it would not be obstructed by a left-sided double-lumen tube. However, the mean distance between the left upper lobe orifice and the carina is 5.4 ± 0.7 cm in men and 5.0 ± 0.7 cm in women.³⁴ The average distance between the openings of the right and left lumens on the left-sided disposable tubes is 6.9 cm.³⁴ Therefore, an obstruction of the left upper lobe is possible while the tracheal lumen is still above the carina. There is also a 20% variation

in the location of the blue endobronchial cuff on the disposable tubes because this cuff is attached at the end of the manufacturing process.

Finally, bronchial cuff herniation may occur and obstruct the bronchial lumen if excessive volumes are used to inflate the cuff. The bronchial cuff has also been known to herniate over the tracheal carina, and in the case of a left-sided double-lumen tube, to obstruct ventilation to the right mainstem bronchus.

Another rare complication with double-lumen tubes is tracheal rupture. Overinflation of the bronchial cuff, inappropriate positioning, and trauma owing to intraoperative dislocation that resulted in bronchial rupture have been described in association with the Robertshaw tube and the disposable double-lumen tube.³⁵ Therefore, the pressure in the bronchial cuff should be assessed and decreased if the cuff is found to be overinflated. If absolute separation of the lungs is not needed, the bronchial cuff should be deflated and then reinflated slowly to avoid excessive pressure on the bronchial walls. The bronchial cuff should also be deflated during any repositioning of the patient unless lung separation is absolutely required during this time.

Contraindications to Use of the Double-Lumen Tube. Use of a double-lumen tube to achieve lung separation is relatively contraindicated in situations in which there is a lesion in the airway itself or a difficult upper airway that results in poor laryngeal visualization. It is also relatively contraindicated in some critically ill patients in whom short periods of apnea or hypoxemia, which may occur during insertion of a double-lumen tube, may be life-threatening. In patients requiring rapid intubation (e.g., with a full stomach), a double-lumen tube is not necessarily contraindicated because the disposable tubes with stylets are as easily inserted as single-lumen tubes in most cases.

Lung Separation in the Patient with a Tracheostomy

Occasionally a patient with permanent tracheostomy is scheduled for surgery on the lung that requires lung separation. Examples of such patients include those who have undergone resection of a tumor in the floor of the mouth or of the base of the tongue, followed by extensive reconstructive surgery with creation of a permanent tracheal stoma. Routine follow-up may reveal a lung lesion that requires a diagnostic procedure. Conventional double-lumen endobronchial tubes are designed to be inserted through the mouth, not through a tracheal stoma. The standard double-lumen tubes are usually too stiff to negotiate the curve required for insertion through a tracheal stoma, and are difficult to position.³⁶

A separately inserted bronchial blocker, either within or alongside a single-lumen tube that has been placed through the tracheostomy, may permit adequate lung separation.³⁷ Compared with an orotracheal or nasotracheal single-lumen tube, passing a Fogarty catheter (to function as a bronchial blocker) through a tracheostomy into a mainstem bronchus may be easier because of the shorter distances involved.

Saito *et al*³⁸ have described a spiral, wire-reinforced, double-lumen endobronchial tube made of silicone (Koken Medical, Tokyo, Japan) that is designed for placement through a tracheostomy.³⁸ The middle section of the tube consists of two thin-walled silicone catheters with an internal diameter of 5 mm, glued together and reinforced with a stainless steel spiral wire and covered in a silicone coating with two pilot balloons. The distal section, which contains the bronchial lumen and the bronchial cuff, is made of wire-reinforced silicone to avoid excessive flexibility. The dimensions are based on the Mallinckrodt double-lumen tube. The bronchial cuff is located 1.2 cm from the tip, and the distance between the tip orifice and the tracheal orifice is 4.9 cm. In a clinical trial in patients with permanent tracheal stomas, the tubes functioned well in achieving lung separation, with no sign of kinking or movement, and permitted easy passage of a suction catheter.

Lung Separation in the Patient with a Difficult Airway

When separation of the lungs is required and the patient has a clearly recognized difficult airway, then awake intubation using a flexible fiberoptic bronchoscope can be planned to place a double-lumen, Univent or a single-lumen tube. The single-lumen tube may then be exchanged for a double-lumen or Univent tube using a tube exchanger plus laryngoscopy, or a Fogarty embolectomy catheter may be passed through the lumen of the single-lumen tube to act as an independent bronchial blocker. Furthermore, depending on the expected extent and the duration of the surgical procedure and the degree of fluid shift, an airway not initially classified as difficult may become difficult secondary to facial edema, secretions, and laryngeal trauma from the initial intubation.

The indications for one-lung ventilation were discussed earlier in this chapter. Recently, the popularity of the VAT procedure has increased. The improvements in video-endoscopic surgical equipment and a growing enthusiasm for minimally invasive surgical approaches have popularized VAT in the practice of surgery for diagnostic and therapeutic procedures. Most of these procedures require a well collapsed lung and should be considered as absolute indications for one-lung ventilation. The lung must be well collapsed to allow the surgeon an optimal view of the surgical field and to palpate the lesion in the lung parenchyma. In addition, it is difficult to place the stapler on a lung that is not completely collapsed, and there is an increase in incidence of postoperative air leaks in these circumstances. Because of its widespread use today, VAT significantly increases the number of cases with a potentially difficult airway that require lung separation. In the past, before the era of VAT, most open thoracotomies were for surgical exposure. Most of the patients were intubated with a double-lumen tube. However, when faced with a difficult intubation, the anesthesiologist often managed these cases with a single-lumen tube, intermittent ventilation, compressing the operated lung with lap pads, or the use of low V_T with a high ventilatory rate to allow the surgeon to proceed with the lung resection. Only rarely was there an absolute need for lung separation in a patient with a difficult airway.

Methods of Lung Separation in the Patient with a Difficult Airway

An airway may be recognized initially as difficult when conventional laryngoscopy reveals a Grade III or IV view. Sometimes, depending on the type and duration of surgery and the degree of fluid shift, an airway that initially was not classified as difficult may become difficult secondary to facial edema, the presence of secretions, and laryngeal trauma from the initial intubation.^{39,40}

A logical approach to lung separation is shown in [Figure 30-13](#). When lung separation is mandated, and the patient has a recognized difficult airway, awake intubation using flexible fiberoptic bronchoscopy can be attempted using a double-lumen tube, Univent, or a single-lumen tube. The same approach may be used for the patient with an unrecognized difficult airway and a failure to intubate with conventional laryngoscopy. When using a double-lumen tube over a fiberoptic bronchoscope, the anesthesiologist should keep in mind that it is a bulky tube with a large external diameter, and because of the length of the double-lumen tube, only a limited part of the fiberoptic bronchoscope is available for manipulation. In addition, the mismatch between the flexibility of the fiberoptic bronchoscope and the rigidity of the double-lumen tube makes the tube harder to advance over the fiberoptic bronchoscope. The Univent tube has the same bulky external diameter and is also often hard to pass between the vocal cords, particularly in a patient who is awake.

Figure 30-13. Lung separation in a patient with a difficult airway.

Single-Lumen Tube Can Be Successfully Placed. If a failure to provide lung separation could result in a life-threatening situation, there are two possibilities to provide one-lung ventilation when a single-lumen tube is already in place. First, depending on the indication for lung isolation, a tube exchanger can be used to switch to a double-lumen or a Univent tube. The second possibility is to direct a bronchial blocker through the single-lumen tube into the selected mainstem bronchus. These two methods, however, offer limited protection or an inadequate seal in cases such as a lung lavage, pulmonary abscess, or hemoptysis, where a double-lumen tube would be the tube of choice.

USE OF A TUBE EXCHANGER. Several tube exchangers are commercially available (Cook Critical Care, Bloomington, IN; Sheridan Catheter Corporation, Argyle, NY). On all of these tube exchangers, the depth is marked in centimeters, and they are available in a wide range of external diameters and easily adapted for either oxygen

insufflation or jet ventilation.

The size of the tube exchanger and the size of the tube to be inserted should be tested *in vitro* before use in a patient. The French size 11 tube changer will pass through a 35–41 French size double-lumen tube, while the French size 14 tube exchanger does not pass through a French size 35. To prevent lung laceration, the tube exchanger should never be inserted against resistance. Finally, when passing any tube over an airway guide, a laryngoscope should be used to facilitate passage of the tube over the airway guide past supraglottic tissues.

USE OF A BRONCHIAL BLOCKER. The use of a bronchial blocker has been discussed earlier in this chapter. An independently passed bronchial blocker may be used with a single-lumen tube to obtain lung isolation, thereby avoiding the use of a double-lumen or Univent tube in a patient with a difficult airway. The most commonly used independent bronchial blocker is a number 7.0 Fogarty embolectomy catheter, which has an occlusion balloon that can range in volume from 5.0–8.0 ml. The balloon should be inflated to a volume sufficient to occlude the lumen of the mainstem bronchus and to hold the catheter in place. The fiberoptic bronchoscope is passed through a bronchoscopy elbow, down a single-lumen tube to visualize the carina, and past the Fogarty balloon-tipped catheter into the appropriate mainstem bronchus. The Fogarty catheter is supplied with a wire stylet in place, which can be curved at the distal end to facilitate passage through the bronchoscopy elbow and down the single-lumen tube. The catheter balloon is then inflated, under direct vision using the bronchoscope, with enough volume to occlude the main bronchus. The balloon of the Fogarty catheter is a high-pressure, low-volume device and can exert significant pressure on the mucosa of the bronchial wall.

Drawbacks to the use of bronchial blockers include difficulty in directing the blocker into the desired bronchus, even with help of a fiberscope, and the inability to effectively suction the airway distal to the blocker; also during the surgical manipulation, the blocker may slip into the trachea, resulting in life-threatening airway obstruction.

In an attempt to overcome these potential problems, a snare-guided bronchial blocker has been introduced (Cook Critical Care, Bloomington, IN). A fiberscope is passed through the loop of the bronchial blocker and then guided into the desired bronchus. The blocker is then slid distally over the fiberscope into the selected bronchus. Bronchoscopic visualization confirms blocker placement and bronchial occlusion. The string (snare) is then removed through the blocker and the 1.8-mm diameter lumen may then be used as a suction port or for insufflation of oxygen. Disadvantages of this new device are its high cost and the inability to reinsert the snare (string) once it has been pulled out, making it impossible to redirect the blocker should it become necessary. Finally, the external diameter is somewhat larger, which requires it to be passed through a single-lumen tube of at least 7.5–8 mm in internal diameter.

Single-Lumen Tube Cannot Be Successfully Placed. If a single-lumen tube cannot be placed with the aid of a fiberscope, and the patient's condition is stable, the clinician may use some alternative devices to assist in placement of the single-lumen tube. There are several commercially available laryngoscopes that can facilitate endobronchial intubation. The two best known are the Bullard laryngoscope (Circon, ACMI, Stamford, CT) and the Wu laryngoscope (Achi Corp., Dublin, CA). The Bullard laryngoscope is an anatomically shaped, rigid instrument that uses a fiberoptic bundle to obtain a view of the larynx. Thus, the oral, pharyngeal, and tracheal axes do not have to be aligned in order to view the larynx. The Wu laryngoscope uses a similar concept but consists of a rigid blade portion and a separate, flexible fiberoptic portion. Successful use of these devices is associated with a relatively lengthy learning curve, and the clinician facing a difficult airway should not be using these laryngoscopes for the first time.

Finally, the Fastrach (Gensia, Inc., San Diego, CA), a new version of the conventional LMA, is a reasonable alternative. First, it permits ventilation of the patient during the airway manipulation, and second, this new form of the laryngeal airway mask permits insertion of a large-diameter (8 mm) single-lumen tube. In rare cases, when none of these methods results in a successful intubation, the plan to perform the procedure should be re-evaluated, or a Combitube (Kendall-Sheridan Catheter Corp., Argyle, NY) can be inserted to allow ventilation, if not lung separation.

Conclusion of the Surgical Procedure

Depending on the extent and the duration of the procedure and the degree of fluid shift, an airway, initially not classified as difficult may become difficult secondary to facial edema, secretions, and laryngeal trauma from the original intubation. In these cases, when planning to provide lung separation, the postoperative period should be considered and the appropriate tube placed. Many procedures that are not considered to represent absolute indications for lung separation are lengthy and complex. Complex lung resection, with or without chest wall resection, thoracoabdominal esophagogastrectomy, thoracic aortic aneurysm resection with or without total circulatory arrest, or an extensive vertebral tumor resection, may result in facial edema, secretion, and hemoptysis, requiring postoperative ventilatory support. Other indications for postoperative ventilatory support are marginal respiratory reserve, unexpected blood loss or fluid shift, hypothermia, and inadequate reversal of neuromuscular blockade.

If a Univent tube was used to provide one-lung ventilation the blocker may be fully retracted and the Univent tube can function as a single-lumen tube. If an independent bronchial blocker was used, then the blocker is removed, leaving the single-lumen tube in place. The problem arises when a double-lumen tube was inserted for lung separation. In a patient with a difficult airway and subsequent facial edema, the double-lumen tube may be left in place after surgery.

If the decision to leave the double-lumen tube in place is made, it is important to keep in mind that the intensive care unit staff is usually less experienced in managing such a tube, which may easily become dislocated. In addition, it is more difficult to suction through the lumen, and a longer, narrower suction catheter is needed to reach the tip of the endobronchial lumen. Another possibility is to withdraw the double-lumen tube to place the 19–20-cm mark at the teeth, so that the endobronchial lumen is above the carina and both lungs can be ventilated. Tracheal extubation from the double-lumen tube should be considered after diuresis and steroid therapy to allow reduction of the facial and airway edema.

If it is decided to change the double-lumen to a single-lumen tube, the decision should not be accomplished blindly. A tube exchanger must be used to maintain access to the airway, as previously discussed. Tube exchange may be performed under direct vision using a Bullard or Wu laryngoscope. With these laryngoscopes, the tube exchanger or a stylet can be placed under direct vision through the vocal cords alongside the existing tube to permit passage of a single-lumen tube (Fig. 30-14).

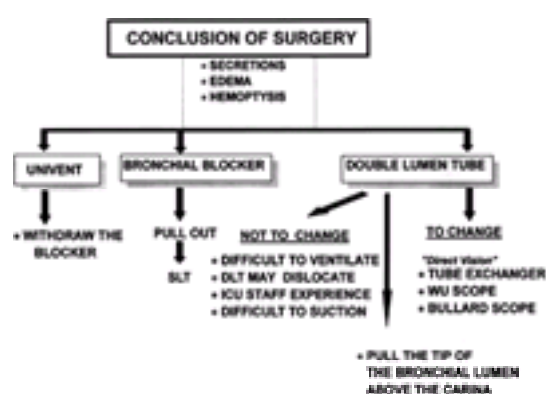

Figure 30-14. Conclusion of the surgical procedure. See text for discussion. (DLT = double-lumen tube; SLT = single-lumen tube.)

In summary, the clinician should be able to master different methods of lung separation and make him/herself familiar with the devices available to provide one-lung ventilation and optimal, and safe management of the patient. In addition, one should always plan in advance for the postoperative period when choosing the method of lung separation. Finally, in these cases, a close dialog with the surgical team is of vital importance.

MANAGEMENT OF ONE-LUNG VENTILATION

This section discusses the management of one-lung ventilation in a paralyzed patient in the lateral decubitus position with an open chest. Inspired oxygen fraction (F_{iO_2}), V_T and respiratory rate, dependent lung, PEEP, and nondependent lung CPAP are reviewed and an approach to the management of one-lung ventilation is presented.

Inspired Oxygen Fraction

An F_{iO_2} of 1.0 is usually used during one-lung ventilation. This high oxygen concentration serves to protect against hypoxemia during the procedure. In many studies,

an F_{IO_2} of 1.0 has been used and resulted in a shunt of 25–30% and mean P_{aO_2} values between 150 and 210 mm Hg during one-lung ventilation.⁴¹ In addition to a higher margin of safety, high F_{IO_2} values cause vasodilatation of the vessels in the dependent lung, which increases the capability of this lung to accept blood flow redistribution due to nondependent lung HPV. A high F_{IO_2} may, however, cause absorption atelectasis and potentially further increase the degree of shunt because of the collapsed alveoli. The risk can be reduced by using a lower F_{IO_2} , by the application of positive-pressure ventilation, or by the use of a high V_T and PEEP. Theoretically, a high F_{IO_2} can also cause lung injury owing to oxygen toxicity, although this complication is unlikely to occur in the time frame of a surgical operation. Lower F_{IO_2} values (0.25–0.50) have also been used, with resulting mean P_{aO_2} values between 62 and 87 mm Hg.^{42,43}

The use of an F_{IO_2} less than 1.0 during one-lung ventilation offers the benefits of reducing the risk of absorption atelectasis and may permit use of lower concentrations of potent inhaled anesthetics, which in higher concentrations might be more depressant to the myocardium, particularly in high-risk patients. An F_{IO_2} of less than 1.0 may also be indicated in patients with bleomycin toxicity. The combination of N_2O/O_2 with pulse oximetry monitoring may represent an optimal solution in such cases. However, the risk–benefit ratio for each patient should always be carefully considered.

Tidal Volume and Respiratory Rate

During one-lung ventilation, the dependent lung should be ventilated with a V_T of 10–12 ml · kg⁻¹. V_{TS} ranging between 8 and 15 ml · kg⁻¹ produced no significant effect on transpulmonary shunt or P_{aO_2} .⁴⁴ A V_T of less than 8 ml · kg⁻¹ can result in a decrease in FRC and enhanced formation of atelectasis in the dependent lung. A V_T of greater than 15 ml · kg⁻¹ can increase the pulmonary vascular resistance of the dependent lung (similar to the application of PEEP) and divert blood flow into the nondependent lung. The value of 10–12 ml · kg⁻¹ is a middle range between 8 and 15 ml · kg⁻¹ and appears to have the smallest effect on P_{aO_2} and percentage shunt.

The respiratory rate should be adjusted to maintain a P_{aCO_2} of 35 ± 3 mm Hg. Elimination of CO_2 is usually not a problem during one-lung ventilation if the double-lumen tube is positioned correctly. The shunt during one-lung ventilation has little influence on P_{aCO_2} values because the arteriovenous P_{CO_2} difference is normally only 6 mm Hg. Furthermore, CO_2 is 20 times more diffusible than O_2 and will be eliminated faster. It is also important not to hyperventilate the patient's lungs because hypocapnia increases vascular resistance in the dependent lung, inhibits nondependent lung HPV, increases shunt, and decreases P_{aO_2} . Hypocapnia is thought to inhibit HPV secondary to a vasodilator effect. Because hypocapnia can only be achieved only by hyperventilating the dependent lung, it raises the mean intra-alveolar pressure and therefore increases the vascular resistance in that lung. Finally, one-lung ventilation decreases the deadspace-to-tidal volume (V_D/V_T) ratio and enhances CO_2 elimination.⁴⁵

Positive End-Expiratory Pressure to the Dependent Lung

The beneficial effect of selective PEEP 10 cm H₂O (PEEP₁₀) to the dependent lung is caused by an increased lung volume at end-expiration (FRC), which improves the \dot{V}/\dot{Q} relationship in the dependent lung. The increase in FRC prevents airway and alveolar closure at end-expiration. Therefore, it is not surprising that attempts have been made to improve oxygenation during one-lung ventilation by the application of PEEP to the dependent lung. However, the results were somewhat disappointing. Most of the studies showed either no change in P_{aO_2} , a decrease, or a slight increase in P_{aO_2} ,^{41,45} probably owing to the PEEP inducing an increase in lung volume that caused compression of the small interalveolar vessels and increased pulmonary vascular resistance. If this increase in resistance is limited to the dependent lung, blood flow can be diverted only to the nondependent (nonventilated) lung, increasing percentage shunt and further decreasing P_{aO_2} .

The studies of PEEP cited previously used an F_{IO_2} of 1.0 with a mean P_{aO_2} during one-lung ventilation of between 150 and 200 mm Hg, at which further improvement in P_{aO_2} is clinically unnecessary. The possibility that the application of PEEP can improve P_{aO_2} in a diseased dependent lung (low lung volume and low \dot{V}/\dot{Q} ratio) with a low P_{aO_2} (<80 mm Hg) during one-lung ventilation has been addressed by Cohen *et al.*⁴⁶ They found that application of PEEP₁₀ during one-lung ventilation in patients with a low P_{aO_2} may increase FRC to normal values, resulting in a lower pulmonary vascular resistance and in an improved \dot{V}/\dot{Q} ratio and P_{aO_2} . Presumably, patients with a higher P_{aO_2} had a dependent lung with an adequate FRC, and the application of PEEP had the negative effect of redistributing blood flow away from the dependent ventilated lung (Fig. 30-15).

Figure 30-15. Effect of 10 cm H₂O PEEP on FRC. It is postulated that, in patients having $P_{aO_2} < 80$ mm Hg with ZEEP, FRC is low. PEEP₁₀ increases FRC and thereby increases P_{aO_2} . (PEEP₁₀ = positive end-expiratory pressure [10 cm H₂O]; OLV = one-lung ventilation; FRC = functional residual capacity; RV = residual volume; ZEEP = zero end-expiratory pressure.)

Continuous Positive Airway Pressure to the Nondependent Lung

The single most effective maneuver to increase P_{aO_2} during one-lung ventilation is the application of CPAP to the nondependent lung. This has been clearly demonstrated in several studies.^{41,43,47} A lower level of CPAP (5–10 cm H₂O) maintains the patency of the nondependent alveoli, allowing some oxygen uptake to occur in the distended alveoli. CPAP should be applied after delivering a V_T to the nondependent lung to keep it slightly expanded. CPAP, applied by insufflation of oxygen under positive pressure, keeps this lung “quiet” and prevents it from collapsing completely. Inflation of oxygen without maintaining a positive pressure failed to improve P_{aO_2} ,⁴¹ although some improvement in P_{aO_2} occurred after 45 minutes of one-lung ventilation (from 140 ± 107 to 206 ± 76 mm Hg) with oxygen insufflation only.⁴⁸ Intermittent reinflation of the collapsed (nondependent) lung with oxygen also resulted in a significant improvement in P_{aO_2} .⁴⁹ The beneficial effects of CPAP 10 cm H₂O (CPAP₁₀) are not attributable solely to the effect of positive pressure in diverting blood flow away from the collapsed lung because (in dogs) the hyperinflation of nitrogen into the nondependent lung under 10 cm H₂O failed to improve P_{aO_2} .

The application of high-level CPAP (15 cm H₂O) is not beneficial. At this pressure, the lung becomes overdistended, which interferes with surgical exposure. Also, this level of CPAP might have hemodynamic consequences, whereas CPAP₁₀ has been shown to have no significant hemodynamic effects.⁴³

Continuous positive airway pressure can be applied to the nondependent lung using a number of simple systems, all of which have essentially the same features: an oxygen source, tubing to connect the oxygen source to the nonventilated lung, a pressure relief valve, and a pressure gauge.³ The catheter to the nondependent lung is usually insufflated with 5 l · min⁻¹ of oxygen using a modified Ayre T-piece pediatric circuit, and the valve on the expiratory limb is adjusted to the desired pressure as read on the attached gauge (Fig. 30-16). Instead of a pressure gauge or manometer inserted into the circuit, a weighted pop-off valve, such as a ball or spring-loaded PEEP valve, can be used.

Figure 30-16. Schematic of a simple, selective up-lung continuous positive airway pressure system. The fresh inflow of oxygen is restricted or limited by a pressure release valve, and therefore a constant distending airway pressure to the nonventilated lung occurs. The dependent lung can be ventilated with positive end-expiratory pressure (PEEP) or zero end-expiratory pressure (ZEEP). (Reproduced with permission from Benumof JL: *Physiology of the open-chest and one lung ventilation*. In Kaplan JA [ed]: *Thoracic Anesthesia*, p 310. New York, Churchill Livingstone, 1983.)

High-frequency ventilation with oxygen to the nondependent lung and conventional ventilation to the dependent lung has also been used to improve P_{aO_2} during one-lung ventilation (see [High-Frequency Ventilation](#), later).

Clinical Approach to Management of One-Lung Ventilation

Once the patient is in the lateral position, the position of the double-lumen tube should be rechecked. Two-lung ventilation should be maintained for as long as possible, and when one-lung ventilation needs to be instituted, it is generally recommended that an F_{iO_2} of 1.0 be used. The lungs should be ventilated using a V_T of 10–12 ml · kg⁻¹ at a rate adjusted to maintain P_{aCO_2} at 35 ± 3 mm Hg. This is usually monitored with the use of a capnometer or other multigas analyzer.

After initiation of one-lung ventilation, P_{aO_2} can continue to decrease for up to 45 minutes.⁴⁴ Frequent monitoring of arterial blood gases and use of a pulse oximeter continue throughout the operative period. It is also essential to work closely with the surgeon. If there are any questions concerning the position of the double-lumen tube, and if fiberoptic bronchoscopy is not available, the surgeon can palpate the tube and help to manipulate it into the correct position with direct digital guidance.

If hypoxemia occurs during one-lung ventilation, the position of the double-lumen tube should be rechecked using a fiberoptic bronchoscope. If the dependent lung is not severely diseased, a satisfactory P_{aO_2} on two-lung ventilation should not decrease to dangerously hypoxic levels on one-lung ventilation. If a left thoracotomy is being performed using a right-sided double-lumen tube, ventilation to the right upper lobe should be ensured. After the tube position has been confirmed as correct, CPAP₁₀ should be applied to the nondependent lung after a V_T that expands the lung. In most cases, the P_{aO_2} increases to a safe level. During thoracoscopy, application of CPAP is usually not possible because it impedes the surgeon. This is especially so during VAT surgical procedures. In this case, PEEP to the ventilated lung may be tried.

In the very rare case in which the P_{aO_2} remains low despite all of these maneuvers, intermittent two-lung ventilation can be reinstated with the surgeon's cooperation. Also, depending on the stage of surgical dissection, if a pneumonectomy is being performed, ligation of the pulmonary artery eliminates the shunt.

During one-lung ventilation, the peak airway pressure, the effective V_T delivered (measured by a spirometer), the shape of the capnogram, and, if available, the pressure–volume loop, should be checked continuously. A sudden increase in peak airway pressure may be secondary to tube dislocation because of surgical manipulation, resulting in impaired ventilation. In addition, the ability to auscultate by a stethoscope over the dependent lung is extremely important.

If any questions arise about the stability of the patient, or if the patient becomes hypotensive, dusky, or tachycardic, two-lung ventilation should be resumed until the problem has been resolved. Because of pericardial manipulation (during left thoracotomy in particular) and pulling on the great vessels, cardiac arrhythmias and hypotension are not uncommon. Cardiotonic drugs should be prepared and kept available for use during any thoracic surgical procedure. Most thoracic surgical procedures represent only relative indications for one-lung ventilation, and the benefits of one-lung ventilation should always be weighed against the risks to the patient.

CHOICE OF ANESTHESIA FOR THORACIC SURGERY

The choice of anesthesia technique for a thoracic surgical procedure must take into account the patient's cardiovascular and respiratory status and the particular effects of anesthetic drugs on these and other organ systems.

Thoracic surgical patients are more likely than others to have increased airway reactivity and a propensity to develop bronchoconstriction. This is because many of these patients are cigarette smokers and have chronic bronchitis or COPD. In addition, surgical manipulation of the airways and bronchial tree by instruments, a double-lumen tube, or the surgeon makes bronchoconstriction more likely to occur. Halothane, enflurane, and isoflurane have all been shown to decrease airways reactivity and bronchoconstriction provoked by hypocapnia or inhaled or irritant aerosols. Their mechanism of action is probably a direct one on the airway musculature itself, and these agents are therefore the drugs of choice in patients with reactive airways. For an inhalation induction, halothane might be preferable because it is the least pungent of the three drugs, although once the patient is asleep isoflurane may be the preferred drug because it raises the cardiac dysrhythmia threshold and provides greater cardiovascular stability. Fentanyl does not appear to influence bronchomotor tone, but morphine may increase tone by a central vagotonic effect and by releasing histamine.

In most patients, anesthesia is safely induced with thiopental, thiamylal, or propofol. In patients with reactive airways, ketamine may be the drug of choice for induction of anesthesia because it has a bronchodilator effect and has been successfully used in the treatment of asthma. Thiopental has been associated with bronchospasm in asthmatic patients, although the reactivity in such cases may be related to inadequate levels of anesthesia before instrumentation of the airway.

The muscle relaxants of choice for thoracic procedures are those that lack a histamine-releasing or vagotonic effect and that have some sympathomimetic effect. In this respect, pancuronium, vecuronium, rocuronium, and cisatracurium probably represent the drugs of choice. Succinylcholine is useful to provide rapid profound relaxation for intubation of the trachea and is not associated with an increase in airways reactivity.

Intravenous lidocaine (1–1.5 mg · kg⁻¹) can be used before manipulations of the airway to prevent reflex bronchospasm. It has also been given by infusion to depress airway reactivity in patients who have poor cardiovascular function and cannot tolerate normal doses of the potent inhaled agents. Intravenous lidocaine has also been used to treat bronchospasm occurring during anesthesia. Lidocaine nebulized and administered *via* the airways has a similar salutary effect on bronchial tone.

Atropine may be used to block the antimuscarinic effects of acetylcholine and thereby protect against cholinergically induced bronchoconstriction. It may be administered intravenously or in nebulized form (see [Bronchoscopy](#)).

HYPOXIC PULMONARY VASOCONSTRICTION

General anesthesia may impair pulmonary gas exchange, and arterial hypoxemia may occur as a result. In patients undergoing halothane–oxygen anesthesia with spontaneous two-lung ventilation, Nunn⁵⁰ found a calculated shunt of 14% of pulmonary blood flow as compared with a calculated shunt of 1% in normal, conscious, supine patients measured using the same techniques. He suggested that the large shunt observed was probably due to perfusion of totally unventilated parts of the lung. Marshall *et al*⁵¹ confirmed this and concluded that postoperative hypoxemia may also be a result of the residual effects of the anesthetic on venous admixture. With this background, many investigators have studied the regulation of the pulmonary circulation through a homeostatic mechanism called hypoxic pulmonary vasoconstriction (HPV), which normally diverts blood away from hypoxic regions of the lung and thereby optimizes the gas exchange function of the lung.

Hypoxic pulmonary vasoconstriction was first described by Von Euler and Liljestrand in 1946.⁵² They were studying changes in the pulmonary circulation of the cat in response to changes in inspired gas mixtures and found that 10.5% inspired O₂ (in N₂) mixtures caused an increase in pulmonary artery pressure. Breathing 100% O₂ caused a decrease in pulmonary artery pressure. They concluded that the increased pressure during hypoxia was caused by a direct effect on the pulmonary vessels. Whereas they delivered hypoxic gas mixtures to both lungs, others have studied the effects of the size of the hypoxic segment and the size of the hypoxic stimulus on

perfusion pressure and on flow diversion. Pulmonary perfusion pressure (in dogs) increased with the size of the hypoxic segment from zero (smallest hypoxic segment) to approximately 2.2 times baseline for the hypoxic whole lung. Flow diversion, as a percentage of flow to the test segment under normoxic conditions, decreased with increasing size of the hypoxic test segment from a maximum of 75% for very small segments to zero when the whole lung was made hypoxic. Flow diversion increased linearly as P_{aO_2} was decreased over the range of 128–28 mm Hg. In both flow diversion and changes in perfusion pressure, the response to HPV was predictable, continuous, and maximal at a predicted P_{aO_2} of 30 mm Hg (4% oxygen). Thus, HPV causes a rise in both perfusion (pulmonary artery) pressure and flow diversion.⁵³

The choice of anesthetic technique for one-lung ventilation must take into consideration the effects on oxygenation and therefore on HPV. Normally, collapse of the nonventilated, nondependent lung results in activation of reflex HPV in this lung. This causes local increases in pulmonary vascular resistance and diversion of blood flow to other, better oxygenated parts of the pulmonary vascular bed (*i.e.*, the dependent oxygenated and ventilated lung). The stimulus to HPV appears to be a function of both P_{aO_2} and $P\bar{V}_{O_2}$ in isolated rat lungs ventilated with hypoxic mixtures, but in the atelectatic lung the stimulus is the $P\bar{V}_{O_2}$.⁵⁴ A decrease in cardiac output may potentiate HPV by lowering $S\bar{V}_{O_2}$. The response is believed to be accounted for by each smooth muscle cell in the pulmonary arterial wall responding to the oxygen tension in its vicinity. Because HPV causes flow diversion, P_{aO_2} should be higher than if there were no HPV. The relationship between P_{aO_2} and the size of the hypoxic segment (Fig. 30-17) shows that, when little of the lung is hypoxic, HPV has little effect on P_{aO_2} because shunt is small in this situation. When most of the lung is hypoxic, there is no significant normoxic region to which the hypoxic region can divert flow, and then it does not matter, in terms of P_{aO_2} , whether the hypoxic region has active HPV or not. When the amount of lung made hypoxic is 30–70%, such as occurs during one-lung ventilation, there may be a large difference between the P_{aO_2} to be expected with normal HPV compared with that expected in its absence. HPV can raise P_{aO_2} from potentially dangerous levels to higher and safer ones. Conversely, inhibition of HPV may cause or contribute to hypoxemia during anesthesia.

Figure 30-17. Role of hypoxic vasoconstriction in preserving P_{aO_2} (in dogs). Assumptions are shown in insert. Lung is ventilated with $F_{iO_2} = 1.0$, while increasing portions of lung are subjected to hypoxia or atelectasis. In the absence of hypoxic pulmonary vasoconstriction, the expected P_{aO_2} would follow the broken line, whereas in the presence of an active hypoxic pulmonary vasoconstriction response, observed P_{aO_2} is maintained close to the solid line. (P_{aO_2} = alveolar P_{O_2} ; P_{aO_2} = arterial P_{O_2} .) (Adapted with permission from Marshall BE, Marshall C, Benumof JL *et al*: Hypoxic pulmonary vasoconstriction in dogs: Effects of lung segment size and alveolar oxygen tension. *J Appl Physiol* 51:1543, 1981.)

Effects of Anesthetics on Hypoxic Pulmonary Vasoconstriction

All of the inhalation anesthetics and many of the intravenous drugs used in anesthesia have been studied for their effects on HPV. The results have not always been consistent. Benumof⁵⁵ has classified the preparations used to study these effects as *in vitro*, *in vivo* nonintact, *in vivo* intact, and human studies. Based on the results of these three types of preparation, it is generally believed that inhaled agents inhibit HPV, whereas intravenous drugs do not have this effect.⁵⁶

Human studies are perhaps the most significant because of their applicability to the clinical situation. Bjertnaes⁵⁷ used perfusion scans (scintigraphy) to assess the effect of anesthetics on human HPV. In his patients, lung separation was achieved using a double-lumen tube. One lung could then be ventilated with 100% O_2 and the other with 100% nitrogen. HPV was assessed in the presence and absence of ether, halothane, and intravenous drugs (thiopental and fentanyl). Based on his scintigraphic findings, Bjertnaes⁵⁷ concluded that the inhaled agents, in clinically useful concentrations, inhibited HPV in humans.

Jolin Carlsson *et al*⁵⁸ used separate lung ventilation and a triple-gas washout technique to study HPV in eight patients. They demonstrated the presence of HPV in response to 8% O_2 in 92% nitrogen in the test lung but found no further change with the addition of 1.0% or 1.5% end-tidal isoflurane, and blood gas readings remained essentially unaltered. Attempts to use higher concentrations caused unacceptable hypotension. These authors concluded that isoflurane might be indicated for anesthesia in the presence of lung disease or during one-lung ventilation because arterial oxygenation might be better preserved than would be the case with an anesthetic that more effectively inhibited HPV. Thus, although it is possible that higher concentrations of isoflurane might have caused a clear change in the differential blood flow distribution, at clinically used concentrations the effect of HPV in their subjects was all but unmeasurable.

Weinreich *et al*⁵⁹ used a ketamine infusion and found a lower incidence of hypoxemia (defined as $P_{aO_2} < 70$ mm Hg) than other studies reporting the use of halothane for one-lung ventilation. Rees and Gaines⁶⁰ compared a ketamine–oxygen technique with an enflurane (1–3% inspired)–oxygen technique for one-lung ventilation and found no differences between the groups in P_{aO_2} or shunt. These findings suggested that ketamine afforded no advantage over enflurane during one-lung ventilation.

Rogers and Benumof⁶¹ compared the effects of inhaled (isoflurane and halothane) with intravenous (methohexital and ketamine) anesthesia during one-lung ventilation and concluded that the inhaled anesthetics at approximately 1 minimum alveolar concentration (MAC) do not significantly affect HPV in humans, as evidenced by a lack of significant differences in P_{aO_2} between use of the two techniques. The conclusions of this study have been questioned because the period of clinical exposure to the potent inhaled agents was very short. Thus, clinically relevant tissue concentrations of anesthetic may not have been achieved.

In a subsequent study, Benumof *et al*⁶² investigated the changes in P_{aO_2} and shunt that occurred after conversion from 1 MAC halothane or isoflurane anesthesia to intravenous anesthesia (fentanyl, diazepam, and sodium thiopental) during one-lung ventilation for thoracic surgery in 12 patients. In this study, they found that during one-lung atelectasis, 1 MAC halothane anesthesia slightly but significantly increased shunt and decreased P_{aO_2} (compared with intravenous anesthesia), whereas 1 MAC isoflurane anesthesia very slightly but nonsignificantly increased shunt and decreased P_{aO_2} (compared with intravenous anesthesia). Fundamental differences between the two studies^{61,62} were in the duration of the periods of one-lung ventilation with the potent inhaled agent and in the MAC multiples of the drugs used. In the earlier study,⁶¹ end-tidal concentrations of halothane and isoflurane were kept constant for approximately 20 minutes at 1.45 and 1.15 MAC, respectively. In the later study,⁶² patients were maintained on one-lung anesthesia with the potent inhaled agent (1 MAC) for 40 minutes before final measurements under these conditions were taken. The authors also concluded that halothane and isoflurane had only a small inhibitory effect on the one-lung HPV response.⁶² A randomized crossover study during one-lung ventilation with an F_{iO_2} of 1.0 found that 1 MAC isoflurane anesthesia was associated with greater P_{aO_2} values than was 1 MAC enflurane.⁶³ Shimizu *et al* compared the effects of isoflurane and sevoflurane on P_{aO_2} during one-lung ventilation in 20 patients undergoing thoracotomy and found no significant difference between the groups in P_{aO_2} , concluding that both agents can be used safely.⁶⁴ In an *in vitro* study Loer *et al* showed that desflurane inhibits HPV, with an ED_{50} of 1.6 MAC.⁶⁵

Thus, overall, the potent inhaled anesthetics are the drugs of choice during thoracic surgery. The technique chosen should, however, always be dictated by the needs of the particular patient, so that in the presence of cardiovascular instability or poor oxygenation when depression of HPV is a possibility, a balanced technique may be chosen. Propofol in doses of 6–12 mg · kg⁻¹ · hr⁻¹ does not abolish HPV during one-lung ventilation in humans.⁶⁶

Other Determinants of Hypoxic Pulmonary Vasoconstriction

Aside from potent inhaled agents, other drugs and maneuvers used during anesthesia may also have an inhibitory effect on regional or whole-lung HPV. Factors associated with an increase in pulmonary artery pressure antagonize the effect of increased resistance caused by HPV and result in increased flow to the hypoxic region. Such indirect inhibitors of HPV include mitral stenosis, volume overload, thromboembolism, hypothermia, vasoconstrictor drugs, and a large hypoxic lung segment. Direct inhibitors of HPV include infection; vasodilator drugs, such as nitroglycerin and nitroprusside; hypocarbia; and metabolic alkalemia. All of these

potential inhibitors should be considered when evaluating a patient for hypoxemia during thoracic surgery.

Potentiators of Hypoxic Pulmonary Vasoconstriction

Whereas in the past most research effort has been directed to studying inhibition of HPV, more recent research has investigated substances that may potentiate it. Almitrine, a respiratory stimulant drug, has been found to improve PaO_2 in patients with COPD and to have this effect in the absence of ventilatory stimulation. Indirect evidence suggested that it may potentiate HPV in intact dogs, although a subsequent and more extensive study with dogs concluded that almitrine caused nonspecific pulmonary vasoconstriction that was greater in the 100% oxygen-ventilated lung than in the hypoxic lung regions, thus causing a reduction of the HPV response.⁶⁷

It has been suggested that prostaglandins may play a role in HPV inhibition, and therefore prostaglandin inhibitors have been investigated as potentiators of HPV. Ibuprofen, a cyclo-oxygenase inhibitor, has been found to potentiate HPV in hypoxic isolated rat lung preparations and to reverse the inhibition of HPV caused by halothane. In an animal model, lidocaine has also been found to have salutary effects in terms of reversing depression of HPV. The value, if any, of such potentiators in humans undergoing one-lung anesthesia has not yet been reported.

Nitric Oxide and One-Lung Ventilation

Nitric oxide is an endothelial-derived relaxing factor that appears to be an important mediator for smooth muscle relaxation.⁶⁸ HPV is inhibited by inhaled nitric oxide. Inhibition of nitric oxide synthase (NOS) improved, but did not completely restore, HPV in dogs suffering from sepsis.⁶⁹ Frostell *et al*⁷⁰ showed that inhalation of nitric oxide selectively induced vasodilation and reversed HPV in healthy humans without causing systemic vasodilatation. It was theorized that intravenous administration of almitrine (to increase HPV) causing vasoconstriction throughout the lung together with inhalation of nitric oxide to inhibit HPV locally and cause increased flow in the ventilated regions, would improve V/Q matching and PaO_2 in patients with V/Q mismatching or during one-lung ventilation.⁷¹

Moutafis *et al*⁷² studied the effects of inhaled nitric oxide in combination with almitrine infusion during one-lung ventilation in 40 patients undergoing thoracoscopic procedures. They found that inhaled nitric oxide alone did not affect PaO_2 during one-lung ventilation but the additional infusion of almitrine $16 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ caused a marked increase in PaO_2 . These authors suggested that this nonventilatory technique should be of value during special thoracic procedures, such as thoracoscopy, where there is a need to manipulate the pulmonary circulation to improve PaO_2 but measures such as PEEP and CPAP cannot be used. Moutafis *et al*⁷³ have also reported the use of almitrine infusion/nitric oxide inhalation to improve PaO_2 during one-lung ventilation for bronchopulmonary lavage.

While the use of almitrine appears to be attractive, this drug is not without side effects.⁷⁴ Also, the manufacturer has not made it available outside of France. Possible alternatives to almitrine might be phenylephrine⁷⁵ and prostaglandin F_{2a} .⁷⁶

ANESTHESIA FOR DIAGNOSTIC PROCEDURES

Bronchoscopy

Early bronchoscopes were of the rigid type, but in 1966 the Machida and Olympus Companies introduced the first practical bronchofiberscopes. Since then, these have been improved dramatically and have simplified many otherwise complicated bronchoscopies. The indications for bronchoscopy are shown in [Table 30-3](#) and the instruments of choice in [Table 30-4](#). Operator preferences and experience may play a major role in the choice of instrument.

| Diagnostic | Therapeutic |
|-----------------------------------|----------------------------------|
| Cough | Foreign bodies |
| Hemoptysis | Accumulated secretions |
| Whooping | Atelectasis |
| Atelectasis | Aspiration |
| Unresolved pneumonia | Lung abscess |
| Diffuse lung disease | Reposition endotracheal tubes |
| Preoperative evaluation | Placement of endobronchial tubes |
| Risk of metastases | Laser surgery of the airway |
| Abnormal chest radiograph | |
| Assess local disease recurrence | |
| Recurrent laryngeal nerve palsy | |
| Diaphragm paralysis | |
| Acute intubation injury | |
| Exclude tracheoesophageal fistula | |
| During mechanical ventilation | |
| Selective bronchography | |

Table 30-4. INSTRUMENTS OF CHOICE FOR BRONCHOSCOPY

Before bronchoscopy is performed, the patient must be evaluated for chronic lung disease, respiratory obstruction, bronchospasm, coughing, hemoptysis, and infectivity of secretions. Medications should be reviewed, and the need for a more major procedure should always be anticipated. Thus, bronchoscopy may lead to thoracotomy or sternotomy. The planned technique for bronchoscopy should be discussed with the surgeon before the operation, and all equipment and connectors should be checked for compatibility. Monitoring during bronchoscopy should include an electrocardiogram, a blood pressure cuff, a precordial stethoscope, and a pulse oximeter. If thoracotomy is planned, an arterial cannula should also be placed as well as other monitors (e.g., PA or CVP catheters) that may be indicated by the patient's condition. Many anesthetic techniques are useful for bronchoscopy.

Local Anesthesia

The patient should first be pretreated with a drying agent. The local anesthetics most commonly used are lidocaine and tetracaine. In all cases, the total dose of anesthetic must be considered and the potential for toxicity recognized. A nebulizer can be used to spray the oropharynx and base of the tongue, or the patient may gargle viscous lidocaine. The tongue is then held forward, and pledgets soaked in local anesthetic are held in each piriform fossa using Krause forceps to achieve block of the internal branch of the superior laryngeal nerve. Tracheal anesthesia is achieved by a transtracheal injection of local anesthetic, or by spraying the vocal cords and trachea under direct vision using a laryngoscope or through the suction channel of the bronchofiberscope. Alternatively, a superior laryngeal nerve block can be performed by an external approach, and a glossopharyngeal block can be used to depress the gag reflex. These blocks cause depression of airway reflexes, so that patients must be kept on nothing by mouth for several hours after the examination. If fiberoptic bronchoscopy is to be performed transnasally, the nasal mucosa should be pretreated topically with 4% cocaine, or viscous lidocaine may be administered through the nares. Local anesthesia for bronchoscopy has the advantages of a patient who is awake, cooperative, and breathing spontaneously. Sedatives may be added to make the patient more comfortable. Disadvantages of local anesthesia include poor tolerance of any bleeding by the patient and the occasional lack of patient cooperation.

General Anesthesia

General anesthesia for bronchoscopy is often combined with topical laryngeal anesthesia so that less general anesthesia is needed. A balanced technique uses N_2O/O_2 , incremental doses of an intravenous drug such as thiopental, an opioid, and a muscle relaxant. A potent inhaled anesthetic technique is also satisfactory, although the use of N_2O may cause some optical distortion for the surgeon because of changes in the refractive index of the gas mixture. In addition, the use of N_2O and potent inhaled agents creates an operating room contamination problem for the waste anesthesia gases, but limited scavenging may be possible by placing a suction catheter in the patient's oropharynx. Unless there is some contraindication, ventilation of the lungs is usually controlled. In any patient undergoing a thoracic diagnostic procedure for a suspected malignancy, the possibility of the myasthenic syndrome with sensitivity to nondepolarizing muscle relaxants must always be considered. Muscle relaxant doses should be titrated to effect using a neuromuscular monitoring system.

Rigid Bronchoscopy

A modern rigid ventilating bronchoscope is essentially a hollow tube with a blunted, beveled tip. Various sizes and designs are available, but in all a side arm is provided for connection to an anesthesia source. A number of techniques have been described for maintaining ventilation and oxygenation during rigid bronchoscopic examination.

Apneic Oxygenation. After preoxygenation and induction of general anesthesia, skeletal muscle paralysis and cessation of intermittent positive-pressure breathing, the P_{aCO_2} increases. During the first minute the increase is ~ 6 mm Hg \cdot min⁻¹. Subsequently, the average rate of increase is 3 mm Hg \cdot min⁻¹. Oxygen is insufflated at 10–15 l \cdot min⁻¹ through a small catheter placed above the carina. If the patient has been adequately denitrogenated, this technique can provide adequate oxygenation for more than 30 minutes.⁷⁷ The apneic period should not be allowed to extend beyond 5 minutes, however, because the technique is limited by buildup of CO_2 , respiratory acidosis, and cardiac dysrhythmias.

Apnea and Intermittent Ventilation. Oxygen and anesthesia gases are delivered to the bronchoscope via the anesthesia circuit. Ventilation is possible only when the eyepiece is in place, which limits the period for instrumentation by the surgeon. Intermittent ventilation of the lungs is achieved by squeezing the reservoir bag. In this way, assuming a good bronchoscope fit in the airway, compliance is constantly monitored, the risk of barotrauma is reduced, and V_T may be estimated. The disadvantage of this technique is that with prolonged bronchoscopies, poor levels of arterial blood gases, and in particular hypercarbia, may result. This may lead to cardiac arrhythmias.

Sanders Injection System. Sanders applied the Venturi principle to provide ventilation of the lungs by attaching a jet ventilator to the bronchoscope.⁷⁸ Oxygen from a high-pressure source (50 psig) is delivered, using a controllable pressure-reducing valve and toggle switch, to a 2.5–3.5-cm 18- or 16-gauge needle inside and parallel to the long axis of the bronchoscope. When the toggle switch is depressed, the jet of oxygen entering the bronchoscope entrains air, and the air–oxygen mixture resulting at the distal tip of the bronchoscope emerges at a pressure to provide adequate ventilation and oxygenation. The intraluminal tracheal pressure depends on the driving pressure from the reducing valve, the size of the needle jet, and the length, internal diameter, and design of the bronchoscope. Increasing the size of the needle jet increases the total gas flow for any given driving pressure. For each combination of gas driving pressure, jet orifice, and bronchoscope diameter, only one inflation pressure can be attained, regardless of the volume or compliance of the lung. As long as the proximal end of the bronchoscope is open, the system is strictly pressure limited, and the pressure does not increase because of obstruction at the distal end. Pressure varies inversely with the cross-sectional area of the bronchoscope, so that insertion of a suction catheter or biopsy forceps into the lumen causes the intratracheal pressure to increase. Provided there is not a tight fit between the bronchoscope and the airway, the risk of barotrauma is low. If the fit is tight, driving pressure should be decreased.

The advantages of the Sanders system are that because continuous ventilation is possible (because the presence of an eyepiece is not necessary for ventilation of the lungs), the duration of the bronchoscopy procedure is minimized, but the efficiency also permits extended bronchoscopy. A disadvantage is that entrainment of air by the oxygen jet results in a variable F_{IO_2} at the distal end of the bronchoscope, ventilation of the lungs may be inadequate if compliance is poor, and adequacy of ventilation may be difficult to assess. A comparison between the intermittent ventilation and Sanders techniques found that P_{aO_2} was satisfactory with either method but was higher in the intermittent ventilation group.⁷⁹ P_{aCO_2} was lower and arterial pH higher in the Sanders group, indicating superiority of this method, particularly for long procedures.

The basic Sanders technique has been modified to increase F_{IO_2} and to deliver N_2O and potent inhaled anesthetics. The 16-gauge oxygen jet has been replaced with a longer jet (Carden side arm) that allows ventilation with 100% oxygen and the development of much higher pressures at the tracheal end of the bronchoscope, while using a driving pressure of 50 psig. The Sanders injector system may also be used with a ventilating bronchoscope, the side arm of which is connected to a supply of anesthesia gases, so that the injection jet entrains the anesthesia gases.⁸⁰

Mechanical Ventilator. Ventilation of the lungs may be achieved by connecting a mechanical ventilator to an anesthesia circuit that is connected to the bronchoscope side arm.

High-Frequency Positive-Pressure Ventilation. High-frequency positive-pressure ventilation (HFPPV) has been used in conjunction with rigid bronchoscopy and has been compared with the Sanders injector in patients with tracheobronchial stenosis. With HFPPV of up to 150 breaths \cdot min⁻¹, blood gases were identical with both techniques. At a frequency of 500 breaths \cdot min⁻¹, oxygenation deteriorated and CO_2 was not removed effectively. HFPPV has the advantage that the tracheobronchial wall remains perfectly immobilized during ventilation.⁸¹

Other Techniques. Cuirass ventilation, external chest compression, and a ventilating catheter or endotracheal tube placed alongside the bronchoscope have also been used to provide ventilation during bronchoscopy.

Fiberoptic Bronchoscopy

The new generations of fiberscopes, with their improved optics and smaller diameters, have revolutionized bronchoscopy. Examination of the fifth order of bronchial branching is now possible, and the diagnostic potential of this instrument is thereby enhanced. The flexibility has also been applied in preoperative assessment of the airway, management of difficult tracheal intubations, endotracheal tube positioning and change, bronchial toilet, correct positioning of double-lumen tubes, bronchial blockade, and evaluation of the larynx and trachea.

Nasal fiberoptic bronchoscopy under topical anesthesia is well tolerated by most awake patients. A suction catheter in the mouth is useful to remove oral secretions. Oral insertion is also possible in both awake and asleep patients and should be performed via a specially designed airway, which guides the fiberscope over the back of the tongue and prevents potential damage to it by the patient's teeth.

Physiologic Changes Associated with Fiberoptic Bronchoscopy. In all patients, insertion of the fiberoptic bronchoscope is associated with hypoxemia. The average decline in P_{aO_2} is 20 mm Hg and lasts for 1–4 hours after the procedure. By 24 hours, the blood gas tensions are usually back to normal. It is therefore recommended that if the initial P_{aO_2} is 70 mm Hg ($F_{IO_2} = 0.21$), bronchoscopy should be performed only with the administration of supplemental oxygen. This can be provided using mouth-held nasal prongs, a special face mask with a diaphragm through which the fiberscope can be passed, or an endotracheal tube with a T-piece diaphragm adapter.

During and after fiberoptic bronchoscopy, patients experience increased airway obstruction. Thus, in 35 patients, insertion of the bronchoscope was associated with an increase in FRC (17–30%) and decreases in P_{aO_2} , vital capacity, FEV_1 , and forced inspiratory flow.⁸² All had returned to baseline by 24 hours. These changes are thought to be secondary to direct mechanical activation of irritative reflexes in the airway and, possibly, to mucosal edema. They may be avoided if atropine, either intramuscular or aerosolized into the airway, is administered before the procedure. Isoproterenol has a similar salutary effect on lung function but is associated with an increased incidence of cardiac arrhythmias. Overall, atropine is recommended as premedication for fiberoptic bronchoscopy. Concern that atropine may have an overall undesirable effect by increasing viscosity of secretions in patients with COPD is unsubstantiated.

The standard adult fiberoptic bronchoscope has an external diameter of 5.7 mm and a 2-mm diameter suction channel. If suction at 1 atm is applied to the fiberscope, air is removed at a rate of 14 l \cdot min⁻¹. If the fiberscope is in the airway, this causes decreases in F_{IO_2} , P_{aO_2} , and FRC, leading to decreased P_{aO_2} . Suctioning should therefore be kept brief. The adult fiberscope passes through endotracheal tubes of 7 mm or greater internal diameter. Clearly, passage through an endotracheal tube decreases the cross-sectional area available for ventilating the patient, so that if fiberoscopy is planned, an endotracheal tube of the largest possible diameter should

be used.

Insertion of the bronchoscope also causes a significant PEEP effect, that may result in barotrauma in ventilated patients. If PEEP is already being used, it should be discontinued before passage of the fiberscope. A postendoscopy chest radiograph is advisable to exclude the presence of mediastinal emphysema or pneumothorax. In patients whose tracheas are intubated with endotracheal tubes of less than 8 mm internal diameter, use of pediatric fiberscopes, which have smaller diameters, would be more appropriate.

The suction channel of the adult fiberoptic bronchoscope has been used to oxygenate and ventilate the lungs of patients. By attaching a jet ventilation system (similar to that used to drive the Sanders injector for rigid bronchoscopy) to the suction connection at the head of a fiberoptic bronchoscope, successful ventilation of the lungs of patients undergoing gynecologic procedures was achieved.⁸³ A driving pressure of 50 psig of oxygen was used with a ventilatory rate of 18–20 breaths · min⁻¹. This technique permitted adequate ventilation of patients with normally compliant lungs and chest walls. Ventilation of the lungs should be performed only with the tip of the instrument in the trachea because a more peripheral location may produce barotrauma.

Neodymium-yttrium-aluminum garnet (Nd-YAG) lasers are used for the resection of obstructing and endobronchial lesions. This procedure is performed under general anesthesia. The lasers may be introduced into the bronchial tree through a fiberoptic bundle passed *via* the suction port of the fiberoptic bronchoscope. During laser resection, F_{IO₂} should be kept to a minimum and titrated against oxygen saturation (as continuously monitored by pulse oximeter) to make endotracheal fire less likely. Laser therapy of bronchial tumors is also possible using a rigid bronchoscope. HFPPV through a rigid bronchoscope provides satisfactory operating conditions for laser resection of tracheal tumors and has the advantage of producing airway immobility.

Complications of Bronchoscopy

Complications of rigid bronchoscopy include mechanical trauma to the teeth, hemorrhage, bronchospasm, loss of a sponge, bronchial or tracheal perforation, subglottic edema, and barotrauma. The incidence of complications is much lower with fiberoptic bronchoscopy. Nevertheless, complications may arise owing to overdose with topical anesthetic, insertion trauma, local trauma, hemorrhage, upper airway obstruction related to passage of the instrument through an area of tracheal stenosis, hypoxemia, and bronchospasm. In most cases, it is best to intubate the trachea with an endotracheal tube after bronchoscopy under general anesthesia. This permits avoidance or treatment of some of these problems, particularly the increased airway irritability. Intubation also facilitates effective suctioning of the trachea and bronchi and allows the patient to recover more gradually from general anesthesia.

DIAGNOSTIC PROCEDURES FOR MEDIASTINAL MASSES

Patients with an anterior mediastinal mass present a special problem for the anesthesiologist. Although such masses may cause obvious superior vena cava obstruction, they may also cause obstruction of major airways and cardiac compression, which are less obvious and may become apparent only on induction of anesthesia. Three cases of anterior mediastinal mass were described,⁸⁴ in two of which airway obstruction occurred after induction of anesthesia and onset of paralysis. In the first case, total occlusion of the trachea starting 2–3 cm above the carina and extending to both mainstem bronchi was observed, and a bronchoscope was passed through the obstruction. In the second case, extrinsic compression of the left mainstem bronchus occurred on inspiration during recovery from anesthesia. In the third case of anterior mediastinal mass, flow–volume studies were performed with the patient in the upright and supine positions and demonstrated marked reductions in FEV₁ and peak expiratory flow in the latter position. These findings suggested potential obstruction with onset of anesthesia; radiation therapy to the mediastinum was commenced, after which the flow–volume studies showed improved function. The planned surgical procedure was then performed under local anesthesia.

One potential disadvantage of preoperative radiation therapy is that it may affect tissue histologic appearance, thereby preventing an accurate diagnosis. Furthermore, if the patient is a child, it may be difficult to obtain tissue samples under local anesthesia. In a series of 44 patients ages 18 years of age or younger with anterior mediastinal masses who underwent general anesthesia before radiation or chemotherapy, no fatalities occurred. However, seven patients had airway compromise.⁸⁵ This report concluded that general anesthesia may be safely induced before radiation therapy and that the benefits of obtaining an accurate tissue diagnosis outweighed the risks.⁸⁵ Others have disagreed with these conclusions, stating that anesthesia is not safe when the reported rate of life-threatening complications is 16–20%.

Airway obstruction caused by an anterior mediastinal mass has been attributed to changes in lung and chest wall mechanics associated with changes in position or to onset of paralysis in muscles that previously maintained airway patency. Preoperative evaluation of a patient with an anterior mediastinal mass in order to avoid life-threatening total airway obstruction is shown in [Figure 30-18](#).⁸⁴ It is important to determine in the history if the patient has dyspnea in the supine position and to examine the computed tomographic scan to determine the extent of the tumor and its effect on surrounding structures. If such obstruction occurs, it may be relieved by passage of a rigid bronchoscope or anode tube past the obstruction, by direct laryngoscopy,⁸⁶ or by changing the position of the patient.

Figure 30-18. Flow chart describing the preoperative evaluation of the patient with an anterior mediastinal mass. (+ indicates positive finding; – indicates negative work-up.) (Reproduced with permission from Neuman GC, Weingarten AE, Abramowitz RM *et al*: Anesthetic management of the patient with an anterior mediastinal mass. *Anesthesiology* 60:144, 1984.)

In a situation in which the biopsy procedure cannot be performed under local anesthesia and there is concern that muscle paralysis may result in airway compression, fiberoptic intubation of the awake patient followed by general anesthesia with spontaneous ventilation has been described for thoracotomy. Thus, during spontaneous inspiration, the normal transpulmonary pressure gradient distends the airways and helps to maintain their patency, even in the presence of extrinsic compression.

Mediastinoscopy

Mediastinoscopy was introduced as a means of assessing spread of carcinoma of the bronchus. The lymphatics of the lung drain first to the subcarinal and paratracheal areas and then to the sides of the trachea, the supraclavicular areas, and the thoracic duct. Examination of these nodes has provided a tissue diagnosis and greater selectivity of patients for thoracotomy. It is most useful in right-lung tumors because left-lung cancers tend to spread to subaortic nodes that are more accessible by an anterior mediastinoscopy in the second or third interspace (Chamberlain procedure). Apart from diagnostic uses, mediastinoscopy has also been used to place electrodes for atrial-triggered pacing. The transcervical approach to the thymus is an adaptation of mediastinoscopy.

The anesthetic considerations for mediastinoscopy follow naturally from an understanding of the anatomy of this procedure and its potential complications. For cervical mediastinoscopy, the patient is placed in a reverse Trendelenburg position, and the mediastinoscope is inserted into the superior mediastinum through a transverse incision just above the suprasternal notch. The instrument is advanced along the anterior aspect of the trachea and passes behind the innominate vessels and the aortic arch ([Fig. 30-19](#)). The left recurrent nerve is vulnerable as it loops around the aortic arch, and any of these structures may be traumatized. Because of scarring, previous mediastinoscopy is a contraindication to a repeat examination. Relative contraindications include superior vena cava obstruction, tracheal deviation, and aneurysm of the thoracic aorta.

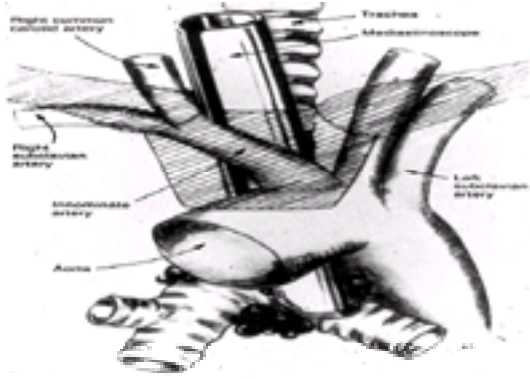

Figure 30-19. Anatomic relationships during mediastinoscopy. Note the position of the mediastinoscope behind the right innominate artery and aortic arch and anterior to the trachea. (Reproduced with permission from Carlens E: Mediastinoscopy: A method for inspection and tissue biopsy in the superior mediastinum. *Dis Chest* 36:343, 1959.)

Preoperative evaluation should include a search for airway obstruction or distortion. Review of a computed tomographic scan is very helpful in this regard. Evidence of impaired cerebral circulation, history of stroke, or signs of the Eaton-Lambert syndrome resulting from oat cell carcinoma should be sought. Blood must be available for the procedure because hemorrhage is a real risk and may be life threatening.

Mediastinoscopy may be performed under local anesthesia, and this approach is claimed to offer greater simplicity and safety in patients with limited pulmonary reserve or in those with cerebrovascular disease. However, most surgeons and anesthesiologists prefer general anesthesia using an endotracheal tube and continuous ventilation because this offers a more controlled situation and greater flexibility in terms of surgical manipulation. The anesthetic technique should include a muscle relaxant to prevent the patient from coughing because this may produce venous engorgement in the chest or trauma by the mediastinoscope to surrounding structures.

The incidence of morbidity with mediastinoscopy has been reported as 1.5–3.0%, and that of mortality, 0.09%. The most common complication is hemorrhage (0.73%) because of the proximity of major vessels and the vascularity of certain tumors. Tamponade may be the only recourse, and thoracotomy or median sternotomy may be required to achieve hemostasis. Needle aspiration of any structure is essential before any biopsy is taken. If severe bleeding occurs, induced arterial hypotension may be helpful in reducing the size of the tear in a vessel. If bleeding is venous, fluids given *via* an upper limb vein may enter the mediastinum, in which case a large-bore catheter should be placed in a lower limb vein. A venous laceration may also result in air embolism, particularly if the patient is breathing spontaneously. Some recommend the use of a precordial Doppler probe if the risk of air embolism is likely.

Pneumothorax is the second most common complication (0.66%). It is usually right-sided, often recognized at the time of the occurrence, and is treated according to size. A symptomatic pneumothorax should be treated by chest tube decompression.

Recurrent laryngeal nerve injury occurred in 0.34% of cases and was permanent in 50% of these cases. The nerve may be damaged by the mediastinoscope or be involved in tumor. Such injury is not a problem unless both nerves are damaged, in which case upper airway obstruction may result. Autonomic reflexes may be initiated by manipulation of the trachea or the aorta, the latter having pressor receptors located in the arch. Vagally mediated reflexes may be blocked by atropine.

“Apparent” cardiac arrest has been reported when the right radial pulse was monitored using a plethysmograph, and the tracing suddenly disappeared in the presence of a normal electrocardiogram. A normal pulse returned after the mediastinoscope was removed, and the cause of the apparent arrest was pressure on the innominate artery by the instrument. Decreases in right arm as compared to left arm blood pressure have been reported in cases undergoing mediastinoscopy. Duration was 15–360 seconds. This is of particular significance if there is a history of impaired cerebral circulation or transient ischemic attacks, or if a carotid bruit is present, because transient left hemiparesis may occur after mediastinoscopy. It is therefore recommended that blood pressure be monitored in the left arm and that the right radial pulse be monitored continuously during mediastinoscopy. A decrease in the right radial pulse amplitude is an indication for repositioning the mediastinoscope, especially in a patient with a history of cerebrovascular disease.

Other reported complications include acute tracheal collapse, tension pneumomediastinum, mediastinitis, hemothorax, and chylothorax. A chest radiograph taken in the immediate postoperative period is a useful precaution in all patients after mediastinoscopy.

Thoracoscopy

Thoracoscopy involves the insertion of an endoscope into the thoracic cavity and pleural space. It is used for the diagnosis of pleural disease, effusions, and infectious disease (especially in immunosuppressed patients and those with acquired immunodeficiency syndrome) and for staging procedures, chemical pleurodesis, and lung biopsy. It is also used in therapeutic procedures such as CO₂ laser treatment of spontaneous pneumothorax or bullous emphysema⁸⁷ and Nd-YAG laser vaporization of malignant pleural tumors. A small incision is made in the lateral chest wall, and with the insertion of the instrument, fluid, and biopsy specimens are easily obtained.

This procedure may be performed using local, regional, or general anesthesia, the choice depending on the expected duration of the procedure and the physical status of the patient. The most common methods are local anesthetic infiltration or intercostal nerve blocks two spaces above and below the usual sixth intercostal space. Intercostal blocks also anesthetize the parietal pleura. The addition of a stellate ganglion block helps to suppress the cough reflex that is sometimes provoked during manipulation of the hilum of the lung.

When air enters the pleural cavity under inspection, a partial pneumothorax occurs, permitting good surgical visualization. Changes in PaO₂, PacO₂, and electrocardiographic rhythm are usually minimal when the procedure is performed using local or regional anesthesia. (The physiology of this situation was discussed in the section on Lateral Position, Awake, Breathing Spontaneously, Chest Open.)

With local anesthesia, the spontaneous pneumothorax is usually well tolerated because the skin and chest wall form a seal around the thoracoscope and limit the degree of lung collapse. Occasionally, however, the procedure is poorly tolerated, and general anesthesia must be induced. The insertion of a double-lumen tube with the patient in the lateral position may be difficult, in which case the patient may be temporarily placed in the supine position for the intubation.

If general anesthesia is required, either a single- or a double-lumen tube may be used. Positive-pressure ventilation interferes with endoscopic visualization, however, and therefore a double-lumen tube is preferable. In addition, if pleurodesis is being performed, general anesthesia through a double-lumen tube allows for complete re-expansion of the lung and avoids the pain associated with instillation of talc for recurrent pneumothorax. To overcome the pathophysiologic effects of the pneumothorax, although small, a high F_IO₂ is recommended for either local or general anesthesia.

Video-Assisted Thoracoscopic Surgery

Video-assisted thoracoscopy (VAT) (see [Chapter 38](#)) entails making small incisions in the chest wall, which allows the introduction of a video camera and surgical instruments into the thoracic cavity.⁸⁸ While the first thoracoscopy was performed by Jacobeus in 1910, using what was at that time a cystoscope, in recent years the surgical techniques, instruments, and video technology have been improved to permit a wide variety of procedures to be performed using VAT. These now include diagnostic procedures for evaluation of pleural disease and effusions, staging of lung cancer, and the identification of parenchymal disease, including nodules, mediastinal tumors and pericardial disease. They also include therapeutic procedures such as operations for pleural disease, including pleurodesis, decortication and drainage of emphysema, resection of lung tissue or bullae, pericardial window or stripping, and esophageal surgery.

Anesthesia Considerations

As with a traditional thoracotomy, for VAT the patient needs to be positioned in the lateral decubitus position, and lung collapse is needed for adequate surgical exposure. This generally mandates use of lung separation. VAT is most commonly performed under general anesthesia with one-lung ventilation. The need for one-lung ventilation is much greater with VAT than with open thoracotomy because it is not possible to retract the lung during a VAT as it is during an open thoracotomy. The operated lung should be deflated as soon as possible after tracheal intubation and positioning, because it may take as much as 30 minutes for complete lung collapse to occur. Also the surgeon enters the thoracic cavity much sooner during a VAT than with open thoracotomy. Suction applied to the airway can help facilitate a more rapid deflation of the lung. In some cases, carbon dioxide is insufflated into the pleural cavity to facilitate visualization by the surgeon. Insufflation

pressures should be as low as possible and the CO₂ inflow rate kept less than 2l · min⁻¹. Higher pressures can cause mediastinal shift, hemodynamic compromise, increases in airway pressure and increases in end-tidal CO₂. Hemodynamic compromise presents a picture similar to that due to tension pneumothorax. Significant hemodynamic changes can be produced when pressures of as little as 5 mm Hg are used to insufflate CO₂ into the chest cavity.⁸⁹

Continuous positive airway pressure (CPAP) is commonly used for the treatment of hypoxemia during one-lung ventilation for thoracotomy and is usually very effective. However, during VAT, CPAP interferes with the surgical procedure, and is only used as a last resort. PEEP to the nonoperated (dependent) lung should be used, rather than CPAP to the operated lung during VAT, and a lower PaO₂ may have to be tolerated during a VAT compared with a thoracotomy.

When a diagnostic VAT is being performed, it is possible to perform the procedure under epidural anesthesia or intercostal nerve blocks. The patient continues to breathe spontaneously, although he or she may require some sedation. During spontaneous respiration, the lung to be operated on collapses because of open chest physiology. If a pneumothorax is created during placement of intercostal nerve blocks, it is not of clinical concern because a pneumothorax occurs as part of the surgical procedure and a chest tube is placed at the conclusion of surgery. For procedures done under local or regional anesthesia techniques, an ipsilateral stellate ganglion block is often placed to inhibit the cough reflex due to manipulation of the hilum of the lung. Anesthesia of the visceral pleura can be achieved using instillation of topical local anesthetic solutions.

Postoperative Concerns

There is less pain after VAT than open thoracotomy and an epidural catheter is usually placed before surgery only if there is a likelihood that a thoracotomy will need to be performed, even though the procedure is starting as a VAT. After a positive biopsy during VAT, an open thoracotomy may be required to perform a lobectomy or pneumonectomy. The patient's respiratory function is better preserved after VAT, and the recovery is faster. However, postoperative arrhythmias, which commonly occur after thoracotomy, have also been reported after VAT. Other complications that may occur include bleeding, pulmonary edema and pneumonia.

ANESTHESIA FOR SPECIAL SITUATIONS

Management of patients with BPFs, empyema, cysts, and bullae, and those requiring tracheal reconstruction is considered here. Many of these cases are appropriately managed using high-frequency ventilatory techniques; therefore, these techniques are described first.

High-Frequency Ventilation

With conventional positive-pressure ventilation, V_T and rates usually exceed or approach those in the normal, spontaneously breathing patient. Gas transport to the alveoli occurs by convection in the larger airways and then by convection and molecular diffusion in the more distal airways and alveoli. High-frequency ventilation differs from conventional positive-pressure ventilation in that smaller V_T and more rapid rates are used. Gas transport may depend more on molecular diffusion, high-velocity flow, and coaxial gas flow in the airways, with gas in the center moving distally and that in the periphery moving proximally.

There are three different types of high-frequency ventilation. *High-frequency positive-pressure ventilation* (HFPPV) uses small V_T at rates of 60–120 breaths · min⁻¹ (1–2 Hz). The ventilator used (e.g., Bronchovent) has a negligible internal compliance, so that the V_T generated, which usually approximates the dead space volume, equals the volume set on the ventilator and represents all fresh gas. The high instantaneous gas flows generated facilitate gas exchange and movement in the conducting airways.

HFPPV may be delivered by an open or a closed system. An example of the former is the percutaneous placement of a transtracheal catheter or placement of a catheter through the nose or mouth with its distal end above the carina. Inflow is intraluminal and outflow is extraluminal. This technique has been used during bronchoscopy, tracheal resection, and reconstructive surgery. When open systems are used, the gas outflow pathway is not established mechanically and depends on natural airway patency. It is therefore subject to compromise. Also, aspiration is a potential complication with open systems.

The closed system is superior because it integrates both airway patency and outflow protection. A closed system is represented by a catheter placed in a short segment of an endotracheal tube for delivery of the HFPPV, whereas the remainder of the tube lumen represents the exit pathway for gas. A quadruple-lumen endotracheal tube (Hi-Lo Jet Tracheal Tube; Mallinckrodt, Inc., Argyle, NY) has been designed specifically for delivery of HFPPV. One lumen is for the HFPPV delivery, one for gas outflow, one for cuff inflation, and one for measuring airway pressures at the distal end of the tube. The use of a closed system also permits application of PEEP, a situation not possible with an open arrangement.

High-frequency jet ventilation (HFJV) uses a pulse of a small jet of fresh gas introduced from a high-pressure source (50 psig) into the airway through a small catheter or additional lumen in an endotracheal tube. Rates used are usually 100–400 breaths · min⁻¹. The fresh gas jet entrains gas from an injection cannula side-port reservoir. This system is somewhat analogous to the Sanders injector system described in the section on Bronchoscopy, and F_{IO₂} is similarly variable. The jet and entrained gas flows cause forward motion of the mass of gas in the airways. HFJV can be used with an open system or with a closed arrangement, as described earlier. In the latter, PEEP may be added to enhance oxygenation. Also, with use of high fresh gas flows from an anesthesia circuit, inhaled anesthetics may be delivered as an entrained gas mixture.

High-frequency oscillation ventilation uses a mechanism that oscillates gas at rates of 400–2400 breaths · min⁻¹. It has not been described in association with thoracic surgical procedures. In this system, V_T is small (50–80 ml), and gas exchange occurs through enhanced molecular diffusion and coaxial airway flow.

The potential advantages offered by HFPPV during thoracic anesthesia are that lower V_T and inspiratory pressures result in a quiet lung field for the surgeon, with minimal movements of airway, lung tissue, and mediastinum. Thus, HFPPV has been used to ventilate both the nondependent and the dependent lung during thoracic surgical procedures, with adequate arterial blood gas measurements obtained throughout. At high frequencies (>6 Hz), however, CO₂ retention may become a problem.

High-frequency jet ventilation has been used to ventilate the nondependent lung to improve PaO₂ during one-lung anesthesia while the dependent lung was ventilated with conventional intermittent positive-pressure ventilation. PaO₂ increased compared with that obtained during simple collapse of the nondependent lung. A study comparing HFJV with CPAP to the nondependent lung during conventional intermittent positive-pressure ventilation to the dependent lung found that both improved PaO₂ significantly during both closed and open stages of the surgery. When the chest was open, HFJV maintained satisfactory cardiac output, whereas CPAP usually decreased cardiac output, but there were no significant differences in PaCO₂ between HFJV and CPAP. Because similar increases in PaO₂ may be obtained using selective CPAP to the nondependent lung and while using much simpler equipment than that necessary to deliver high-frequency ventilation, the use of CPAP would seem preferable to high-frequency ventilation to increase PaO₂ during most one-lung anesthesia situations.

In certain situations, HFJV to the nondependent lung may offer some advantage. Thus, combined unilateral HFJV and contralateral intermittent positive-pressure ventilation in the management of a patient who required a right lower lobectomy for bronchial carcinoma associated with emphysema, pneumoconiosis, and a previous thoracoplasty for pulmonary tuberculosis is reported. This technique has been recommended in any patient requiring partial lung resection in the presence of severe pulmonary impairment.⁹⁰

The lower pressures and V_Ts associated with high-frequency ventilation result in a small leak through BPFs, and HFJV is now generally considered the conservative treatment of choice in this condition. Another advantage of high-frequency ventilation is that the rapid rate small V_T can be delivered through small tubes or catheters, so that if an airway has to be divided, the passage of a small tube across the surgical field permits ventilation of the distal airway and lung tissue. This use has been applied during sleeve resection of the lung, tracheal reconstruction, and surgery for tracheal stenosis. In all three situations, the surgeon is able to work easily around the small catheter used to provide the high-frequency ventilation.

Conventional intermittent positive-pressure ventilation (650 ml × 14 breaths · min⁻¹) to the dependent lung has been compared to HFJV (150–200 breaths · min⁻¹; minute volume 10–15 l) to the dependent lung during one-lung ventilation using an F_{IO₂} of 0.5. There were no significant differences between the groups in PaO₂, PaCO₂, or hemodynamic indices, although shunt fraction was higher in the HFJV group. A significant PEEP effect was also noted in this group, but not in the intermittent positive-pressure ventilation group. The unintentional generation of PEEP during HFJV is well known and is thought to be due to expiratory flow limitation. The PEEP to the dependent lung increases pulmonary vascular resistance in this lung and causes diversion of blood flow to the nondependent, nonventilated lung, thereby increasing shunt fraction (32.9% versus 42.4%). It was concluded that the theoretical benefits of HFJV on the cardiovascular system are outweighed by the effects of mean airway pressure increasing shunt to the nonventilated lung during one-lung anesthesia. Although adequate gas exchange was maintained with HFJV during one-lung anesthesia with F_{IO₂} of 0.5, it was found to be more difficult to assess the adequacy of ventilation during HFJV. Its routine use during one-lung anesthesia is

therefore not recommended.

Bronchopleural Fistula and Empyema

A BPF is an abnormal communication between the bronchial tree and the pleural cavity. Occasionally, there is an additional communication to the surface of the chest, a cutaneous BPF. A BPF occurs most commonly after pulmonary resection for carcinoma. Other causes include traumatic rupture of a bronchus or bulla (sometimes caused by barotrauma or PEEP), penetrating chest wound, or spontaneous drainage into the bronchial tree of an empyema cavity or lung cyst. The incidence of BPF is higher after pneumonectomy than following other types of lung resection. The problems associated with BPF and empyema are that positive-pressure ventilation may result in contamination of healthy lung, loss of air, decreased alveolar ventilation leading to CO₂ retention, and the development of a tension pneumothorax.

If an empyema is present, it should be drained under local anesthesia before any surgery to close the BPF. Drainage is performed with the patient sitting up and leaning toward the affected side. Empyemas are often loculated and complete drainage is not always possible. A drain to an underwater seal system is left in the cavity before administration of anesthesia for surgery of the BPF, and after drainage of an empyema a chest radiograph should be obtained to determine the efficacy of the procedure.

The priorities in the anesthetic management of BPF are the isolation of the affected side in terms of contamination and ventilation. The ideal approach is intubation of the trachea while the patient is awake using a double-lumen tube with the patient breathing spontaneously. Supplemental oxygen should be administered, and the patient should be constantly reassured. Neuroleptanalgesia is satisfactory in providing a suitably cooperative patient, and the airway is then pretreated with topical anesthesia. The endobronchial tube selected should be such that the bronchial lumen is on the side opposite the BPF. Selection of the largest possible tube provides a close fit in the trachea, which helps to stabilize the tube. Once the tube is adequately positioned in the trachea, there may be a considerable outpouring of pus from the tracheal lumen if an empyema is present, and therefore this lumen should be immediately suctioned using a large-bore suction catheter. The healthy and, possibly, the affected lung may then be ventilated; adequacy of oxygenation and ventilation is assessed by pulse oximetry and arterial blood gas analysis.

An alternative technique is to insert the double-lumen tube under general anesthesia, with the patient breathing spontaneously to avoid a tension pneumothorax. With either technique, the chest drainage tube must be left unclamped to avoid any bouts of coughing and to prevent the buildup of a tension pneumothorax in the event that a predisposing valvular mechanism exists. In patients who do not have an empyema, use of a single-lumen tube has been described and may be satisfactory if the BPF and air leak are small. A rapid-sequence induction with ketamine or thiopental followed by a relaxant has also been described but is associated with considerable risk of contamination and tension pneumothorax.

Bronchopleural fistula may also be treated conservatively using various ventilatory techniques. Thus, the bronchus of the normal lung may be intubated and ventilated, allowing the BPF to rest and heal. This approach may result in an intolerable shunt, however, and PEEP may be necessary to maintain PaO₂. Differential lung ventilation using a double-lumen tube has also been described, the healthy lung being ventilated with normal V_T, while the affected lung is exposed to a smaller V_T or to CPAP with oxygen at pressures just below the critical opening pressure of the fistula. The critical opening pressure of the BPF can be assessed by determining the lowest level of CPAP that must be applied to the bronchus on the affected side to produce continuous bubbling through the underwater seal chest drain.

For a large BPF, HFJV may be the nonsurgical treatment of choice. The use of small V_T results in minimal gas loss through the fistula, which may heal more quickly. In addition, hemodynamic effects are usually minimal and spontaneous efforts at ventilation are usually abolished, thereby decreasing the work of breathing and eliminating the need for relaxants or excessive sedation.

High-frequency jet ventilation may not always be superior to conventional ventilation in the conservative management of BPF. Thus, HFJV is less effective in reducing the ventilatory leak through a BPF when the peripheral leak is combined with severe injury and decreased compliance in the remainder of the lung than when only an airway is disrupted. In one series,⁷⁸ HFJV was compared with controlled ventilation of the lungs, and it was found that adequate gas exchange could not be achieved at comparable mean airway pressures with HFJV, although peak airway pressures decreased. Indeed, in some patients, flow through the BPF actually increased with HFJV. Thus, HFJV should be used selectively in patients with BPF.⁹¹

Lung Cysts and Bullae

Air-filled cysts of the lung are usually bronchogenic, postinfective, infantile, or emphysematous. They may be associated with COPD or be an isolated finding. A bulla is a thin-walled space filled with air that results from the destruction of alveolar tissue. The walls are, therefore, composed of visceral pleura, connective tissue septa, or compressed lung tissue. In general, bullae represent an area of end-stage emphysematous destruction of the lung.

Patients may be considered for surgical bullectomy when dyspnea is incapacitating, when the bullae are expanding, when there are repeated pneumothoraces owing to rupture of bullae, or if the bullae compress a large area of normal lung. Most of these patients have severe COPD and CO₂ retention and little functional respiratory reserve. The first consideration in management is maintenance of a high F_{IO₂}. If the bulla or cyst communicates with the bronchial tree, positive-pressure ventilation may cause it to expand or even to rupture if it is compliant, producing a situation analogous to tension pneumothorax. If the bulla is very compliant, most of the applied V_T may be wasted in this additional dead space. Nitrous oxide should be avoided because it causes expansion of any air spaces in the body, including bullae. Once the chest is open, even more of the V_T may enter the compliant bulla, which is no longer limited by chest wall integrity, and an increase in ventilation is needed until the bulla is controlled.

The anesthetic management of these patients is challenging, particularly if the disease is bilateral. Ideally, a double-lumen tube is inserted with the patient awake or under general anesthesia but breathing spontaneously. The avoidance of positive-pressure ventilation (when possible) helps to decrease the likelihood of the potential problems described previously, although oxygenation may be precarious with spontaneous ventilation. Once the endotracheal tube is in place, each lung may be controlled separately, and adequate ventilation can be applied to the healthy lung if bilateral disease is not present. Gentle positive-pressure ventilation with rapid, small V_T and pressures not to exceed 10 cm H₂O may be used during the induction and maintenance of anesthesia, especially if the bullae have been shown to have no or only poor bronchial communication by preoperative ventilation scanning. While the surgery is being performed, as each bulla is resected, the operated lung can be separately ventilated to check for air leaks and the presence of additional bullae.

If positive-pressure ventilation is to be applied before the chest is opened, the possibility of a tension pneumothorax must be kept in mind, and treatment should be readily available. The diagnosis of pneumothorax may be made by a unilateral decrease in breath sounds (this may be difficult to distinguish in a patient with bullous disease), increase in ventilatory pressure, progressive tracheal deviation, wheezing, or cardiovascular changes. Treatment of a pneumothorax involves the rapid placement of a chest tube. An added risk of chest tube placement is the creation of a cutaneous BPF, which causes problems for ventilation. Alternatively, general anesthesia is induced only after the surgeon has prepared the operative field and draped the patient. In the event of sudden deterioration in the patient's condition during induction, the surgeon may perform an immediate median sternotomy. In any event, the time from induction of anesthesia to sternotomy must be kept to a minimum. Thoracoscopic laser ablation of bullae has also been described.⁸⁸

To avoid these problems in a patient with known bullae, HFJV has been used in a patient with a large bulla undergoing coronary artery bypass graft and in another patient undergoing bilateral bullectomy. If bilateral bullectomy is to be performed, a median sternotomy usually is used. Benumof⁹² has described the use of sequential one-lung ventilation using a double-lumen tube in the management of a patient needing bilateral bullectomy. The side with the largest bulla and least lung function, as assessed before surgery by ventilation and perfusion scans, should be operated on first. In this way, the lung with the better function should support gas exchange first. If hypoxemia develops during this one-lung situation, application of CPAP to the nonventilated lung during the deflation phase of a tidal breath should increase PaO₂.

In an extreme situation in which no respiratory reserve exists, it may not be possible to maintain an adequate PaO₂ on one-lung ventilation, and in such a situation it may be necessary to use an extracorporeal oxygenator and femorofemoral bypass may be needed. Heparinization is an additional surgical problem in such cases. Such a severe situation may also be well suited to surgery in a hyperbaric chamber. Oxygenation can be ensured, and the cyst or bulla shrinks under hyperbaric conditions.

Unlike most cases of pulmonary resection, patients after bullectomy are left with a greater amount of functional lung tissue than was previously available to them, and the mechanics of respiration are improved. At the end of the procedure, the double-lumen tube is replaced by a single-lumen tube, and the patients generally require several days to be weaned from the respirator. During this time, the positive airway pressure used should be minimized to avoid causing a pneumothorax owing to rupture of suture or staple lines or of residual bullae.

Lung Volume Reduction Surgery

Emphysematous changes are common in the general population, occasionally resulting in pneumothoraces; a significant number of these patients require surgical intervention. Many surgical procedures have been performed to alleviate the dyspnea in severely emphysematous patients, some with beneficial effect and others

without any proven beneficial outcome. (Table 30-5). Recently, laser and videoscopic technology has been used to ablate small bullae.^{87,93,94} and ⁹⁵

| Unproven Efficacy | Proven Efficacy |
|-------------------------|-------------------------------|
| Costochondrectomy | Transtracheal oxygen catheter |
| Transverse sternotomy | Tracheostomy |
| Thoracoplasty | Needle aspiration of bullae |
| Phrenic nerve resection | Tube thoracostomy |
| Pneumoperitoneum | Bullectomy |
| Abdominal binding | Lung volume reduction |
| Talc pleurodesis | Lung transplantation |
| Sympathectomy | |
| Vagotomy | |

Table 30-5. SURGICAL TREATMENT OF END-STAGE EMPHYSEMA

In 1959, Brantigan, from the University of Maryland, reported on the surgical management of diffuse emphysema. "In patients with distended lungs caused by severe COPD, the normal outward circumferential pull on the bronchioles had been lost, causing their collapse during expiration. Reducing overall lung volume, by means of multiple wedge excisions or plications, would restore the elastic pull on the small airways and reduce expiratory airway obstruction."⁹⁶

He suggested that, in these patients with severe dyspnea, a distended chest, and a flattened diaphragm, surgical excision of a functionless but nonbullous area by multiple wedge resection, can relieve the dyspnea. He proposed an operation ". . . directed at restoration of a physiologic principle . . . and not concerned with the removal of pathologic tissue." Thus, lung volume reduction results in the use of "bilateral multiple wedge excisions of bullous and nonbullous areas of the lung in patients with diffuse emphysema to improve pulmonary mechanics."

Lung volume reduction surgery (LVRS) should not be confused with excision of bullous emphysema or of giant bullae. In these cases, the presumed mechanism of improvement in lung function, exercise tolerance, and oxygenation is secondary to re-expansion of more normal, underlying compressed lung.⁹⁷

The Brantigan procedure did not receive wide acceptance. In the absence of an automated stapler, surgery was performed with a hand-sutured line of resection, which resulted in a high incidence of persistent air leak and an 18–20% mortality rate. The procedure was resurrected by Cooper *et al*⁹⁸ after their experience with lung transplantation in patients with severe emphysema. The critical issue was to determine the optimal size of donor lungs for emphysematous recipients. The TLC of the recipient is much larger than that of the donor lung. If the lung does not fill the recipient chest, complications such as prolonged air leak and pleural effusion will persist. To their surprise, "the distended thorax and the flattened diaphragms in the recipient immediately assumed a more normal configuration postoperatively."⁹⁸ This ability of the chronically distended chest to configure to a smaller volume gave credence to the notion that downsizing the lungs in an emphysematous patient might improve respiratory mechanics by alleviating the overdistention. This is the basis of a resurgence of interest in the Brantigan proposal as to the surgical options for diffuse bullous emphysema (*e.g.*, lung volume reduction).

Outcome of Lung Volume Reduction Surgery

Lung volume reduction surgery (LVRS) gained popularity rapidly.^{99,100} and ¹⁰¹ Because of the possible dramatic increase in the number of procedures without sufficient evidence of beneficial outcome, the National Institutes of Health and the Health Care Finance Agency concluded in 1995 that "although initial results were promising, LVRS was often being performed with insufficient evaluation and a randomized study should be undertaken to evaluate the procedure critically."¹⁰² The National Emphysema Treatment Trial (NETT) was established as a randomized, multicenter, prospective clinical trial of medical versus surgical therapy (LVRS) for treatment of patients with severe bilateral emphysema. Although the outcome of the randomized NETT study is not yet known, there is evidence of beneficial effect of LVRS (at least in the short term). It is beyond the scope of this chapter to review all the published data on LVRS, and the reader is referred to excellent reviews of the subject.^{103,104} and ¹⁰⁵ In brief, Brenner *et al*, in 256 consecutive patients with LVRS reported an 85% survival rate at 1 year and 81% at 2 years.¹⁰⁶ However, there is evidence that the initial improvement in FEV₁, as an indicator of pulmonary function and improvement in airflow, peaks at 6 months and subsequently deteriorates. Alternatively, Gelb *et al* reported that 2 years after LVRS, relief of dyspnea remained improved in 110 out of 112 patients with decrease in TLC as a result of reduction in RV and air trapping.¹⁰⁷

Patient Selection

The patient selection criteria are summarized in Table 30-6. Indications for a good outcome include age younger than 75 years, FEV₁ greater than 0.5 l (FEV₁ of 15–20% of predicted is less useful as a predictor of postoperative respiratory support), PaO₂ greater than 55 mmHg, Paco₂ 40–45 mmHg (>50 mmHg is of concern).

| |
|---|
| PATIENT SELECTION |
| Progressive emphysema |
| Severe, symptomatic dyspnea |
| Radiographic evidence of diffuse emphysema |
| Identifiable distention and hyperinflated lung tissue |
| FEV ₁ < 40%, RV > 150%, TLC > 120% predicted |
| No previous chest surgery |
| Smoking cessation |
| Acceptable cardiac function |
| CONTRAINDICATIONS |
| Age >75 years |
| Uniformly destroyed lungs |
| FEV ₁ < 15% of predicted |
| Paco ₂ > 55 mm Hg |
| O ₂ > 6 l/min |
| Pulmonary hypertension |
| Severe kyphoscoliosis |
| Predominance of chronic bronchitis, asthma |
| Active infection |
| Inability to complete preoperative rehabilitation program |
| FEV ₁ = forced expiratory volume in 1 second, RV = residual volume, TLC = total lung capacity. |

Table 30-6. LUNG VOLUME REDUCTION SURGERY

Lung-Volume Measurement. Body plethysmography (BP) versus inert gas technique (IG) provides some information on the degree of trapped gas in the emphysematous lung (trapped gas index = IG/BP).

Ventilation–Perfusion Scan. The ideal candidate presents with 30–40% reduction in perfusion to the upper lobes. In case of α₁-antitrypsin deficiency, decreased perfusion also is evident in the lower lobes. The least favorable candidates by scanning are those with a patchy, mottled pattern, uniformly affecting the lung.¹⁰⁸

Anesthetic Management

Bronchodilator therapy is continued until the morning of surgery. Morphine and atropine premedication is administered to facilitate insertion of bronchoscopes and tracheal intubation. In addition to steroids, intraoperative bronchodilators are commonly used.

During induction of anesthesia, increases in intrathoracic pressure after neuromuscular blockade should be avoided. These patients are intravascularly depleted and have large wasted muscle mass. They commonly present with polycythemia, which may give a false impression of adequate hydration. Therefore, hydration, stable hemodynamic induction with an agent such as etomidate, and gentle ventilation may attenuate the increase in intrathoracic pressure and the degree of hypotension. Patients who have undergone surgery for emphysematous conditions are best managed with spontaneous respiration as soon as possible after the procedure. Therefore, short-acting neuromuscular blocking agents (rocuronium, atracurium, vecuronium) are indicated. Opioid analgesia can be achieved with fentanyl or

remifentanil infusion.^{109,110}

Pain relief must be optimal as soon as possible because it enables early tracheal extubation and early mobilization, which is crucial to the recovery of these patients. A thoracic epidural catheter is best placed before induction of anesthesia in the sitting position at T3–T4 level.^{111,112} In case of technical difficulty in placing the thoracic catheter, lumbar epidural catheters are used; however, the doses of medication should be increased for effective analgesia.

One-lung ventilation is an absolute requirement, whether the procedure is performed by sternal split or bilateral thoracoscopy.¹¹³ The author (EC) prefers using a double-lumen tra-cheal tube over a Univent for complete and reliable isolation and rapid lung deflation. However, whichever tube is used in these patients with a marginal respiratory reserve, perfect isolation and confirmation with fiberoptic bronchoscopy is mandatory.

In the PACU, it is important to recognize the early signs of tension pneumothorax and dynamic hyperinflation as possible complications. Adequate analgesia, chest physiotherapy, incentive spirometry, and early ambulation are all important for a successful outcome. The most commonly used medications with the epidural catheter are opioids and low-dose bupivacaine combinations, often with a patient-controlled analgesia mode.¹¹²

Anesthesia for Resection of the Trachea

Tracheal resection and reconstruction are technically difficult for the surgeon and challenging for the anesthesiologist. Indications for this type of procedure include congenital lesions (agenesis, stenosis), neoplasia (primary or secondary), injuries (direct or indirect), infections, and postintubation injuries (caused by an endotracheal tube or tracheotomy). For the surgical team, the major problems are maintenance of ventilation to the lungs while the airway is being operated on and postoperative integrity of the anastomoses. In this respect, the presence of lung disease sufficiently severe to require postoperative ventilatory support is a relative contraindication to tracheal resection or reconstruction.

Monitoring of these patients should include placement of an arterial cannula in the left radial artery to permit continuous measurement of blood pressure during periods of innominate artery compression. Steroids should be administered to help reduce any tracheal edema, and a high FiO_2 should be used throughout the procedure to ensure an adequate oxygen reserve at all times in the FRC, so that temporary interruptions of ventilation are less likely to produce hypoxemia.

Numerous methods have been reported to provide oxygenation and ventilation of the lungs during these procedures. A small-bore anode tube may be pushed through and distal to an upper lesion, so that resection may occur around the tube. This technique is useful only in mild stenoses. Alternatively, an endotracheal tube may be passed through the glottis to above the stenosis, and a sterile endotracheal or bronchial tube may later be inserted into the trachea opened distal to the site of stenosis, with the sterile anesthesia tubing being led across the surgical field. After resection of the lesion, the sterile and distally placed endotracheal tube is withdrawn, and the upper tube (originally passed through the glottis) is advanced across the anastomosis. With low tracheal or bronchial lesions, resection and reconstruction may be performed around an endobronchial or double-lumen tube. During these procedures, the patient is kept in a head-down position to minimize aspiration of blood and debris into the alveoli, and ventilation must be carefully monitored throughout.

Clearly, the presence of large-bore tubes in the airway may make these resections technically difficult, and the use of high-frequency ventilation techniques may improve surgical access. Thus, a small-diameter catheter or catheters may be placed across or through the stenotic lesion or transected airway(s) and ventilation to the distal airways and lungs maintained using HFPPV or HFJV. Potential disadvantages of these high-frequency ventilation techniques are that, by necessity, the system is “open” (see [High-Frequency Ventilation](#)), and egress of gas during exhalation may be compromised if the stenosis is tight. Also, the catheter may become occluded by blood and become displaced, and distal aspiration of debris or blood may occur. With complex resections, two anesthesia teams with two machines and anesthesia circuits or sets of ventilating equipment may be necessary to ensure adequate ventilation of the two distal airway segments, although during carinal resections, HFPPV to the left lung alone usually provides adequate oxygenation and ventilation.

In very difficult cases, cardiopulmonary bypass has been used to provide oxygenation and carbon dioxide removal during the period of resection; after resection, anesthesia can be maintained using a standard endotracheal tube. Cardiopulmonary bypass carries an attendant risk of massive hemorrhage as a result of the necessary heparinization.

After tracheal resection or reconstructive surgery, patients should be kept with their neck and head flexed to reduce tension on the anastomotic suture lines. In some cases, this is maintained by using sutures between the chin and the anterior chest wall. Extubation of the trachea is performed as early as possible to minimize tracheal trauma due to the endotracheal tube and cuff.

Bronchopulmonary Lavage

This procedure involves irrigation of the lung and bronchial tree and is used as a treatment for alveolar proteinosis, radioactive dust inhalation, cystic fibrosis, bronchiectasis, and asthmatic bronchitis. Lung lavage is performed under general anesthesia using a double-lumen tube, so that one lung may be ventilated while the other is being treated with lavage fluid.¹¹⁴

The preoperative assessment of these patients should include ventilation–perfusion scans so that lavage can be performed first on the more severely affected lung (*i.e.*, the one with the least ventilation). If involvement is equal, the left lung is generally lavaged first because gas exchange should be better through the larger, right lung. Patients are premedicated and supplied with supplemental oxygen *en route* to the operating room.

Anesthesia is induced with an intravenous drug and maintained with an inhaled agent in oxygen to maintain the highest possible FiO_2 . Muscle relaxation facilitates placement of the double-lumen tube, and the cuff seal should be checked to maintain perfect separation at a pressure of 50 cm H_2O to prevent leakage of lavage fluid around the cuff. A fiberoptic bronchoscope is useful to check the position of the bronchial cuff of the double-lumen tube. Monitoring should include an arterial catheter, and a stethoscope should be placed over the ventilated lung to check for rales, the presence of which may indicate leakage of lavage fluid into this lung.

The patient is maintained on an FiO_2 of 1.0 throughout the procedure. Before lavage this serves to denitrogenate the lungs, so that only oxygen and carbon dioxide remain. Instillation of fluid then allows these gases to be absorbed, resulting in greater access by the fluid to the alveolar spaces than if the more insoluble nitrogen bubbles remained.

Once the trachea is intubated, the patient is turned so that the side to be lavaged is lowermost, and the double-lumen tube position and seal are checked once again. With the patient in a head-up position, warmed heparinized isotonic saline is infused by gravity from a reservoir 30 cm above the midaxillary line into the catheter to the dependent lung, while the nondependent lung is ventilated. When fluid ceases to flow in (usually after 700–1000 ml in an adult), the patient is placed in a head-down position and fluid is allowed to drain out. The lavage is continued until the effluent is clear (as opposed to the milky fluid that drains initially when lavage is being performed for alveolar proteinosis), at which point the lung is suctioned and ventilation is re-established with large V_T (and pressures), because compliance is decreased owing to loss of surfactant. With each lavage, inflow and outflow volumes are monitored so that the patient is not “drowned” in fluid and there is no excessive absorption or leakage to the ventilated side. At least 90% of the saline volume should be recovered with each lavage. Two-lung ventilation is re-established and, as compliance improves, an air–oxygen mixture (addition of nitrogen) may be introduced to help maintain alveolar patency. After a further period of ventilation, most patients' tracheas can be extubated in the operating room. In the post-treatment period, patients are encouraged to cough and engage in breathing exercises to fully re-expand the treated lung. From 3 days to 1 week after lavage of the first lung, the patient may return to the operating room for lavage of the other lung.

Problems sometimes encountered with this procedure include spillage of lavage fluid from the treated to the ventilated lung. This must be managed by stopping the lavage and ensuring functional separation of the lungs before continuing. Double-lumen tube positioning is critical. Spillage may cause profound decreases in oxygenation, which may necessitate terminating the procedure and maintaining two-lung ventilation with oxygen and PEEP.

During periods when lavage fluid is being instilled into the dependent lung, oxygenation usually improves because the increased intra-alveolar pressure caused by the fluid produces diversion of the pulmonary blood flow to the nondependent, ventilated lung. Conversely, when the fluid is drained out of the dependent lung, hypoxemia may occur.¹¹⁴ In some cases in which severe hypoxemia was anticipated during right lung lavage, the risk has been reduced by passing a balloon-tipped catheter into the right main pulmonary artery (checked by radiography) and inflating the balloon during periods of right lung drainage. In this way, blood flow to the dependent, right, nonventilated lung is minimized during periods of drainage. This technique is not without risk (*e.g.*, pulmonary artery rupture) and is reserved for those patients considered to be at greatest risk for hypoxemia during lavage. Almitrine by infusion and nitric oxide by inhalation have also been reported to improve oxygenation during bronchopulmonary lavage.⁷³

If the patient has recently had a diagnostic open lung biopsy, a BPF may be present. If this is a possibility, a chest tube should be inserted on the side of the BPF, and this side should be lavaged first. The chest drain is removed several days later.

Limitations in the sizes of available double-lumen tubes preclude their use for lavage in patients weighing less than 40 kg. In such cases, cardiopulmonary bypass may be required to provide oxygenation during lavage.

Myasthenia Gravis

The thoracic anesthesiologist will most likely have to manage patients with myasthenia gravis (MG) for thymectomy, which is now considered the treatment of choice in most cases of MG. MG is a disorder of the neuromuscular junction, the function of which is altered routinely in the modern practice of anesthesia. The worldwide prevalence of the disease is 1 per 20,000 to 30,000 of the population; it is more common in women than men in 6:4 ratio. People of any age may be affected, but peaks of incidence occur in the third decade for women and the fifth decade for men. MG is a chronic disorder characterized by weakness and fatigability of voluntary muscles with improvement following rest.¹¹⁵ Onset usually is slow and insidious, any skeletal muscle or group of muscles may be affected, and the condition is associated with relapses and remissions. The most common onset is ocular; if the disease remains localized to the eyes for 2 years, the likelihood of progression to generalized MG is low. In some cases, the disease is generalized and may involve the bulbar musculature, causing problems with breathing and swallowing. Peripheral muscle involvement may cause weakness, clumsiness, and difficulty in holding up the head or in walking. The most commonly used clinical classification of MG is shown in [Table 30-7](#).

| | |
|------|--|
| I | Ocular myasthenia—Involvement of ocular muscles only. Mild with ptosis and diplopia. Electrophysiologic testing of other musculature is negative for MG. |
| IA | Ocular myasthenia with peripheral muscles showing no clinical symptoms but showing a positive electromyogram for MG. |
| II | Generalized myasthenia |
| IIA | Mild—Slow onset, usually ocular, spreading to skeletal and bulbar muscles. No respiratory involvement. Good response to drug therapy. Low mortality rate. |
| IIIB | Moderate—No life but progressing to more severe involvement of skeletal and bulbar muscles. Dysarthria, dysphagia, difficulty chewing. No respiratory involvement. Patient's activities limited. Fair response to drug therapy. |
| IIIC | Acute fulminating myasthenia—Rapid onset of severe bulbar and skeletal symptoms with involvement of muscles of respiration. Progression usually within a week. Poor response to therapy. Patient's activities limited. Low mortality rate. |
| IV | Late severe myasthenia—Severe MG developing at least 2 years after onset of Group I or Group II symptoms. Progression of disease may be gradual or rapid. Poor response to therapy and poor prognosis. |

MG = myasthenia gravis.
Adapted from Osserman KE, Giordano G: Studies in myasthenia gravis—a review of a 30-year experience in over 1200 patients. *Ann Intern Med* 28:497, 1971.

Table 30-7. CLINICAL CLASSIFICATION OF MYASTHENIA GRAVIS

In MG there is a decrease in the number of postsynaptic acetylcholine receptors at the end plates of affected muscles. This causes a decrease in the margin of safety of neuromuscular transmission. MG is an autoimmune disorder, and most of the affected patients have circulating antibodies to the acetylcholine receptors. These antibodies may cause complement-mediated lysis of the postsynaptic membrane or direct blockade of the receptors, or may modulate the receptor turnover such that the degradation rate exceeds the resynthesis rate. Studies of the end plate area show loss of synaptic folds and a widening of the synaptic cleft.

The diagnosis of MG is suspected from the history and confirmed by pharmacologic, electrophysiologic, or immunologic testing. Patients cannot sustain or repeat muscular contraction. The electrical counterpart of this is a decrement in the muscle action potentials evoked by repetitive stimulation of a motor nerve. Mechanical and electrical (electromyography) decrements improve with 2–10 mg of intravenous edrophonium (Tensilon test). Myasthenic patients characteristically are sensitive to α -tubocurarine. When the routine electromyographic results are equivocal, a regional curare test may be performed using a tourniquet to isolate the limb and to limit the action of the drug. In the regional curare test, electromyograms are performed before and after the administration of 0.2 mg of curare. In equivocal cases, a positive result of a test for anti-acetylcholine receptor antibodies is considered diagnostic.

Medical Therapy

Anticholinesterases are used to prolong the action of acetylcholine at the postsynaptic membrane and may also exert their own agonist effect at the acetylcholine receptors. They are the most commonly used therapy in MG ([Table 30-8](#)). Myasthenic patients learn to regulate their medication and titrate dose against optimum effect. Overdosage causes the muscarinic effects of acetylcholine and may cause a cholinergic crisis. Underdosage causes weakness or a myasthenic crisis. In a patient with weakness, distinction between the two types of crisis may be made by performing a Tensilon test or by examining pupillary size, which will be large (mydriatic) in a myasthenic but small (miotic) in a cholinergic crisis. Muscarinic side effects are treatable with atropine.

| Drug | Dose (mg) | | | Efficacy |
|---------------------------|-----------|-----|---------|----------|
| | Oral | iv | im | |
| Pyridostigmine (Mestinon) | 60 | 2.0 | 2.0–4.0 | 1 |
| Neostigmine (Prostigmine) | 15 | 0.5 | 0.7–1.0 | 1 |
| Amibenonium (Myclase) | 6 | NA | NA | 2.5 |

iv = intravenous; im = intramuscular; NA = not available.

Table 30-8. ANTICHOLINESTERASE DRUGS USED TO TREAT MYASTHENIA GRAVIS

The immunologic basis of MG has led to the use of immunosuppressive drugs such as steroids, azathioprine, cyclophosphamide and, most recently, cyclosporine. Steroids often produce initial deterioration before an improvement. The usual regimen is prednisone 1 mg · kg⁻¹ on alternate days. The other drugs mentioned represent third and fourth lines of treatment.

Plasma exchange or plasmapheresis may produce dramatic but transient improvements in muscle strength with decreases in anti-acetylcholine receptor antibody titers. Usually reserved for severe MG, plasma exchange has been shown to improve respiratory function in both operated and nonoperated patients with MG. Plasmapheresis causes a decrease in plasma cholinesterase levels that may prolong the effect of drugs such as succinylcholine that are normally broken down by this enzyme system.

Abnormalities are found in 75% of thymus glands removed from patients with MG (85% show hyperplasia; 15% thymoma). After thymectomy, approximately 75% of patients either go into remission or are improved. Thymectomy is now considered the treatment of choice in most patients with MG, except for those in Osserman Class I.

Management of General Anesthesia

When possible, patients with MG should be admitted for elective surgery while in remission. On admission, the patient's physical and emotional states should be optimized. Other diseases occasionally associated with MG should be excluded ([Table 30-9](#)). The patient's current drug therapy should be reviewed and possible drug interactions considered. Because patients are less active while in the hospital, their anticholinesterase dosage may need to be decreased. If the patient has a history of respiratory disease or bulbar involvement, preoperative evaluation should include respiratory function studies. Breathing exercises and instruction in the use of incentive spirometers may be indicated. Patients should be told of the possible need for postoperative intubation of the trachea and ventilation of the lungs. Ideally, patients with MG should be scheduled to be the first case of the day in the operating room. Patients receiving steroid therapy should receive perioperative coverage.

| | |
|-------------------------------------|-------------------------|
| Thymoma | Multiple sclerosis |
| Thyroid disease | Ulcerative colitis |
| Hyperthyroidism | Leukemia |

| Rheumatoid arthritis | Polymyositis |
| Systemic lupus erythematosus | Sjögren's syndrome |
| Anemias | Scleroderma |
| Pernicious | |
| Hemolytic | |

Table 30-9. DISORDERS ASSOCIATED WITH MYASTHENIA GRAVIS

Because the trachea is to be intubated and the lungs ventilated for the planned procedure in the patient with MG, anticholinesterase therapy should be withheld on the morning of surgery so that the patient is weak on arrival at the operating room. This avoids interactions with other drugs used in the operating room. Anticholinesterase therapy may be continued if the patient is physically or psychologically dependent on it. Pre-medication is satisfactorily achieved with a benzodiazepine or barbiturate. Opioids are usually avoided because of the risk of producing respiratory depression.

Monitoring should be dictated by the patient's state and planned surgical procedure, but should include an assessment of neuromuscular transmission (mechanomyogram/twitch monitor or integrated electromyographic monitor) if agents affecting neuromuscular transmission are to be used.¹¹⁶

Induction of anesthesia is readily achieved with a short-acting barbiturate or propofol. In elective cases, intubation of the trachea, maintenance, and relaxation are readily achieved using potent inhaled anesthetics. Anesthesia may be deepened using a potent inhaled agent and the trachea intubated under its effect. Myasthenic patients are more sensitive than normal patients to the neuromuscular depressant effects of the potent inhaled agents. In patients with MG, isoflurane at 1.9 MAC end-tidal concentration induced a neuromuscular block of 30–50%, whereas halothane at 1.8 MAC induced a block of 10–20%. Both agents produced fade in the train-of-four ratio of 41% and 28%, respectively.¹¹⁷ Because these drugs are easily administered and withdrawn, they are the most commonly used anesthetic drugs for patients with MG. At the end of the procedure, the drug is discontinued and recovery of neuromuscular function begins.

Nondepolarizing Relaxants. In some cases, patients with MG cannot tolerate the cardiovascular depressant effects of the potent inhaled anesthetics, in which case muscle relaxants may be used, titrating dose against monitored effect. Patients with MG are sensitive to the nondepolarizing relaxants. A usual defasciculating dose in a normal patient may represent an ED₉₀ in a patient with MG.¹¹⁶ All of the nondepolarizing relaxants have been successfully and uneventfully used, with careful monitoring, in patients with MG. They should be titrated in 1/10 to 1/20 of the usual dose. Atracurium is probably the preferred agent because of its short elimination half-life (20 minutes), small volume of distribution, lack of cumulative effect, and high clearance. The Hofmann elimination pathway results in atracurium having very reproducible pharmacodynamics and kinetics, and most patients do not require reversal if monitored carefully. The ED₉₀ of atracurium in patients with MG is approximately one-fifth of that in normal patients.¹¹⁸ Relaxation is readily maintained thereafter using an atracurium infusion, and recovery time is not prolonged with this drug. Cisatracurium is also an appropriate choice.¹¹⁹

Although other short- or intermediate-duration nondepolarizing agents may be used, they do have cumulative effects, which may represent a potential disadvantage. Long-acting relaxants are probably best avoided in patients with MG. Myasthenic patients show increased sensitivity to mivacurium. Because mivacurium is metabolized by cholinesterase, anticholinesterase drugs prolong the recovery from this relaxant.¹²⁰ If necessary, the other nondepolarizers may be reversed by increments of anticholinesterase drugs while neuromuscular transmission is carefully monitored to obtain maximum antagonism yet avoid a cholinergic crisis. All anticholinesterases have been safely used. Edrophonium may be the drug of choice because its onset of action is rapid and higher doses have a prolonged duration of action. Because of the risk of cholinergic crisis with anticholinesterase agents, the rapid, predictable, spontaneous recovery from atracurium (or cisatracurium) may represent an additional advantage in that reversal may not be necessary.¹¹⁶

The sensitivity of patients with MG to nondepolarizing relaxants is very variable, depending on the individual patient, the severity of MG, and the treatment. There are conflicting reports as to the sensitivity of patients with MG in remission. All such patients should be considered sensitive to nondepolarizers until proved otherwise.

Succinylcholine. Myasthenic patients are resistant to the neuromuscular blocking effects of succinylcholine. The ED₉₅ is 2.6 times normal in these patients.¹²¹ Clinically, however, the use of succinylcholine has been without incident, with normal clinical doses producing adequate relaxation for endotracheal intubation and a normal recovery time, despite the occasionally reported early onset of Phase II block. Doses of 0.2–1.0 mg · kg⁻¹ have been used in a number of patients with MG, and most did not show fasciculation before becoming paralyzed. Fade in response to train-of-four stimulation was observed in some patients during recovery, but recovery was not delayed. Prior administration of an anticholinesterase may complicate the response to succinylcholine by delaying its metabolism.

When a rapid-sequence intubation of the trachea is required, rapid onset of muscle relaxation may be achieved with succinylcholine or with moderate doses of a nondepolarizer in the latter case, with an associated prolongation of effect. A succinylcholine (1.5 mg · kg⁻¹)–vecuronium (0.01 mg · kg⁻¹) sequence has been safely used in three patients with MG for thymectomy. The authors suggested that this technique may be particularly advantageous when rapid-sequence induction of anesthesia is indicated.¹²²

Other Drug Interactions. Medications with neuromuscular blocking properties should be used with caution in patients with MG, particularly if relaxants are being used concurrently. Such drugs include antiarrhythmics (quinidine, procainamide, calcium channel blockers), diuretics (by causing hypokalemia), nitrogen mustards, quinine, and aminoglycoside antibiotics. Dantrolene has been used safely in a patient with MG.

Recovery from Anesthesia. Recovery from anesthesia must be carefully monitored in these patients. Extubation of the trachea should be performed when the patients are responsive and able to generate negative inspiratory pressures of greater than –20 cm H₂O. After extubation of the trachea, patients are carefully observed in the recovery area or the intensive care unit. As soon as possible, patients should resume their usual pyridostigmine regimen. Cases of mild respiratory depression may be treatable with parenteral anticholinesterase; more severe cases may require reintubation of the trachea and mechanical ventilation of the lungs. In the immediate postoperative period, post-thymectomy patients often show a marked improvement in their condition and a decreased need for anticholinesterase therapy.

Postoperative Respiratory Failure

Myasthenic patients are at increased risk for development of postoperative respiratory failure. There have been several attempts to predict before surgery which patients with MG will require prolonged postoperative ventilation of the lungs.¹²³ For patients who underwent trans-sternal thymectomy, positive predictors were a duration of MG greater than 6 years; history of chronic respiratory disease, other than that directly caused by MG; pyridostigmine dosage greater than 750 mg · day⁻¹; and a preoperative vital capacity of less than 2.9 l. This predictive system was not found useful when applied in patients with MG undergoing trans-sternal thymectomy at other centers, and of no value in patients with MG undergoing other types of surgical procedure.¹²³ Each patient should therefore be treated on his or her own merits.

A study of patients undergoing trans-sternal thymectomy suggested that the need for postoperative mechanical ventilation correlated best with preoperative maximum static expiratory pressure. It was concluded that expiratory weakness, by reducing cough efficacy and ability to clear secretions, was the main predictive determinant. Adequate clearance of secretions is essential in these patients and may occasionally necessitate bronchoscopy.

In general, the postoperative morbidity in terms of respiratory failure is lower after transcervical rather than trans-sternal thymectomy.¹²³ Techniques described that may be useful in reducing postoperative ventilatory failure include preoperative plasma exchange and high-dose perioperative steroid therapy. If the anticipated duration of the surgical procedure is 1–2 hours, preoperative oral anticholinesterase therapy may be of value because the peak effect of the drug coincides with the conclusion of the surgical procedure and attempts at tracheal extubation.

Postoperative Care

In the immediate postoperative period, pain relief for patients with MG is usually provided by opioid analgesics, such as meperidine, but in reduced doses. The analgesic effect of morphine and other opioid analgesics has been reported to be increased by anticholinesterases, which has led to the recommendation that the dose

of opioid analgesics be reduced by one third in patients receiving anticholinesterase therapy. Combined regional and general anesthesia techniques have also been used to provide good surgical conditions and improved postoperative analgesia in patients with MG undergoing thymectomy. Combined epidural–general anesthesia has been reported to provide excellent intraoperative and postoperative conditions for both surgeon and patient.^{124,125}

Myasthenic Syndrome (Eaton-Lambert Syndrome)

The myasthenic syndrome is a very rare disorder of neuromuscular transmission that is sometimes associated with small cell carcinoma of the lung. Complaints of weakness may be mistaken for MG, but in Eaton-Lambert syndrome, symptoms do not respond to administration of anticholinesterases or steroids, and activity improves strength. The defect in this condition is thought to be prejunctional, associated with diminished release of acetylcholine from nerve terminals, and improved by agents such as 4-aminopyridine, guanidine, and germinate that increase repetitive firing. Affected patients are particularly sensitive to the effects of all muscle relaxants, which should be used with great caution or avoided entirely. The possibility of Eaton-Lambert syndrome should be considered in all patients with known malignant disease and those patients undergoing diagnostic procedures for suspected carcinoma of the lung. Anesthesia considerations in these patients are essentially the same as in those with MG.¹²⁶

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Atelectasis

Patients who require thoracotomy often have pre-existing pulmonary disease that, when combined with the operative procedure, is likely to result in significant pulmonary dysfunction and possibly pneumonia. Atelectasis, the most significant cause of postoperative morbidity, has been reported to occur in up to 100% of patients undergoing thoracotomy for pulmonary resection. It occurs more commonly in the basal lobes than in the middle or upper lung regions. It may be secondary to reduction of normal respiratory effort due to splinting from pain, obesity, intrathoracic blood and fluid accumulation, and decreased compliance, all of which lead to rapid, shallow, constant V_T . Such a respiratory pattern produces small airway closure and obstruction with inspissated secretions, resulting ultimately in alveolar air resorption and terminal airway collapse. A poor cough and limited clearance of secretions add to the problem. Other sources of atelectasis include mucus plugging, which can obstruct a lobe or even an entire lung, and incomplete re-expansion of the remaining lung tissue after one-lung anesthesia. The diagnosis of atelectasis can be made by clinical findings, chest radiography, or arterial blood gas analysis. This problem is best resolved by increasing resting lung volume or FRC. FRC can be increased by an increase in transpulmonary pressure (difference between airway pressure and intrapleural pressure) or in lung compliance.

The tracheas of many patients can be extubated shortly after brief thoracic surgical procedures using standard extubation criteria. However, most patients with COPD undergoing extensive thoracic surgical procedures require postoperative ventilation to avoid atelectasis and other pulmonary complications. Mechanical ventilation increases airway pressure and, to a lesser extent, intrapleural pressure; therefore, transpulmonary pressure increases. Most postoperative thoracotomy patients are ventilated using intermittent mandatory ventilation and PEEP. Ventilation settings include: $V_T = 12 \text{ ml} \cdot \text{kg}^{-1}$, rate = 8 breaths $\cdot \text{min}^{-1}$, $F_{I_{O_2}} = 0.5$, and PEEP = 5–20 cm H_2O . The goal is to keep the Pa_{O_2} between 80 and 100 mm Hg and the Pa_{CO_2} and pH normal. The intermittent mandatory ventilation rate is decreased as tolerated to 2 breaths $\cdot \text{min}^{-1}$, and then the PEEP level is reduced to 5 cm H_2O . When arterial blood gases are adequate at these settings and the vital capacity is greater than 10 ml $\cdot \text{kg}^{-1}$, inspiratory force is greater than –20 cm H_2O , and the level of consciousness is adequate, the patient's trachea is ready for extubation.

In addition to the use of incentive spirometry and bronchodilators, coughing and clearance of secretions, and mobilizing the patient, adequate analgesia is essential to the prevention and treatment of atelectasis. Atelectasis caused by collapse of lung tissue distal to a mucus plug can be treated by positioning the patient in the lateral decubitus position with the fully expanded lung in the dependent position. This improves V/Q matching and facilitates clearance of mucus from the nondependent obstructed lung. However, the patient should not be placed with the operative side in the dependent position after a pneumonectomy because of the risk of cardiac herniation.

Postoperative Pain Control

After extubation of the trachea, respiratory therapy and pain management become critical components of postoperative care. Adequate postoperative pain control is necessary to ensure a good respiratory effort.¹¹⁵ Administration of intravenous opioids has been the standard form of pain management for years. These drugs may improve pulmonary function slightly or allow respiratory therapy maneuvers; however, meperidine (50 mg) has been shown to be relatively ineffective at allowing patients to increase their ability to cough. Advantages of intravenous opioids are the ease of administration, relatively low toxicity, and the lack of a need for close medical supervision. The key disadvantage is the inadequate pain relief leading to postoperative atelectasis and great discomfort on the part of the patient. The administration of sufficient opioid to treat pain adequately is likely to cause sedation and respiratory depression.

Patient-controlled analgesia has been reported to decrease the amount of postoperative pain, drug use, sedation, and pulmonary complications.¹²⁷ Patient-controlled analgesia also eliminates the delays associated with personnel-administered medications and in general is very well accepted by patients. Subcutaneous patient-controlled analgesia with hydromorphone has been reported to be as effective as intravenous patient-controlled analgesia. Complications related to the use of patient-controlled analgesia are presented elsewhere in this volume (see [Chapter 54](#)).

Many clinicians have suggested the use of intercostal nerve blocks before, during, or after thoracic surgery to decrease pain and improve postoperative respiratory function. Studies have documented a decrease in requirements for postoperative opioids, improved respiratory function, and some decrease in time of hospital stay. The intercostal block can be performed externally before or after surgery using a standard technique. However, the easiest method during thoracic surgery is to have the surgeon perform the block under direct vision from inside the thorax while the chest is open. Bupivacaine 0.5%, in doses of 2–3 ml, can be placed in the five intercostal spaces around the incision and in intercostal spaces where chest tubes will be placed. This provides 6–24 hours of moderate pain relief, but patients still complain of diaphragmatic and shoulder discomfort caused by the chest tubes. Higher volumes of local anesthetic (e.g., 5–10 ml) should not be used in the intercostal space because of the high absorption rate and attendant systemic toxicity that can be produced, as well as the possibility of pushing the drug centrally and producing a paravertebral sympathetic or epidural block with central sympatholysis and severe hypotension. The intraoperative placement of catheters in intercostal grooves allows for a continuous postoperative intercostal nerve block. The technique reduces pain and improves pulmonary function. Although bupivacaine has been used in most reports, lidocaine has also been used.

A prolonged intercostal nerve block may be obtained by cryo-analgesia, a technique of freezing the nerve under direct vision at the time of thoracotomy. A cryoprobe is applied directly to the nerve to disrupt the axon but not the support structures. In this way, conduction is interrupted until the nerve regenerates over the next 1–6 months, by which time full structure and function are usually restored. Hypoesthesia in the scar and adjacent skin is a common late finding. During the postoperative period, the patients are numb in the segments thus treated. Ideally, any drains or chest tubes should be located within the area made analgesic with the cryoprobe to minimize immediate postoperative discomfort. Cryoanalgesia provides excellent analgesia when supplemented with other pain treatments. Because cryoanalgesia is of prolonged duration, it is not used routinely after thoracotomy but rather in cases in which prolonged analgesia would be necessary, such as after surgery for chest trauma.

Another approach to postoperative pain control after thoracic surgery is the use of epidural or intrathecal opioids. Epidural morphine produces profound analgesia lasting from 16–24 hours after thoracotomy and does not cause a sympathetic block or sensory or motor loss. These are significant advantages over other methods of administering opioids or local anesthetics. The opioids have been successfully used by both the thoracic and lumbar epidural routes. Morphine, in a dose of 5–7 mg diluted in 15–20 ml of fluid, has been used in the lumbar epidural technique. This technique has led to a 30% increase in postoperative expiratory flow rates without significant side effects, even in patients with chronic lung disease.

Epidural morphine has been shown to decrease pain and improve respiratory function in post-thoracotomy patients.¹²⁸ The successful use of lumbar epidural sufentanil or fentanyl diluted to 20 ml has also been reported. There have been reports of severe respiratory depression with epidural fentanyl and several reports with sufentanil. The addition of epinephrine, 5 mg $\cdot \text{ml}^{-1}$, to sufentanil administered in the thoracic epidural space decreases the plasma concentration of sufentanil and increases the duration of block. Lumbar epidural hydromorphone (1.25–1.5 mg) has been reported to provide excellent analgesia, with fewer side effects than epidural morphine. Severe respiratory depression was reported in one patient who received hydromorphone via a thoracic epidural catheter. A prophylactic low-dose infusion of naloxone, or nalbuphine, an agonist–antagonist drug, can reduce the incidence of respiratory depression.

Subarachnoid (intrathecal) morphine, in a dose of 10–12 $\mu\text{g} \cdot \text{kg}^{-1}$, has been successfully used after thoracic surgery.¹²⁹ With this technique, the drug acts directly on the spinal cord, and analgesia can be produced with a lower dose than by the epidural or intravenous routes. When morphine is given intrathecally before the induction of anesthesia, a decrease in the dose of anesthetic drugs required may occur. All patients who have received intrathecal or epidural opioids must be closely observed for potential side effects, including delayed respiratory depression, urine retention, pruritus, nausea, and vomiting. These effects appear to be dose related and may be reversed with naloxone.

Noxious stimuli, including surgical incision, may lead to changes in the central nervous system that exacerbate postoperative pain. The administration of analgesic

agents before surgery is termed *pre-emptive analgesia* and may prevent these neuroplastic changes, thereby decreasing postoperative pain. The administration of lumbar epidural fentanyl before thoracotomy incision reduced postoperative pain scores and use of patient-controlled analgesia morphine by a small but significant amount, compared with administration of lumbar epidural fentanyl after skin incision.¹³⁰

Interpleural analgesia is another technique for postoperative pain treatment. Although the mechanism has not been fully elucidated, the injection of local anesthetic between the pleural layers is thought to block multiple intercostal nerves or the pain fibers traveling with the thoracic sympathetic chain. The surgeon can place the catheter under direct vision while the chest is open. Catheter malposition has been documented after percutaneous placement, especially if the patient is not breathing spontaneously. The chest tubes should not be suctioned for approximately 15 minutes after injection of local anesthetic to avoid loss of the anesthetic into the drainage. The efficacy of interpleural blockade for post-thoracotomy pain relief has been reported to be both poor and good.¹²⁷

Respiratory Therapy Techniques

Physiotherapy is one of the oldest forms of therapy for the prevention and treatment of respiratory complications. Techniques include postural drainage, breathing exercises, vibration, deep breathing, coughing, and percussion. Many clinicians feel that chest physiotherapy is useful despite the sparse data to support its physiologic benefits. Decades ago, it was also felt that forced exhalation against resistance would create increased airway pressures and inflation of the lungs. Thus, water-filled blow bottles were designed for postoperative use. However, studies subsequently showed that a forced exhalation decreases the expiratory transpulmonary pressure and lung volumes and should be avoided in postoperative patients. It was suggested that the blow bottles were useful only because of the large inspiration that preceded the forced exhalation.

Intermittent positive-pressure breathing has also been used extensively in the postoperative period to prevent and treat respiratory insufficiency. Most of the studies demonstrated little physiologic benefit and, in fact, some authors showed that intermittent positive-pressure breathing could be harmful after thoracotomy because of the hypoventilation that subsequently occurred after the forced hyperventilation. The hyperventilation led to decreased FRC and P_{aCO_2} secondary to the decreased expiratory transpulmonary pressure.

Incentive spirometry is the most widely used postoperative respiratory care device. This device, producing a long, deep breath, has been shown to cause fewer complications and less atelectasis than intermittent positive-pressure breathing, blow bottles, or chest physiotherapy. Patients with a decreased FRC and decreased P_{aO_2} experience a reduction of atelectasis on chest radiography and improved arterial oxygenation. The technique produces an increase in inspiratory transpulmonary pressure but not an increase in expiratory pressure. Expiratory transpulmonary pressure can best be increased by the use of CPAP by mask. A comparison of mask CPAP with chest physiotherapy, postural drainage, and endotracheal suction in the treatment of postoperative atelectasis found that 15 cm H_2O CPAP applied once an hour for 25–35 breaths led to clinically significant improvement within 12 hours, whereas the other techniques produced little change. This technique appears to be very useful in the treatment of atelectasis to avoid reintubation of the trachea in patients after surgery. Gastric distention, regurgitation, and pulmonary aspiration are the potential dangers of mask CPAP.

Other Complications After Thoracic Surgery

The other major complications after thoracic surgery can be grouped into cardiovascular, pulmonary, and related problems. The cardiovascular complications are often the most difficult to manage in patients with associated respiratory insufficiency. The low cardiac output syndrome and postoperative cardiac arrhythmias are the most common and life-threatening of these problems. In the postoperative period, advanced hemodynamic monitoring is used to make the differential diagnosis of left or right ventricular failure and the low output syndrome. A key monitor is the PA catheter, which facilitates the construction of Starling function curves. Other diagnostic modalities, such as echocardiography, may be required to rule out the presence of pericardial effusions or tamponade after opening the pericardium during certain types of thoracic surgical procedure. The low cardiac output syndrome must be differentiated from hypovolemia resulting from intrathoracic hemorrhage, tamponade, pulmonary emboli, or the effects of mechanical ventilation with PEEP. Postoperative fluid administration can lead to pulmonary edema resulting from the resection of lung tissue and the concomitant reduction of the pulmonary vascular bed. A postoperative pulmonary embolism can originate from the remaining pulmonary artery stump or tumor tissue. Therapeutic interventions for postoperative myocardial dysfunction include inotropic drugs, vasodilators, and combinations of these drugs, as needed, to improve ventricular function. The goal is to shift the Starling function curve up and to the left by reducing preload of either the left or right side of the heart and increasing cardiac output. Vasodilators are very effective at decreasing right ventricular afterload and improving right ventricular function because this side of the heart is especially afterload dependent. Combinations of inotropes and vasodilators, such as isoproterenol and nitroglycerin, or combined drugs, such as amrinone, can be especially useful in the treatment of right-sided heart failure.

Postoperative cardiac dysrhythmias are common after thoracic surgery. Patients undergoing pulmonary resection have postoperative supraventricular tachycardias with a frequency and severity proportional to both their age and the magnitude of the surgical procedure. Many factors contribute to these arrhythmias, including underlying cardiac disease, degree of surgical trauma, intraoperative cardiac manipulation, stimulation of the sympathetic nervous system by pain, a reduced pulmonary vascular bed, effects of anesthetics and cardioactive drugs, and metabolic abnormalities.

In a series of 300 thoracotomies for lung resection, it was found that atrial fibrillation occurred in 20% of patients with malignant disease but in only 3% with benign disease. A 22% incidence of dysrhythmias has been reported after pneumonectomies.⁹⁰ Multifocal atrial tachycardia often occurs in patients with COPD and concomitant right-sided cardiac dysfunction. The right side of the heart may be further strained by the reduction in the size of the pulmonary vasculature from the lung resection, and especially after right pneumonectomy. The prophylactic use of digitalis in thoracic surgical patients is controversial, particularly in patients with signs of congestive heart failure. Factors against its use include the potential toxic effects of the drug and the difficulty in assessing adequacy of digitalization in the absence of heart failure. A prospective, placebo-controlled, randomized study demonstrated no advantage to prophylactic digitalization of patients undergoing thoracic surgery.¹³¹ A factor in favor of its use is the drug's efficacy in reducing the incidence of potentially fatal complications in older patients. In some studies it has been reported to reduce the incidence of perioperative dysrhythmias. If digitalis is to be instituted, normokalemia should be ensured to reduce the likelihood of digitalis toxicity.

Supraventricular tachycardias can also be treated with either β blocking or calcium channel blocking drugs after ruling out underlying reversible physiologic abnormalities, such as hypoxia. Verapamil has been the standard treatment for these problems until the introduction of the ultrashort-acting β blocker, esmolol. Esmolol has been shown to be equally effective in controlling the ventricular rate in patients with postoperative atrial fibrillation or flutter and in increasing the conversion rate to regular sinus rhythm from 8 to 34%. Owing to its short duration of action (β elimination half-life of 9 minutes) and β_1 -cardioselectivity, it is the drug of choice in the postoperative period to control these dysrhythmias. Esmolol, in an iv loading dose of $500 \mu\text{g} \cdot \text{kg}^{-1}$ given over one minute followed by an infusion of $50\text{--}200 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ has been shown to be effective in the control of supraventricular tachycardias.

Hemorrhage and pneumothorax are always major concerns after intrathoracic surgery. Because of these problems, interpleural thoracostomy tubes with an underwater seal system are routinely used after thoracic surgery. Slippage of a suture on any major vessel or airway in the chest can lead to the slow or rapid development of hypovolemic shock or a tension pneumothorax. Drainage of more than $200 \text{ ml} \cdot \text{hr}^{-1}$ of blood is an indication for surgical re-exploration for hemorrhage. Management of the pleural drainage system is fraught with confusion. The chest bottles must be kept below the level of the chest, and the tubes should not be clamped during patient transport. These tubes can be life saving, but errors in technique can lead to serious complications. The creation of a pneumothorax in the nonoperative chest by central venous catheter placement is very hazardous because this lung is essential both intraoperatively during one-lung anesthesia and postoperatively after contralateral lung resection. Dehiscence of the bronchial stump may lead to the formation of a BPF, which carries a mortality rate of 20%. Surgical treatment may be needed, in which case ventilation of the patient may be difficult because of loss of V_T through the fistula. A double-lumen endobronchial tube positioned in the contralateral mainstem bronchus or the use of HFJV may be required for safe management. HFJV allows ventilation with lowered peak airway pressures. However, there have been reports in which ventilation by HFJV was difficult. If a double-lumen endobronchial tube is placed, the lung with the fistula can be ventilated independently with either CPAP or HFJV.

Both central and peripheral neurologic injuries can occur during intrathoracic procedures. Such injuries often result in serious and disabling loss of function and are very distressing to the patient. Peripheral nerves can be injured, either in the chest or in other parts of the body, by pressure or stretching. It has been recognized for years that most of these postoperative neuropathies are caused by malpositioning of the patient on the operating table, with subsequent stretching or compression of the nerves. The nerve injury may be apparent immediately after surgery or may not become obvious until several days later. These patients often complain of a variety of unpleasant sensations, including paresthesias, cold, pain, or anesthesia in the area supplied by the affected nerves. The brachial plexus is especially vulnerable to trauma during thoracic surgery owing to its long superficial course in the axilla between two points of fixation, the vertebrae above and the axillary fascia below. Stretching is the chief cause of damage to the brachial plexus, with compression playing only a secondary role. Branches of the brachial plexus may also be injured lower in the arm by compression against objects such as an ether screen or other parts of the operating table. Intrathoracic nerves can be directly injured during a surgical procedure by being transected, crushed, stretched, or cauterized. The intercostal nerves are the ones most frequently injured during intrathoracic surgical procedures. The recurrent laryngeal nerve can become involved in lymph node tissue and injured at the time of a node biopsy, especially when the biopsy is performed through a mediastinoscope. This nerve can also be injured during tracheostomy or radical pulmonary dissections. The phrenic nerve is frequently injured during pericardiectomy, radical pulmonary hilar dissections, division of the diaphragm during esophageal surgery, or dissection of mediastinal tumors.

Prevention is the treatment of choice for all these intraoperative nerve injuries. Analgesics may be necessary to control postoperative pain in the distribution of the

nerve injury and to aid in maintaining joint mobility during the healing phase. Subsequent surgical procedures may be necessary to move a swollen ulnar nerve at the elbow or to stent a partially paralyzed vocal cord.

The perioperative management of patients during either cardiac or noncardiac surgery requires an extensive knowledge of cardiovascular anatomy and physiology.

ANATOMY

Heart

Transesophageal echocardiography¹ ([Fig. 31-1](#)) visualizes the functional anatomy of the four cardiac chambers, four valves, and great vessels.

Figure 31-1. The functional anatomy of all four cardiac chambers, atrioventricular valves, aortic outflow track, and inter-atrial and inter-ventricular septa are easily visualized using either transthoracic or transesophageal echocardiography.

Right Atrium

Systemic veins drain into the right atrium (RA) via the superior vena cava (SVC), inferior vena cava (IVC), and the coronary sinus. The ostium of the IVC is guarded by the eustachian valve while the ostium of the coronary sinus is guarded by the thebesian valve. The right and left atria are separated by the interatrial septum with its central ovoid portion, the fossa ovalis, the remnant of the fetal foramen ovale.

Blood leaving the RA passes through the tricuspid valve, which consists of three leaflets—anterior, posterior, and medial—comprising an area of 8–11 cm² ([Fig. 31-2](#)). The anterior leaflet, the largest, is attached to the crista supraventricularis (described below) and controlled by the anterior papillary muscle (APM). The APM originates from a prominent intraventricular muscle, the moderator band, and the anteriolateral ventricular wall. Connecting the papillary muscles to the valve leaflets are strong, fibrous structures known as the chordae tendineae.

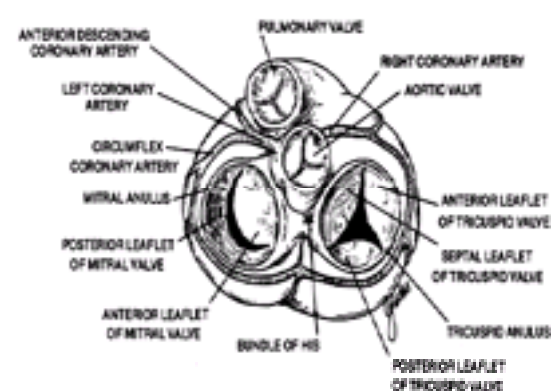

Figure 31-2. A coronal section of the heart at the level of the valves. The close proximity of all four cardiac valves is easily recognized. (Reprinted with permission from Lowe DA: Abnormalities of the atrioventricular valves. In Lake CL (ed): Pediatric Cardiac Anesthesia, 3rd ed. Norwalk, CT, Appleton & Lange, 1998.)

Right Ventricle

The right ventricle (RV) is a pocket wrapped around one third of the left ventricle (LV). Its muscle fibers are continuous with those of the LV. Anatomically, it consists of inferoposterior inflow (sinus) and anterosuperior outflow (infundibular) portions divided by the crista supraventricularis. The inflow portion contains prominent muscle bands (moderator, septal, and parietal) and muscle bundles known as trabeculae carneae. The crista supraventricularis also joins the interventricular septum and LV to the right ventricular free wall and may help to integrate right and left ventricular function.²

Pulmonary Artery and Peripheral Pulmonary Circulation

The pulmonic valve separates the right ventricular infundibulum from the main pulmonary artery (PA). It is a trileaflet valve (right, left, and anterior cusps), normally about 4 cm² in area (see Fig. 31-2). As it originates from the superior portion of the RV, the PA passes under the aorta before it bifurcates into the right and left pulmonary arteries. The remnant of the fetal ductus arteriosus, the ligamentum arteriosum, connects the upper aspect of the bifurcation to the inferior aortic surface.

The pulmonary arteries and veins of the lower lobes are normally larger and more prominent than those of the upper lobes. Pulmonary arteries branch into arterioles and thence into capillaries, which spread over the alveolar surfaces between two alveolar endothelial layers. The size of the peripheral pulmonary vessels indicates pulmonary blood volume and flow. With left-to-right cardiac shunts, the main pulmonary artery and hilar vessels are prominent. With pulmonary hypertension, however, dilation of the main pulmonary artery and abrupt tapering of the peripheral pulmonary vessels are noted.

Left Atrium

The left atrium (LA) is slightly larger than the right and receives one or two pulmonary veins on its left and two or three on its right side. Leaving the LA, blood traverses the mitral valve consisting of two major anteromedial and posterolateral leaflets, papillary muscles, and chordae tendineae. The normal adult mitral valve is about 6–8 cm² in area. Valves of less than 1 cm² are severely stenotic. The blood supply to the mitral chordae and papillary muscles is often quite tenuous.³

Left Ventricle

Normally, the LV is thicker (8–15 mm) and more densely trabeculated than the right. Its internal dimension is also greater, about 4.5 cm compared with 3.5 cm for the RV.⁴ The interventricular septum, with its membranous superior portion near the aortic valve and muscular inferior portion, divides the RV from the LV. Both ventricles consist of an inner layer, the endocardium covered with endothelium, the myocardium or muscle layer, and the outer layer, the epicardium.

Aorta and Its Branches

The aortic valve is adjacent to the mitral valve, separated only by the fibrous tissue framework that comprises the annuli of both valves (see Fig. 31-2). Three pocket-like structures of unequal size, the right and left (coronary) and posterior (noncoronary) cusps, form the aortic valve. A normal aortic valve is about 3–4 cm² in area. The aorta at the level of the valve dilates to form the sinuses of Valsalva in which the coronary ostia are located.

The ascending aorta, just beyond the aortic valve, has no branches. Major branches of the aorta, the innominate, left carotid, and left subclavian arteries, arise from the aortic arch. The innominate artery subdivides into the right subclavian and right carotid arteries.

Arterial Circulation

The anatomy of many peripheral arteries is important to anesthesiologists, for direct arterial cannulation, as targets to be avoided during venous cannulation, and in prevention of complications arising from certain surgical procedures. Among these are the coronary, carotid, cerebral, renal, bronchial, and spinal cord circulations (Fig. 31-3A).

Figure 31-3. (A) The major arteries of the human body used by anesthesiologists to directly monitor arterial pressure include the radial, ulnar, femoral, brachial, axillary, dorsalis pedis, and superficial temporal. (B) The major veins of the human body accessible for cannulation include the internal and external jugular, subclavian, femoral, basilic, cephalic, median cubital, and saphenous.

Coronary Circulation

Two coronary arteries, right and left, originate from the sinuses of Valsalva in the aortic valve to supply blood to the myocardium. The left coronary artery usually has a short common or left main coronary artery before bifurcation into anterior descending and circumflex branches. The anterior descending artery courses downward over the anterior left ventricular wall and supplies the interventricular groove through its diagonal and septal perforator branches. Occlusive disease in the anterior descending distribution produces ischemic electrocardiographic changes in leads V₃–V₅. The circumflex branch follows the atrioventricular groove, giving off the obtuse marginal branch and supplying all the posterior LV and part of the right ventricular wall.⁵ Electrocardiographic (ECG) changes resulting from circumflex coronary artery disease are seen in leads I and a_VL (Fig. 31-4 and Table 31-1).

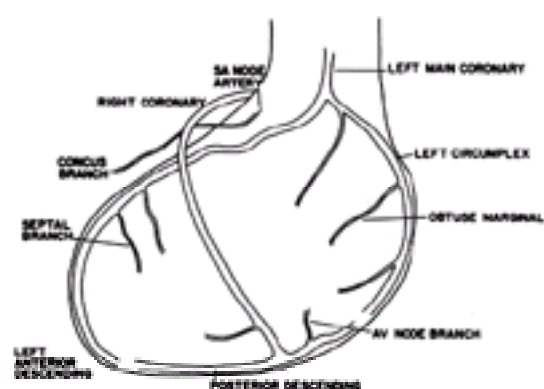

Figure 31-4. In this lateral view, the normal left coronary artery divides into the anterior descending (LAD) and circumflex (CFX) coronary arteries. The right coronary artery usually gives off the arteries to the sinus and atrioventricular nodes before terminating on the inferior surface of the heart as the posterior descending artery.

| Lateral left ventricle |
| RIGHT CORONARY ARTERY |
| SA and AV nodes |
| Right atrium and ventricle |
| Posterior interventricular septum |
| Posterior fascicle of left bundle branch |
| Interatrial septum |

Table 31-1. CORONARY ARTERY DISTRIBUTION

The sinus node and atrioventricular nodal arteries originate from the right coronary artery. The right atrial myocardium is also supplied by the sinus node artery. The right coronary artery terminates on the diaphragmatic surface of the heart as the posterior descending artery⁶ (Fig. 31-4). The blood supply to the atrioventricular node and common bundle of His is the atrioventricular branch of the right coronary artery (in 90% of hearts) and the septal perforating branches of the left anterior descending coronary artery (in 10% of hearts).⁷ Branches to the interatrial septum and posterior interventricular septum also arise from the atrioventricular nodal artery. The right bundle branch and the left anterior fascicle are supplied by branches of the left anterior descending artery but can be supplied by the atrioventricular nodal artery.⁷ Both the left anterior and posterior descending coronary arteries supply the posterior fascicle.⁷ Significant right coronary artery occlusion causes ischemic changes in ECG leads II, III, and a V_F as well as conduction abnormalities. However, the amount of myocardium jeopardized by a clinically significant coronary stenosis cannot be completely determined from angiographic evaluation.

Coronary Dominance. Descriptions of the coronary circulation often refer to the dominance of one or the other coronary artery. Dominance is determined by which artery crosses the crux or junction between atria and ventricles to supply the posterior descending coronary branch. In about 50% of humans, the right coronary artery is dominant, in 20%, the left, and in 30%, a balanced pattern exists. Areas of the myocardium affected by stenosis or occlusion of individual coronary arteries are listed in Table 31-1. Collateral vessels may develop between the major coronary arteries in response to myocardial ischemia.⁸

Cerebral Circulation

The cerebral circulation consists of the anterior communicating arteries, the internal carotid arteries, the posterior communicating arteries, and the vertebral arteries. Together these vessels form the circle of Willis (Fig. 31-5). The external carotid arteries supply the face and neck but not the brain.

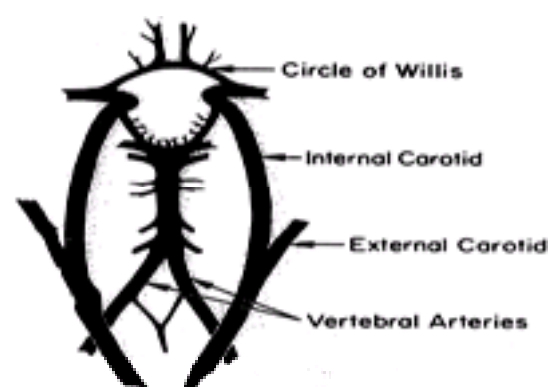

Figure 31-5. The cerebral circulation includes the internal carotid and the vertebral arteries. Together with the anterior communicating and posterior communicating arteries, the carotid arteries from both sides join to form the circle of Willis, which provides collateral circulation to the brain in the event of stenosis or occlusion of one carotid artery. (Modified with permission from Lake CL: Cardiovascular Anesthesia, p 411. New York, Springer-Verlag, 1985.)

Arteries of the Upper Extremity

In the upper extremity the subclavian artery gives rise to the axillary, brachial, radial, and ulnar arteries (see Fig. 31-3). Because the brachial artery is beneath the basilic vein, it may be punctured during attempted basilic vein cannulation in the antecubital fossa. Aberrant radial arteries often traverse the radial styloid process to enter the thenar webbed space. Attempted cannulation of veins over the anatomic “snuffbox” may result in cannulation of an aberrant radial artery.

Intra-abdominal and Lower Extremity Arteries

The abdominal branches of the aorta include the superior mesenteric, inferior mesenteric, and celiac arteries, principally supplying the gastrointestinal tract (see Fig. 31-3). The kidneys are perfused via the renal arteries, receiving about 20% of the cardiac output. The aorta bifurcates into right and left iliac arteries in the lower torso. At the level of the inguinal ligament, the iliacs bifurcate into superficial and deep femoral arteries. The femoral artery can be easily cannulated just below the inguinal ligament. Just below the knee, the femoral artery bifurcates into anterior and posterior tibial arteries. In the foot, the superficial arteries are the dorsalis pedis, located just lateral to the extensor hallucis longus tendon and the posterior tibial artery behind the medial malleolus of the ankle.

Spinal Cord

The major blood supply (75%) to the spinal cord consists of the anterior spinal arteries which traverse the length of the cord and arise from the vertebral arteries. Only the posterior parts of the posterior columns and posterior horns are supplied by the posterior spinal artery (25%), originating from the terminal portion of the anterior spinal arteries. Anastomoses between the anterior and posterior spinal arteries (circumflex arteries) are inconstant and insufficient to sustain adequate cord circulation. In addition, there are radicular arteries that are branches of the intercostal and lumbar arteries; these arteries anastomose with the anteroposterior spinal artery system (Fig. 31-6). There are usually eight (varying from four to ten) radicular branches, at least one in the cervical, two in the thoracic, and one in the lumbar region. The largest of these is the arteria radicularis magna, or artery of Adamkiewicz, in the lower thoracic or upper lumbar region. When this vessel originates from the suprarenal aorta in the lower thoracic or upper lumbar region, it is generally the only significant radicular artery. However, if the origin of the arteria radicularis magna is infrarenal (lumbar segments 2–4), the segmental blood supply to the cord is usually good and there is another major radicular vessel in the thoracic area. Precise radiologic verification of the spinal cord blood supply can be difficult.⁹

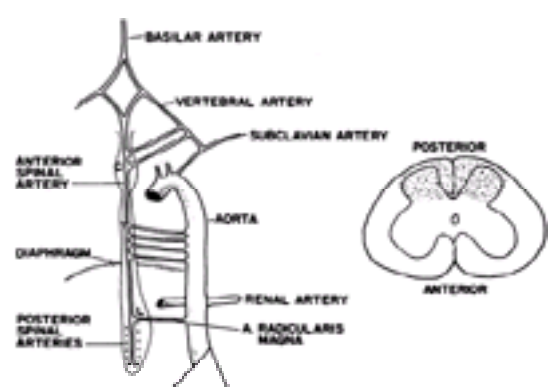

Figure 31-6. The circulation to the spinal cord is often tenuous. It consists of anterior and posterior spinal arteries which arise from the vertebral arteries and radicular

arteries which originate from the intercostal and lumbar arteries. However, the radicular branches are quite variable and ligation of a significant radicular branch causes spinal cord ischemia. In the cross section of the spinal cord (*right*), the stippled portion indicates the posterior spinal artery distribution to the posterior columns and horns. C, T, and L are cervical, thoracic, and lumbar portions of the spinal cord.

Bronchial Circulation

Three bronchial arteries (two for the left lung and one for the right lung) originate from the thoracic aorta at T5 and T6 or intercostal arteries to provide nutrients to the lung and heat and water exchange in the airways. The bronchial circulation, normally small, can enlarge in response to injury, tumor growth, and inadequate pulmonary blood flow (as in cyanotic congenital heart disease) and function in gas exchange.¹⁰

Hepatic and Portal Circulations

Surgery for hepatic transplantation or portal hypertension requires a knowledge of the blood supply to the liver. The liver is supplied by the hepatic artery and portal vein. Total hepatic blood flow is about 20% of the cardiac output and averages $100 \text{ ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ of tissue. Portal venous flow supplies about 65–80% of the total hepatic blood flow, with the remainder coming from the hepatic arterial system. The portal vein, which carries nutrients from the gut to the liver, arises from the superior mesenteric, splenic, and renal veins.

Peripheral Venous Circulation

Major veins follow a course similar to that of the arteries. From the head, the internal and external jugular veins join the subclavian veins of either side (see [Fig. 31-3B](#)). The course of the external jugular vein is often tortuous and variable, and it has two sets of valves, one at the entrance to the subclavian vein and the other about 4 cm superior to the clavicle. From the arms, the basilic (medial aspect) and cephalic veins join as the brachial vein. This vein becomes the axillary vein in the axilla and thence the subclavian. Normally, subclavian veins from both sides unite to form the SVC.

Cardiac veins, the great and middle cardiac veins and the posterior left ventricular vein, drain into the coronary sinus. Near the orifice of the great cardiac vein, the oblique vein of Marshall (vein of the left atrium) enters the coronary sinus. Anterior cardiac veins and the small cardiac vein may enter the right atrium independently of the coronary sinus. Thebesian veins, which traverse the myocardium, drain into various cardiac chambers. Thebesian venous flow, coupled with bronchial and pleural venous flows, contributes the normal 1–3% arteriovenous shunt.

In the legs there are both superficial and deep veins. The greater and lesser saphenous veins are the principal superficial veins. The greater saphenous vein, overlying the medial malleolus, is frequently used as a conduit during aortocoronary bypass grafting. The lesser saphenous vein is located in the posterior aspect of the calf. The saphenous vein joins the femoral vein in the thigh to enter the pelvis as the iliac vein. Right and left iliac veins unite to form the IVC. Veins leaving the liver, the right, left and middle hepatic veins, enter the IVC.

Bronchial veins from the extrapulmonary portions of the proximal tracheobronchial tree drain via the azygos and hemiazygos veins into the SVC. The azygos vein also drains the perispinal areas and the esophagus. These veins assume greater importance if the IVC is occluded. Bronchial venous drainage from the intrapulmonary branches is to the pulmonary veins (left side of the heart).

Cardiac Conduction System

The system for electrical activation of the heart, the conduction system, consists of the sinoatrial (SA) node, the atrioventricular (AV) node, the bundle of His, right and left bundle branches, and the Purkinje system. Pacemaker cells found in these areas include the P cells or round cells and transitional or T cells.¹¹ The SA node is in the right atrial wall at the junction of the RA with the SVC. The SA and AV nodes are connected via the internodal conduction system, which consists of three tracts: the anterior (Bachmann's bundle), middle, and posterior internodal systems.¹² Conduction also spreads rapidly through the atrial musculature to the left atrium via Bachmann's bundle. In human hearts, the AV node is located in the floor of the right atrium, near the ostium of the coronary sinus.⁷ The AV node consists of three areas, the A-N transitional zone containing cells smaller than normal atrial cells, the N region of round or P cells similar to those in the SA node, and the N-H region, a transitional zone near the bundle of His. The fibers forming the common bundle of His pass along the superior edge of the membranous interventricular septum to the apex of the muscular portion of the septum (see [Fig. 31-2](#)). Here the bundle divides into right and left bundle branches, which extend subendocardially along the surfaces of both ventricles. The right bundle branch emerges in the right ventricular endocardium near the moderator band at the base of the anterior papillary muscle. It usually extends for some distance without dividing, but one branch passes through the moderator band and the other passes over the right ventricular endocardial surface. Subdivision of the left bundle into anterior and posterior fascicles occurs shortly after its origin. There is also a small collection of short medial fascicles that originate from the left bundle just after the anterior fascicle and activate the septal myocardium. The posterior fascicle terminates in the posterior papillary muscle.

Peripherally, the fascicles of both right and left bundle branches subdivide to form the Purkinje network. The left bundle branch fascicles make their initial functional contact with the endocardium of the interventricular septum below the aortic valve. Right bundle branch fascicles contact ventricular subendocardium near the base of the anterior papillary muscle.

Cardiac and Vascular Nerves

Sympathetic System

Nerves to the heart and blood vessels originate from sympathetic neurons of the thoracolumbar region and parasympathetic nerves originate from the cervical region. Sympathetic fibers come from the stellate ganglion and the caudal cervical sympathetic trunks. From these trunks arise the right dorsal medial and dorsal lateral cardiac nerves, which frequently unite to form one large nerve that follows the course of the left main coronary artery. It further separates into branches along the anterior descending and circumflex coronary arteries.

Parasympathetic System

Parasympathetic preganglionic neurons arise in the medulla oblongata in the dorsal vagal nucleus and the nucleus ambiguus. These fibers enter the thorax as branches from the recurrent laryngeal and thoracic vagus nerve. The dorsal and ventral cardiopulmonary plexuses between the aortic arch and the tracheal bifurcation receive both sympathetic and parasympathetic branches. From the plexuses emerge three large cardiac nerves, the right and left coronary cardiac nerves and the left lateral cardiac nerve. Ganglia occur within the heart, usually close to the structures innervated by the short postganglionic neurons. Postganglionic transmission occurs from stimulation of nicotinic cholinergic receptors at the postganglionic junction by acetylcholine. Release of acetylcholine at the neuroeffector junction activates muscarinic receptors in the heart.

Cerebral Vasomotor Center

Afferent nerves from the heart ascend via the 10th cranial nerve (vagus) and spinal cord to the nucleus tractus solitarius and the dorsal vagal nucleus and nucleus ambiguus to form the parasympathetic motor efferent system of the medullary vasomotor center. Sympathetic activation of heart and vasculature originates in the rostral ventrolateral (RVL) medulla, ventromedial rostral medulla, and the parvocellular region of the paraventricular nucleus. The RVL neurons receive multiple inputs from other medullary nuclei and modulate sympathetic output.¹³ Although the vasomotor center independently regulates arterial pressure, blood flow distribution, and cardiac contractility, higher centers such as the cerebral cortex, hypothalamus, and pons also influence cardiovascular responses (see [Fig. 31-7](#)).

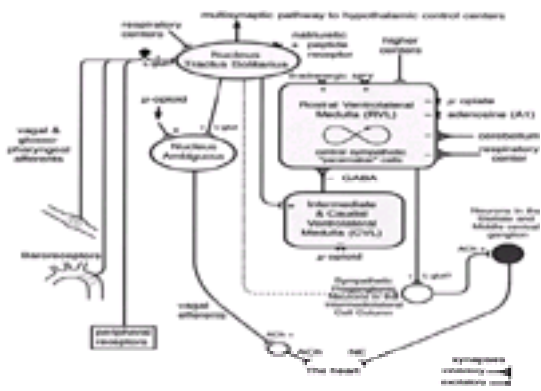

Figure 31-7. The central nervous system exerts considerable control over the heart and circulation via the rostral ventrolateral medulla (RVL), nucleus tractus solitarius, and intermediate and caudal ventrolateral medulla. The RVL contains neurons that provide regular output to sympathetic preganglionic neurons like a pacemaker. The baroreceptor pathway, effects of GABAergic input, and opioid effects on RVL are also depicted. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al*: Cardiac, Vascular and Thoracic Anesthesia, p 136. Philadelphia, Churchill Livingstone, 2000.)

Cardiac Receptors. Vagal receptors located in various cardiac chambers are sensitive to changes in heart rate or chamber pressure. Vagal innervation affects the atrial musculature, the SA and AV nodes, and the ventricular myocardium.¹⁴ The greatest concentrations of parasympathetic nerves are in the SA node, with lesser numbers in the AV node, RA, LA, and ventricles. Parasympathetic α_1 but not α_2 receptors have been identified.

Sympathetic fibers extend to all portions of the atria, ventricles, and conduction system. α_1 , α_2 , β_1 , and β_2 subtypes of adrenergic receptors are present. Human RA contains about 74% β_1 and 26% β_2 receptors.¹⁵ The proportions of β receptors differ in the ventricle, with 86% β_1 and 14% β_2 .

Neural Supply of the Peripheral Vasculature

Innervation of the peripheral circulation, with the exception of the cerebral and coronary vasculature, originates from the thoracolumbar sympathetic fibers. Vasodilation results from reduced sympathetic tone or activation of vasodilatory receptors. Stimulation of α -adrenergic fibers causes constriction in the arterial vascular beds of the skin, skeletal muscle, splanchnic organs, kidneys, and systemic veins. Stimulation of β_2 receptors dilates systemic veins and arteries of the muscle, splanchnic, and renal circulations.

Pericardium

The normal pericardium consists of thick fibrous and serous visceral layers. It has certain anatomic functions, among which are the isolation of the heart from other mediastinal structures, maintenance of the heart in optimal functional shape and position, minimization of cardiac dilatation, and prevention of adhesions.¹⁶ The pericardium also contains vagal nerve branches.

CARDIOVASCULAR CATHETERIZATION AND ANGIOGRAPHY

Abnormalities of both the anatomy and physiology of the cardiovascular system are diagnosed by invasive catheterization when noninvasive procedures such as echocardiography insufficiently define the defects.

Catheterization

In all age groups, cardiac catheterization is usually performed via the femoral vessels. Occasionally, the brachial vessels are used in adults if the femoral vessels cannot be entered or catheters cannot be manipulated through the abdominal aorta.¹⁷ Direct vascular cutdowns are rarely necessary because the Seldinger technique, with various sizes of sheaths and introducers, provides adequate access in most patients.¹⁸ The passage of catheters through either the venous or the arterial system is guided by fluoroscopy. Pressure measurements are made in each cardiac chamber or great vessel, their pressure waveforms recorded, and vascular or ventricular angiography performed. Normal pressure values and oxygen saturations are presented in [Table 31-2](#). Oxygen saturation is greater in the IVC than in the SVC owing to the contribution of blood from the renal veins. Normal pressure waveforms are seen in [Figure 31-8](#). Measurements commonly made or calculated during cardiac catheterization are detailed in [Table 31-3](#) and [Table 31-4](#). These include cardiac output (Fick, dye dilution or thermodilution), measurement of valve areas,¹⁹ and calculation of shunt flows.

| Site | Pressure (mm Hg) | Oxygen Saturation (%) |
|--------------------|------------------|-----------------------|
| Inferior vena cava | 0-8 | 80 ± 5 |
| Superior vena cava | 0-8 | 70 ± 5 |
| Right atrium | 0-8 | 75 ± 5 |
| Right ventricle | 15-30/0-8 | 75 ± 5 |
| Pulmonary artery | 15-30/4-12 | 75 ± 5 |
| Pulmonary wedge | 5-12 (mean) | 75 ± 5 |
| Left atrium | 12 (mean) | 95 ± 1 |
| Left ventricle | 100-140/4-12 | 95 ± 1 |
| Aorta | 100-140/60-90 | 95 ± 1 |

Table 31-2. NORMAL CATHETERIZATION DATA

Figure 31-8. The events of the cardiac cycle from filling of the atria to ventricular emptying are demonstrated using waveforms from the aorta, pulmonary artery, right and left ventricles, and central veins. The relationship between the electrocardiogram and the phases of the cardiac cycle shows that ventricular systole occurs immediately following the QRS complex. The changes in ventricular pressure–volume waveform coincide with ventricular ejection and filling.

| Left Ventricle Cardiac Output | Right Ventricle Cardiac Output |
|---|---|
| $CO = \frac{SV}{HR}$ SV = stroke volume HR = heart rate $CO = \frac{SV}{HR} = \frac{SV \times 60}{HR}$ | $CO = \frac{SV}{HR}$ SV = stroke volume HR = heart rate $CO = \frac{SV}{HR} = \frac{SV \times 60}{HR}$ |
| $CO = \frac{CI \times BSA}{60}$ CI = cardiac index BSA = body surface area $CO = \frac{CI \times BSA}{60}$ | $CO = \frac{CI \times BSA}{60}$ CI = cardiac index BSA = body surface area $CO = \frac{CI \times BSA}{60}$ |

Table 31-3. MEASUREMENTS DURING CARDIAC CATHETERIZATION

| Variable | Calculation | Normal Values |
|---|---|------------------------------|
| Cardiac index (CI) | CI/BSA | 2.5–4.0 l/min/m ² |
| Stroke volume (SV) | $CI \times BSA$ | 60–100 ml/beat |
| Stroke index (SI) | SI/BSA | 40–60 ml/beat/m ² |
| Mean arterial pressure (MAP) | Diastolic pressure + one third pulse pressure | 80–120 mm Hg |
| Systemic vascular resistance (SVR) | $MAP - CVP/CO \times 79.4$ | 100–200 dyne/cm ⁵ |
| Pulmonary vascular resistance (PVR) | $PAP - PWP/CO \times 79.4$ | 100–300 dyne/cm ⁵ |
| Right ventricular stroke work index (RVSWI) | $CO(PAP - PWP) \times 0.0136$ | 5–8 g/m ² /beat |
| Left ventricular stroke work index (LVSWI) | $CO(MAP - PWP) \times 0.0136$ | 6–8 g/m ² /beat |

CVP = mean central venous pressure; BSA = body surface area; CI = cardiac output; CVP = mean pulmonary artery pressure; PWP = pulmonary wedge pressure; MAP = mean arterial blood pressure.

Table 31-4. HEMODYNAMIC VARIABLES: CALCULATIONS AND NORMAL VALUES

Angiography

Cineangiography with iodinated dyes is performed to quantitate ventricular contractility, to evaluate shunting between cardiac chambers, to demonstrate valvular regurgitation, or to delineate vascular outlines (e.g., pulmonary venous return, aortic dissection, pulmonary embolism). Angiography assesses the amount of valvular regurgitation by grading the amount of contrast agent re-entering the chamber preceding the valve. For instance, in the case of aortic regurgitation, 1+ regurgitation is a small amount of contrast material entering the left ventricle during diastole but clearing with each systole. The left ventricle is faintly opacified during diastole and fails to clear with systole with 2+ regurgitation. In 3+ aortic regurgitation, the left ventricle is progressively opacified during diastole and eventually completely opacified, whereas in 4+ aortic regurgitation, the left ventricle is completely opacified on the first diastole and remains opacified for several beats.

Coronary Arteriography

Selective coronary angiography using either the retrograde brachial technique of Sones or the percutaneous femoral approach of Amplatz or Judkins selectively evaluates each coronary artery for the presence and extent of coronary occlusive disease, aneurysm formation, or congenital anomalies (see Fig. 31-4). Coronary arteriography occasionally causes ventricular ectopy, the Bezold–Jarisch reflex, ventricular asystole, or fibrillation. More common are T-wave changes, bradycardia, and mild hypotension. Even in normal coronary arteries, injection of the right coronary artery produces T-wave inversion in lead II and injection of the left artery produces T-wave peaking in lead II.²⁰ These changes revert to normal when the catheter is removed from the coronary ostia or the blood pressure is increased by having the patient cough.

Determination of Shunts

A shunt exists when arterial and venous blood mix at either an intracardiac or an extracardiac location, usually as a result of a congenital cardiac malformation. The site of a shunt can be determined by measurement of oxygen saturations in various cardiac chambers. A 10% step-up in oxygen saturation at the atrial level indicates left-to-right shunting into the right atrium. A 5% step-up at the ventricular or aorticopulmonary level indicates shunting at that site.

PHYSIOLOGY

Cardiac Cycle

The cardiac cycle begins with the filling of the right and left atria while the tricuspid and mitral valves are closed (see Fig. 31-8). For a complete discussion of the events of the cardiac cycle in normal and abnormal hearts, the reader should consult Pagel *et al.*^{21,22} The V wave on the venous pressure waveform represents the gradual increase in atrial blood volume as blood returns from the periphery. Once the aortic valve has closed but ventricular pressure still exceeds atrial pressure, the ventricle undergoes isovolumetric relaxation. About 0.02–0.04 sec after closure of the aortic valve, atrial and ventricular pressures equalize, and a small gradient develops across the AV valves as ventricular pressure decreases further. The AV valve cusps bulge into the ventricle and separate slightly. After cross-over of the atrial and ventricular pressure waves, the AV valves open completely. The V wave of the atrial pressure waveform crests when the atria are filled, and the tricuspid and mitral valves open to initiate ventricular filling. The Y wave results from opening of the AV valves combined with ventricular relaxation. Effective atrial systole at resting heart rates contributes about 5–20% of the stroke volume. Acute atrial fibrillation increases atrial pressures, reduces atrial compliance, increases atrial oxygen consumption, and eliminates the contribution of the atria to ventricular filling.²³

During initial ventricular filling, ventricular volume increases rapidly, the rapid filling phase, during which time the ventricular pressure continues to decrease because ventricular expansion exceeds filling. Peak ventricular filling in early diastole occurs at 500–700 ml · sec⁻¹ as ventricular relaxation actually produces a negative intracavitary pressure (diastolic suction). The elastic recoil of the heart and great vessels during diastole contributes to the accelerated filling phase of the ventricle, particularly during tachycardia.

A period of reduced ventricular filling follows the rapid filling phase. The third heart sound, S₃, occurs at the point of transition from rapid ventricular filling to reduced filling. The nadir of the ventricular pressure curve at the end of the rapid filling phase probably marks the end of ventricular relaxation and the beginning of elastic distention of the ventricle. The upswing in the ventricular pressure abolishes forward movement of blood and can force the AV valves into a semiclosed position unless venous return is great. The previous ventricular contraction provides much of the energy for the subsequent diastolic expansion through the energy expenditure of the gross movement and deformation of the heart during systole.²⁴ Atrial systole, the A wave on the venous pressure waveform, which coincides with the P wave on the ECG, concludes ventricular filling.

Right atrial pressure, a guide to right atrial and right ventricular function, is indirectly assessed by observation of the level of jugular venous pressure, the end-expiratory peak pulsation of the internal jugular vein above the sternal angle with the subject in a 30° reverse Trendelenburg position. Normally, the level is <4 cm. A sustained increase in the level of more than 1 cm during abdominal compression (hepatojugular reflux) indicates abnormal right ventricular function. Only when biventricular function is normal can the central venous pressure be used as a guide to left ventricular function.

There are three phases of activity in the left atrium: (1) the reservoir phase of inflow during ventricular diastole; (2) a conduit phase of passive emptying during ventricular end diastole; (3) contraction and active emptying during ventricular end diastole.²⁵ All of these left atrial functions are affected by atrial relaxation, stiffness, and contractility.²⁵

In hearts with poorly functioning ventricles, atrial contraction is important and a fourth heart sound, S₄, which occurs 0.04 sec after the P wave, results from vibrations of left ventricular muscle and mitral valve. The S₄ is most likely to occur with vigorous atrial contraction. The adequacy of ventricular filling is determined by the

distensibility (compliance) of the ventricles, the filling time, and the effective filling pressure. The effective filling pressure is the transmural ventricular pressure. Tachycardia also decreases the time available for ventricular filling, decreasing filling time from 400–500 ms at a heart rate of 60 beats per minute to 10 ms or less at 160 beats per minute. Mitral stenosis, ischemic heart disease, and hypertrophic cardiomyopathy slow ventricular filling and alter ventricular distensibility. The intraventricular pressure just prior to the beginning of ventricular contraction is end-diastolic pressure (see [Table 31-2](#)). However, normal end-diastolic pressures do not imply normal ventricular function. Increased end-diastolic pressures occur with hypervolemia or changes in ventricular compliance as well as decreased contractility.

The period just before the sudden increase in ventricular pressure is presystole, which includes atrial systole and the time just before isovolumetric ventricular contraction. The Z point on the venous pressure waveform is the period when atrial and ventricular pressures are essentially equal immediately preceding ventricular systole. The isovolumetric phase of ventricular contraction is marked by the C wave on the venous waveform. Isovolumetric contraction is the period between closure of the AV valves and opening of the semilunar (aortic, pulmonic) valves. Intraventricular pressure increases, but there is no change in intraventricular volume. After this point, the AV valves close, atrial diastole begins, the ventricles begin to contract, and ventricular pressure soon exceeds atrial pressure. Ventricular systole occurs immediately after the QRS complex on the electrocardiogram, about 0.12–0.20 sec after atrial contraction. AV valve closure is facilitated by the increased ventricular pressure and the cessation of atrial systole. Closure of the AV valves is noted clinically by the normally split first heart sound, S_1 .

The aortic and pulmonic valves open at the summit of the C wave. The atrial pressure decreases, resulting in the X descent, because blood goes into the aorta and pulmonary artery. Once the ventricular pressure exceeds the aortic pressure, the aortic and pulmonic valves open. The majority of ventricular ejection occurs during the rapid ejection phase. The pressure in the aorta is slightly lower, whereas ventricular pressure increases rapidly. Initially the output into the aorta exceeds the runoff into the peripheral circulation. Peak aortic pressure occurs slightly after peak aortic blood flow. As aortic runoff and ventricular output equilibrate, the period of reduced ventricular ejection occurs. Forward flow continues until the end of ventricular diastole, protodiastole, when a brief period of retrograde flow initiates aortic and pulmonic valve closure. On pressure waveforms, semilunar valve closure is marked by a notch or incisura. The second heart sound, S_2 , results from rapid deceleration of blood causing vibration of the outflow tracks and great vessels and closure of the semilunar valves.

Cardiac Electrophysiology

Cellular Electrophysiology

Cardiac pacemaker cells have an intracellular ionic composition which differs from that found in the extracellular fluid. The most important ions are calcium, sodium, and potassium. An active transport system in the cell membrane, the sodium–potassium pump, maintains normal concentration gradients for sodium and potassium by pumping sodium ions out of the cell and potassium ions into the cell. Extracellular ions cross the cell membrane through specialized membrane proteins, the ion channels, which are characterized by their conductance, selectivity, gating, and density. Conductance is the rate (ions \cdot ms $^{-1}$) at which ions pass through the channel. In a given channel, each ion has a particular conductance. Channels are named for the ion most rapidly transferred since some ions, but not others, are transported. Density is described as the number of channels per square micrometer. However, density may be variable over the cellular sarcolemma. Gating is the property of the channel that allows it to be activated or inactivated in response to voltage changes or binding of an agonist. Examples of these channels, which directly or indirectly control cardiac function, are given in [Table 31-5](#).

| Channel | Activation Kinetics | Inactivation Kinetics |
|--|---------------------|--|
| Sodium (I_{Na}^+) | Fast | Fast, except for a fraction that recovers |
| Calcium (I_{Ca}^{2+}) | Fast | Fast |
| L-type or high-voltage-activated (I_{CaL}) | Fast | Variable, Ca^{2+} -dependent component |
| T-type | Fast | Minimal |
| Potassium | | |
| Transient outward | Fast | Mg^{2+} and polyamine block of outward current |
| Phase 4 background | Slow | None |
| Delayed rectifier | Fast | None |
| Transient outward | Fast | None |
| ACH, adenosine 5'-triphosphate-activated | Fast | None |
| ATP-sensitive | Fast | None |
| Slowly activated | Slow | None |
| Rapidly inactivated | Fast | None |
| Delayed rectifier | Fast | None |
| Transient outward | Fast | None |
| CFTR (not well understood) | Fast | None |

Table 31-5. CARDIAC ION CHANNELS

b Receptors, consisting of the receptor, the G protein (guanosine triphosphate binding protein) system,²⁶ and adenylyl cyclase are also located in the cell membrane. Receptors recognize and bind agonists, activating the G protein G_s , which, in turn, activates adenylyl cyclase to stimulate hydrolysis of adenosine triphosphate to cyclic adenosine monophosphate. Cyclic adenosine monophosphate opens the calcium channel, permitting calcium influx. The entire complex forms a transmembrane signaling system (see [Fig. 31-8](#)).

The SA node is normally the dominant pacemaker because, in it, automaticity is most highly developed and impulses are initiated at the fastest rate. In SA nodal cells, when the internal membrane potential reaches -50 mV, the depolarization rate increases to $1-2$ V \cdot sec $^{-1}$, causing a slowly depolarizing action potential. Automaticity decreases in order from SA node, AV node, His bundle, proximal Purkinje fibers, and distal Purkinje fibers. The rate of Phase 4 depolarization is faster in the SA node than in the AV node and faster in the AV node than in the terminal Purkinje fibers, causing less highly developed pacemakers to be depolarized by the propagated wave from above before they spontaneously depolarize. Interactions between sympathetic and parasympathetic innervations also affect the intrinsic depolarization rate.

The compound action potential in cells results from local ionic transmembrane fluxes or currents through the channels ([Fig. 31-9](#)). Ionic transfer is facilitated by the energy released from the hydrolysis of adenosine triphosphate. Pacemaker cells in the unexcited state are maintained at a resting potential of -80 mV by the inward (anomalous) rectifier current I_{K1} . As the slow spontaneous depolarization of Phase 4 proceeds, there is an increase in the permeability of the membrane, which permits positively charged sodium ions to move across the cell membrane into the cell, resulting in depolarization. This sodium influx (fast sodium current, I_{Na}) reverses the transmembrane potential from -80 mV to $+20-30$ mV and initiates the rapid depolarization (Phase 0) of the action potential in a cardiac pacemaker cell ([Fig. 31-9](#)). During Phase 0 there is also a decrease in permeability to potassium. At about -30 mV, inward calcium transfer (I_{Ca}) begins through the L-type (long-lasting, high-threshold) channels which require greater than -40 mV to activate for opening. The spread of depolarization throughout the atrial and ventricular muscle results in the P wave and the QRS complex of the electrocardiogram, respectively. After excitation, the cell membrane undergoes an initial period of rapid repolarization (Phase 1), followed by a variable period when the membrane potential is close to 0, the plateau of the action potential. The plateau is caused by decreasing sodium and calcium influx (through the L-type calcium channel) and increasing potassium efflux. Four K^+ currents participate in repolarization, including I_{to} , the transient outward current during the initial phase of repolarization; the I_K plateau and delayed K current (I_K) during the plateau; and I_{K1} or inward rectifier during final repolarization.²⁷ The duration of the action potential is rate-dependent owing to enhanced calcium entry. Phase 3, the repolarization phase that results from “delayed outward” potassium current I_{X1} , corresponds to the T wave of the electrocardiogram. During Phase 4, the resting membrane potential is generated by active exchange of intracellular sodium for potassium through the sodium–potassium ATPase or sodium pump. The resting potassium conductance that maintains the resting potential is G_{K1} , the inward (anomalous) rectifier. In the latter part of Phase 4, the resting membrane potential is stable in ventricular muscle cells until the cell is excited again. In automatic cells such as the SA and AV nodes, slow, spontaneous depolarization occurs during Phase 4 as a result of the pacemaker currents calcium I_f and I_{K2} .

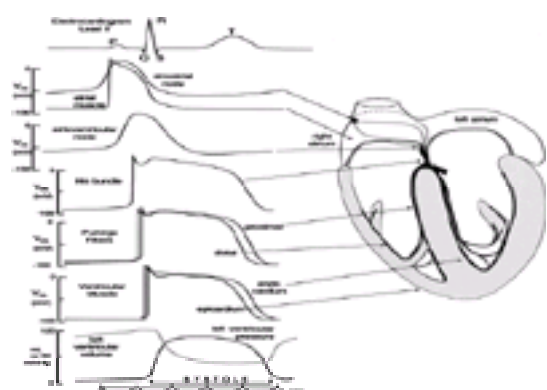

Figure 31-9. The action potential of an automatic cell such as the sinoatrial node differs from that of the ventricular muscle cell in that the cell slowly depolarizes spontaneously during Phase 4. The action potential in a Purkinje cell has the most rapid rate of depolarization, $400\text{--}800\text{ V} \cdot \text{sec}^{-1}$. When the cell is stimulated, an action potential occurs due to a rapid influx of sodium ions into the cell (Phase 0). Phase 1 includes a notch caused by the “early outward current”, I_{to} , which is a transient K efflux, probably activated by an intracellular calcium increase. Phase 2 is the plateau of the action potential resulting principally from calcium entry through the slow channel of the cell membrane. During Phase 3, repolarization of the cell occurs while during Phase 4, the sodium entering during Phase 0 is actively pumped out of the cell. In a ventricular muscle cell, unlike the automatic cells, there is no spontaneous Phase 4 depolarization. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 87. Philadelphia, Churchill Livingstone, 2000.)

During depolarization, the cell membrane is absolutely refractory to other stimuli because almost all of the sodium channels inactivate. The end of the absolute refractory period is signaled by the earliest transient depolarization that can be elicited because sufficient numbers of activatable sodium channels are present. The absolute refractory period ends at the beginning of the T wave of the electrocardiogram. Once repolarization reaches the threshold potential, the cell is relatively refractory, since an unusually strong stimulus can produce depolarization. This period is marked by the T wave of the ECG. The earliest propagated action potential defines the end of the effective or functional refractory period.

Action Potential Alterations

Changes in the action potential itself or factors that affect the action potential alter the rate of firing of an automatic cell. The rate of an automatic cell depends on the slope of Phase 4 depolarization, the maximum diastolic potential (the maximum level of resting membrane potential achieved at the end of repolarization), the RMP, and the threshold potential.²⁸ The variable expression of the previously described ion channels in different parts of the heart produces the characteristic electrophysiology of the pacemakers, conduction tissue, atria, and ventricles. Factors affecting the action potential are listed in Table 31-6.^{28, 29,30} and ³¹ In addition to effects on the action potential, alterations in potassium current affect membrane electrical stability. Low extracellular K^+ reduces conductance through the inward rectifier channel (G_{K1}). Thus, there is greater cellular excitability and tendency for ectopy. With increased extracellular K, more potassium current escapes from the cell and the membrane is relatively stable.

Table 31-6. ACTION POTENTIAL ALTERATIONS

Clinical Electrophysiology

The first wave of the normal electrocardiogram is the P wave, which is produced by atrial depolarization resulting from an action potential in the SA node. It is usually upright, except in lead aV_R , and 0.11 sec in duration. Sinus node rate exhibits a circadian rhythm, decreasing nocturnally. Sinus node recovery time is also prolonged at night.³²

An electrical impulse travels from the SA node to the AV node in 0.04 sec via atrial tissue, specialized atrial conducting tissue, or the anterior, middle, and posterior tracts of the right atrium. Transmission is further delayed in the AV node because its conduction velocity is about $0.2\text{ m} \cdot \text{sec}^{-1}$. The effective refractory period of the AV node demonstrates circadian rhythm and is increasingly prolonged at night.³² The PR interval (normally 0.2 ms or less), which occupies the time between atrial and ventricular depolarization, is nearly isoelectric, because atrial repolarization is not recordable. Significant interactions between the parasympathetic and sympathetic nervous systems control the conduction through the AV node with predominantly sympathetic activity.³³

Ventricular depolarization begins $\sim 0.12\text{--}0.20$ sec in adults and $0.15\text{--}0.18$ sec in children after depolarization of the SA node to produce the QRS complex.³⁴ The entire QRS complex should be <10 sec. The first negative wave of the QRS complex is the Q wave, which should be ≤ 0.04 s in duration and less than one fourth of the subsequent R wave in amplitude. The first positive wave in the QRS is the R wave, and the second negative wave is the S wave. The right and left branches of the bundle of His connecting with the Purkinje fibers conduct the depolarizing impulse rapidly over the endocardial surface of the heart. Normally in sinus rhythm the earliest area of ventricular activation is the trabecular area on the anterior right ventricular surface about 18–25 ms after the surface QRS complex. Activation then spreads toward the apex and base of the heart, with the latest activation at the cardiac base. Electrical activation also spreads from endocardium to epicardium.

On the electrocardiogram the time from the end of ventricular depolarization to the beginning of repolarization, the ST segment, is isoelectric. More than 1 mm of elevation in the standard leads or 2 mm of elevation in the precordial leads is abnormal in this segment. No more than 0.5 mm of depression should be seen in any lead. The J point, the junction between the QRS complex and the ST segment, is depressed or elevated with the ST segment. Ventricular repolarization results in the T wave. T waves are normally upright in leads I, II, and $\text{V}_3\text{--}\text{V}_6$, inverted in lead aV_R , and variable in leads II, aV_L , aV_F , V_1 , and V_2 . The T wave should not exceed 5 mm in height in the standard leads or 10 mm in the precordial leads. The QT interval, varying inversely with heart rate, should be slightly less than one half of the RR interval.³⁵ The U wave, a small upright deflection after the T wave, is usually nondetectable.

Physiology of the Cardiac Nerves

Neural Regulation

Neural regulation of the heart is complex. The dominance of either the sympathetic or the parasympathetic system varies with age and physical condition, but the inhibitory parasympathetic system usually predominates.^{36,37} Parasympathetic stimulation, particularly of the right vagus nerve, decreases heart rate by slowing the SA node. Lower pacemakers such as the AV node or His bundle may take over, causing “nodal rhythm.” Vagal stimulation tends to suppress ventricular automaticity, which may facilitate termination of ventricular dysrhythmias. Intense vagal stimulation depresses both atrial and ventricular contractility by stimulation of cardiac muscarinic receptors that alter the myocyte cyclic adenosine monophosphate level, by inhibition of norepinephrine release from nearby sympathetic nerve terminals by acetylcholine, and by inhibition of adrenergic receptor activation. One of the G proteins, G_i , which inhibits adenylcyclase, lowering the levels of cyclic adenosine monophosphate, is coupled with the muscarinic receptor to control potassium channels and decrease heart rate (Fig. 31-10).

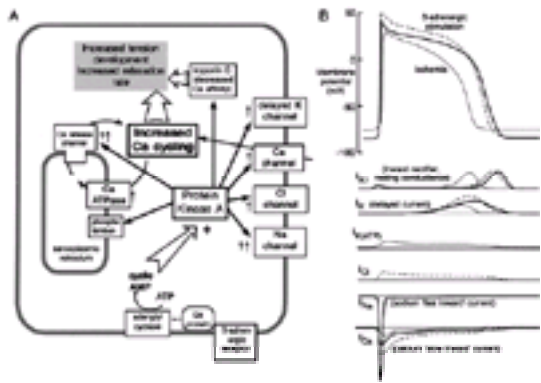

Figure 31-10. Effects of adrenergic stimulation on the heart. β -Adrenergically stimulated protein phosphorylation occurs owing to activation of protein kinase A and increased cyclic adenosine monophosphate (cAMP) production. Increased cycling of Ca^{2+} and phosphorylation of multiple ion channels (Ca, Cl, Na, and delayed K) occurs. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 100. Philadelphia, Churchill Livingstone, 2000.)

Stimulation of the stellate ganglion or other sympathetic cardiac fibers increases heart rate, contractility, and ejection fraction. The right stellate ganglion has a greater effect on heart rate, whereas the left has more effect on contractility. Abnormalities of sympathetic cardiac nerve tone occur in long QT interval syndromes.³⁸

The role of the cardiac α receptors is unclear, but their action is modulated by G protein signal transduction. β_1 Receptors of the heart have positive chronotropic, inotropic, and lusitropic effects on the heart by stimulation of adenylylase. Action potentials may be restored by β_1 stimulation owing to increased numbers of activatable calcium channels in sufficient density to permit regenerative ionic flux along a fiber. Activation of cardiac β_2 receptors also increases rate and contractility, particularly in end-stage heart failure. The effects of norepinephrine on contractility are mediated by increased calcium entry through more active calcium channels and increased sarcoplasmic uptake of calcium. Increased sarcoplasmic uptake of calcium has a lusitropic effect while making the increased calcium (in the sarcoplasmic reticulum) available for subsequent contractions (see Fig. 31-10).

Atrial Receptors

Parasympathetic receptors Type A, Type B, and receptors innervated by Group C fibers reflexly alter intravascular volume or heart rate. The primary locations of Types A and B receptors are the cavoatrial junction, pulmonary venous–atrial junction, atrial appendage, and atrial body.³⁹ Type A receptors may actually respond to heart rate rather than atrial pressure.³⁹ Type B receptors are stretch receptors whose discharge is closely related to atrial volume and varies with the rate of atrial pressure increase.

Ventricular Receptors

Stimulation of ventricular receptors causes either cardiovascular excitation or depression. Types of ventricular receptors include the pressure-sensitive coronary baroreceptors, mechanoreceptors (innervated by nonmyelinated vagal afferent fibers), and sympathetic mechanosensitive or chemosensitive receptors.³⁹

The Bainbridge reflex, described below, is mediated by the parasympathetic receptors. Myocardial ischemia increases discharge of both vagal and sympathetic receptors. The sympathetic afferent fibers may transmit the pain sensation associated with coronary occlusion. Postcardiotomy hypertension results from a cardiogenic reflex transmitted through the sympathetic afferent fibers of the stellate ganglion.³⁹ Finally, opiate receptors of the K type, found in vagus, cardiac, and sympathetic ganglia, may mediate dysrhythmias, particularly during ischemia and reperfusion.^{40,41}

Both cardiac contraction and conduction are modulated through the β -adrenergic receptors and guanine nucleotide binding proteins or G proteins. G protein molecules consist of seven transmembrane α -helical segments, which create a central cleft to which various ligands can bind. When binding occurs, the receptor undergoes a conformational change. An example of the G protein signaling system in the heart is the binding of catecholamines to the β -adrenergic receptor, which in turn, activates the stimulatory G protein and adenylylase, increasing intracellular cyclic AMP, cardiac contractility, and heart rate. However, a detailed discussion of the G proteins is beyond the scope of the chapter and may be found in other sources.⁴²

Coronary Circulatory Physiology

About 5% of the cardiac output, or $250 \text{ ml} \cdot \text{min}^{-1}$, perfuses the coronary arteries of a 70-kg person. Physiologically, the coronary circulation consists of large, low-resistance epicardial vessels and higher-resistance intramyocardial arteries and arterioles. Myocardial flow, pressure, and oxygen consumption are integrally related. Coronary blood flow is locally regulated by metabolic, mechanical, anatomic, and possibly myogenic factors.⁴³ Numerous methods to measure human myocardial blood flow have been described.⁴⁴ Coronary flow is determined by the duration of diastole and the difference between diastolic aortic pressure and left ventricular end-diastolic pressure. During systole about 15–25% of the coronary flow distends and is stored in the extramural coronary arteries. Only a small amount actually perfuses the myocardium. During diastole, this stored blood perfuses the myocardium⁴⁵ (Fig. 31-11). The majority of left coronary artery flow occurs in diastole because intramyocardial pressure is lowest at that time.⁴⁶ Right coronary artery flow occurs in both systole and diastole because intramyocardial pressure is lower in the thinner right ventricle. Intramyocardial pressure affects coronary flow to a small extent because of the varying stiffness of ventricular muscle over the cardiac cycle.⁴⁶ Coronary flow also decreases from epicardium to endocardium as a consequence of extravascular pressure.

Figure 31-11. This diagrammatic relationship between aortic pressure and coronary flow demonstrates that little coronary flow occurs during systole while the majority occurs during diastole. This relationship is particularly true to the left coronary artery which supplies the left ventricle. The right ventricle, being thinner and developing less pressure, produces less impediment to systolic coronary flow.

The zero flow pressure, normally about 12–50 mm Hg, is a minimum coronary pressure required to initiate flow. The source of this pressure is the collapsed intramyocardial coronary microvessels when tissue pressures exceed intraluminal pressures and intracavitary back pressure. At least half of coronary vascular resistance results from vessels larger than 100 μm in diameter, whereas 10% results from coronary veins.⁴⁷ Coronary flow ceases completely at 20 mm Hg, the critical closure or critical flow pressure.⁴⁸

Myocardial oxygen consumption is high; therefore, coronary venous blood is only 30% saturated and its PO_2 of 18–20 mm Hg is the lowest anywhere in the body. Because oxygen extraction cannot be increased further, coronary flow must increase if the heart requires additional oxygen.

Coronary Autoregulation

Coronary perfusion is autoregulated to maintain a constant flow over a range of perfusion pressures (usually between 50 and 120 mm Hg) at any given myocardial oxygen demand.⁴⁹ Above and below these limits, coronary flow varies with perfusion pressure. The term *autoregulation* refers strictly to pressure-dependent changes in coronary resistance unrelated to changes in myocardial metabolism.⁴⁹ The principal site of coronary autoregulation is the coronary arteriole, a <150- μm -diameter vessel, although small coronary arteries (>150 μm) can be recruited to increase flow during hypoperfusion.⁵⁰ Nevertheless, the coronary arterioles are not fully dilated even during hypoperfusion states.⁵¹

However, changes in myocardial oxygen demand alter autoregulation. The involved metabolite, therefore, is oxygen (specifically, myocardial oxygen tension, PO_2) acting through mediators such as adenosine.⁴⁵ Adenosine-induced vasodilation is inversely related to arterial diameter, with the greatest dilation occurring in smaller vessels.⁵⁰ Hyperoxia decreases, and a low PO_2 of 49 mm Hg increases coronary blood flow and myocardial oxygen consumption independently of changes in oxygen content or delivery.⁵² The threshold oxygen tension for autoregulation is 32 mm Hg.⁵³ Coronary autoregulation is also closely coupled with coronary venous PO_2 , particularly at $\text{PO}_2 < 25$ mm Hg.^{45,53} Decreased heart rate attenuates autoregulation, whereas pharmacologic coronary constriction augments it.⁵³

The autoregulatory mechanism may even extend into different myocardial layers.⁴⁵ Autoregulation is greater in the subepicardium than in the subendocardium, possibly because of the transmural gradient to which the subendocardial vessels are exposed.⁴⁹ Autoregulation in the right coronary artery may be less than in the left coronary artery. Pressure and flow-dependent changes in myocardial oxygen consumption in the right ventricle explain these differences.⁴⁹

Immediately after occlusion of a coronary artery, reperfusion flow increases beyond preocclusion levels, a process termed *reactive hyperemia*. In a related process, *reactive dilation*, large coronary arteries dilate after relief of occlusion; but unlike in reactive hyperemia, the onset is delayed to 60 sec and sustained for 150 sec after relief of occlusion.⁵⁴

The most important regulators of coronary vascular tone are metabolic and involve multiple pathways. Modulation of basal tone and normal autoregulation is mediated by glybenclamide-sensitive K_{ATP} channels, which are enhanced by adenosine receptor activation.^{55,56} Other mediators and pathways such as oxygen, potassium, pH, carbon dioxide, endothelium-derived relaxing factor, prostaglandins, prostacyclin, histamine, and adenosine triphosphate may also be involved in regulating coronary tone.⁴³ Prostaglandin E_1 dilates the coronary arteries, probably acting through adenosine as a mediator. Prostaglandin E_2 , however, is a coronary vasoconstrictor.⁵⁷ Acetylcholine increases coronary flow. Acting through the H_1 receptor, histamine contracts epicardial coronary arteries, provoking spasm, but the H_2 receptor mediates vasodilation.⁵⁸ Histamine also promotes production of prostaglandin in the heart.⁵⁸ Although norepinephrine (or sympathetic cardiac nerve stimulation) causes coronary constriction through its α effects, the associated increase in myocardial contractility increases coronary flow. Similarly, vagal stimulation may directly produce coronary vasodilation, but the associated decrease in heart rate and contractility causes secondary coronary vasoconstriction.

Coronary Flow Reserve

Coronary flow increases during maximal dilation of the coronary arteries. The difference between resting and maximal coronary flow is the coronary flow reserve. Coronary flow is heterogeneous throughout the myocardium, although there is correlation between regional flow in neighboring myocardial areas.⁵⁹ Although coronary vasodilation occurs in response to ischemia or other endogenous stimuli, maximal flow, which is normally unavailable to the heart, may be achieved with pharmacologic agents. Exhaustion of autoregulatory vasodilator reserve does not necessarily mean that exhaustion of pharmacologic vasodilator reserve has occurred. Coronary flow reserve can be decreased by (1) decreased maximal flow and (2) increased regulated coronary flow.⁶⁰ Maximal coronary flow is decreased by tachycardia, increased blood viscosity, increased myocardial contractility, and myocardial hypertrophy.⁴⁵

As epicardial coronary artery stenosis occurs, so does arteriolar vasodilation in order to maintain flow at normal levels. Once the vasodilator reserve is exhausted (usually at stenoses of >90%), however, an increase in the stenosis of the coronary artery will decrease flow. Administration of a vasodilator to a vascular bed served by a normal and a stenotic coronary artery connected by collaterals will dilate the normal arterioles but produce little change in the arterioles served by the stenotic artery, since they are maximally dilated. The increased flow to the normal arterioles is termed "coronary steal."

Endocardial/Epicardial Flow Ratio

The distribution of coronary flow is as important as total flow. The ratio of flow in the endocardium to that in the epicardium, the endo/epi ratio, is used to assess flow distribution. Subepicardial flow is usually adequate; thus, if the endo/epi ratio remains constant, adequate subendocardial blood flow is inferred.⁶⁰ However, with maximal coronary vasodilation, the endo/epi ratio varies with the coronary perfusion pressure.⁴⁵ The ratio is minimally affected by changes in afterload but reduced by increased left ventricular preload. The latter results either from a disproportionate increase in subendocardial diastolic tissue pressure or an increase in coronary sinus pressure.⁴⁵ However, increased right ventricular preload decreases right ventricular blood flow without altering its intramyocardial distribution.⁶¹

Transient subendocardial ischemia accompanies the onset of severe exercise. Although anemia increases coronary blood flow by autoregulation, severe anemia decreases the endo/epi ratio, indicating subendocardial ischemia.⁴⁵ Hypoxia, on the other hand, increases both coronary blood flow and the endo/epi ratio.

Neural Influences

Coronary arteries are also responsive to neural stimuli.⁶² Parasympathetic and sympathetic nerves extend to the precapillary coronary vessels. Parasympathetic stimulation directly activates coronary muscarinic receptors, inducing dilation.

Sympathetic stimulation causes coronary dilatation as a result of the metabolic factors produced by increased MVO_2 and direct β receptor stimulation. α_2 Adrenoceptors or muscarinic receptors are present in the sympathetic nerve endings of coronary arteries. Activation of α -adrenergic receptors by norepinephrine and acetylcholine (via the vagus nerve) reduces sympathetic neurotransmitter output, which would reduce the dilation of these vessels causing coronary vasoconstriction. α_2 Agonists also mediate release of endothelial-derived relaxing factor in coronary arteries. β_1 -Adrenergic receptors predominate over α_1 receptors in canine circumflex coronary artery.⁶³ Termination of the sympathetic cardiac effects results from extensive neuronal uptake of norepinephrine.⁶⁴ Only small amounts of the norepinephrine released by the heart enter the systemic circulation.⁶⁴

Coronary artery spasm may result from unopposed α_1 -adrenoceptor stimulation in the presence of β -adrenergic blockade or when a pure α agonist is given. Acute coronary occlusion attenuates the baroreflex responses of heart rate and systemic vascular resistance.⁵¹

Cardiac Output

Cardiac output is the volume of blood pumped by the heart each minute. It is the product of the heart rate and the volume of each beat (stroke volume) but is determined by preload, afterload, heart rate, contractility, and ventricular compliance. Cardiac output measurements are usually corrected for the size of the patient by dividing the output by the body surface area to give the cardiac index. A normal cardiac index is $2.5\text{--}3.5 \text{ l} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ and may be determined by Fick principle or indicator-dilution methods (Fig. 31-12 and Table 31-4). Cardiac output increases with increased heart rate, preload, or contractility and decreased afterload.

Figure 31-12. A normal dye dilution curve has an uninterrupted buildup slope, a steep disappearance slope with a short disappearance time, and a prominent recirculation peak. In right-to-left shunts (A), there is a deformity on the buildup slope by the abnormal early appearance of the dye in the arterial circulation. Left-to-right (B) shunting causes a decreased peak dye concentration, absence of the recirculation peak, and a prolongation of the disappearance time. (Reprinted with permission from Lake CL: Cardiovascular Anesthesia. New York, Springer-Verlag, 1985.)

Determinants

Preload. Preload is defined as the end-diastolic stress on the ventricle (end-diastolic fiber length or end-diastolic volume). The determinants of preload are blood volume, venous tone, ventricular compliance, ventricular afterload, and myocardial contractility. The distribution of the blood volume between intrathoracic and extrathoracic compartments also affects preload. Extrathoracic blood volume increases with standing, whereas the negative intrathoracic pressure during inspiration increases intrathoracic blood volume.

Stroke volume is determined by the volume of blood in the heart at the beginning of systole (end-diastolic volume or EDV) and the amount of blood remaining in the ventricle at closure of the aortic valve at the end of systole (end-systolic volume or ESV). The degree of stretch of the left ventricular fibers, influenced by the amount of blood in the ventricle, determines the amount of work the ventricle can do.⁶⁵ An increase in preload increases end-diastolic volume and wall tension.

End-diastolic volume is not synonymous with end-diastolic pressure; nor are the two linearly related. The ejection fraction, normally 0.6–0.7, is the ratio of the stroke volume to the end-diastolic volume:

$$\text{Ejection fraction} = \frac{\text{EDV} - \text{ESV}}{\text{EDV}}$$

Severe impairment of ventricular function is present when the ejection fraction is <0.4.

Afterload. Afterload is the wall stress or tension faced by the myocardium during ventricular ejection. It is the force opposing ventricular fiber shortening during ejection. Left ventricular afterload depends upon the shape, size, radius, and wall thickness of the ventricle, the principal factors being the radius (related to preload and chamber volume) and aortic impedance (controlled by arterial compliance and systemic vascular resistance). Other factors involved in afterload include arterial wall stiffness (aortic), blood viscosity, and the mass of blood in the aorta. Usually, the ejection phase stress is implied in discussions of afterload, although there are wall stresses during the isovolumetric contraction phase.

Clinically, systemic vascular resistance is frequently used as an estimate of afterload (see Table 31-4). However, systemic vascular resistance reflects only peripheral arteriolar tone rather than left ventricular systolic wall tension. A true measure of left ventricular afterload, such as left ventricular end-systolic wall stress, which incorporates left ventricular chamber pressure, ventricular dimensions, wall thickness, and peripheral loading conditions, should be used to accurately assess afterload.⁶⁶ However, these measurements require direct intraventricular pressure determination and echocardiographic evaluation of wall thickness and ventricular dimensions. Compared with left ventricular end-systolic wall stress, systemic vascular resistance underestimates afterload when afterload is increased or decreased or contractility is improved.⁶⁶

When afterload is reduced, the ventricle shortens more quickly and completely.⁶⁷ An increase in afterload decreases the extent and velocity of shortening and increases active tension and the time to peak tension in cardiac muscle. Wall tension, ventricular radius, and end-diastolic volume are also increased to maintain stroke volume. In the poorly contractile heart, acute increases in afterload severely reduce stroke volume. Hypertrophy occurs in ventricles facing a chronic increase in afterload, so that wall stress and shortening characteristics return toward normal.

Heart Rate. Heart rate is primarily determined by the automaticity of the sinus node. However, its intrinsic rate depends upon neural and humoral influences. An increase in heart rate increases cardiac output, even if the stroke volume remains constant, by increasing the extent and velocity of shortening and dP/dt .⁶⁸ The increase of dP/dt with heart rate is even more pronounced if end-diastolic dimensions are maintained by volume infusion.⁶⁸ At heart rates between 120 and 160 beats \cdot min^{-1} , cardiac output increases but not as much as at more optimal heart rates (Fig. 31-13). An increase in heart rate shortens the filling time between beats, reducing end-diastolic volume. Because most cardiac filling occurs during the first half-second of the rapid filling phase, cardiac output decreases at heart rates >160 beats \cdot min^{-1} because of inadequate filling time.

Figure 31-13. The effect of heart rate on cardiac output varies with age. In children, an increase in heart rate increases cardiac output because the immature heart is relatively noncompliant and does not increase its stroke volume in response to increased demands. In the adult, however, an increase in heart rate beyond 120 beats/ min^{-1} does not increase cardiac index. (Reprinted with permission from Wetsel RC: Critical Care State of the Art, 1981.)

Cardiac output is also increased during the heartbeat after a ventricular extrasystole. This extrasystolic potentiation results from increased ejection fraction, decreased left ventricular end-diastolic volume, and enhanced diastolic filling. The mechanism is probably increased availability of calcium to the contractile mechanism.⁶⁹

Contractility. Contractility is the inotropic state independent of changes in preload, afterload, or heart rate.

Cardiac Systole. Myocardial contraction begins when the action potential, acting through the T-(tubule) system of the sarcoplasmic reticulum, results in calcium release into the sarcoplasm. A cyclic adenosine monophosphate-dependent protein kinase in the heart stimulates calcium transport by the vesicles of the sarcoplasmic reticulum (see Fig. 31-14). Intracellular cyclic adenosine monophosphate protein kinase is activated and transfers the terminal phosphate of adenosine triphosphate to troponin I, phospholamban, or other intracellular proteins. Troponin has three components: troponin I, the inhibitory factor inhibiting the magnesium-stimulated adenosine triphosphatase of actomyosin; troponin C, which is the calcium-sensitive factor; and troponin T, the tropomyosin binding subunit.

Figure 31-14. (Left) A schematic diagram of the actin filament with its individual monomers and active myosin binding site (m). The myosin head (S1 fragment) is dissociated from actin by binding with ATP. Subsequent ATP hydrolysis and release of inorganic phosphate (P_i) “cocks” the head group into a tension-generating conformation. Attachment of the myosin head to actin allows the head to apply tension to the myosin rod and to the actin filament. (Right) Calcium binding to troponin C causes troponin I, the inhibitory subunit, to decrease its affinity for actin. Via tropomyosin, seven m sites on actin monomers are revealed. (Adapted from Rayment I, Holden HM, Whitaker M *et al*: Structure of the actin–myosin complex and implications for muscle contraction. *Science* 261:58, 1993; reproduced with permission of C. Lynch III.)

The actin and myosin filaments forming the myofibrils of the cardiac myocyte are functionally divided into sarcomeres. The sarcomere is further divided into three major subdomains, the electron-lucent I band composed primarily of actin; the Z line, where actin filaments from adjacent sarcomeres meet and sarcoplasmic reticulum is juxtaposed to the t-tubule system (junctional SR); and the electron-dense A band composed of myosin thick filaments (further subdivided by the M band into two symmetric bundles). Junctional SR is characterized by a larger lumen containing calsequestrin, a protein that provides extra “releasable” calcium and has low calcium-binding affinity. Calcium entering the myocyte through the L-type calcium channels primarily activates release of SR calcium, a process called calcium-induced calcium release (CICR). A portion of the entering calcium binds to calcium release channels (CaRC) to activate their opening, permitting rapid efflux of stored calcium from the SR lumen into the myoplasm to bind to troponin C.

Phospholamban, a membrane-bound protein that modulates the activity of calcium-stimulated magnesium adenosine triphosphatase, permits increased calcium uptake and calcium release by the SR in its phosphorylated state.⁷⁰ Adenosine triphosphatase from the calcium pump, which couples hydrolysis of one molecule of adenosine triphosphate with the active transport of two calcium ions, is the channel through which the activator calcium is released to initiate systole. The increased free calcium is bound to troponin C, releasing the inhibition of actin–myosin interaction by the troponin–tropomyosin complex. Contraction of actin and myosin occurs (see Fig. 31-13). The strength of contraction depends upon the length of the sarcomere and the amount of activator calcium because cardiac contractility is controlled by the degree of activation of the myocytes. Likewise, relaxation depends upon the rate of calcium delivery to troponin, the quantity of available calcium, and the rate of calcium removal from troponin.⁷¹

Diastole. Myocardial relaxation occurs as a result of reuptake of or binding of calcium ion by the SR, a lusitropic or relaxing effect of cyclic adenosine monophosphate.⁷² Relaxation is a load-dependent process. In the relaxing heart, load is the premature lengthening of cardiac muscle. Myocardial relaxation depends upon internal restoring forces such as cardiac fibers, hemodynamic loading such as the impedance of the arterial system, and external restoring forces resulting from deformation of the wall of the intact heart.⁷³

Alterations in Contractility. Cardiac output is increased by increasing load, either volume or pressure (heterometric autoregulation); by the Anrep effect (homeometric autoregulation); the treppe phenomenon; or by a change in the inotropic state independent of the above mechanisms.

The Anrep effect improves ventricular performance several beats after the initial stretching of the myocardial fibers owing to abruptly increased aortic or left ventricular pressure. It results from increased contractility with more rapid activation of the contractile process, increased developed force, and increased velocity of shortening. Homeometric autoregulation is operative for only a few minutes as the initially increased ventricular end-diastolic volume and circumference decrease with recovery of stroke work.⁷³

The treppe phenomenon (force–frequency relation, staircase effect, or Bowditch's phenomenon) is a progressive increase in contractile force associated with a sudden increase in heart rate. It results from a variation in myofibril calcium sensitivity and an alteration in activator calcium. A long pause between beats also increases the force of contraction; this is known as the Woodworth phenomenon or reverse (negative) staircase effect.⁷⁴ Increasing contractility increases the ejection fraction if end-systolic volume decreases while end-diastolic volume remains the same. Contractility is decreased by hypoxia, cardiomyopathy, myocardial ischemia, or infarction.

Compliance. Compliance is the nonlinear change in ventricular end-diastolic volume/change in end-diastolic pressure. The rapidity of diastolic filling is a major determinant of cardiac output, which is reduced by decreased compliance. Although ventricular contractility may be normal, reduced relaxation from coronary artery disease, hypertrophic cardiomyopathy, cardiac tamponade, and hypertensive heart disease impairs diastolic filling which, in turn, limits cardiac output.

Myocardial Mechanics

The mechanical function of the heart is evaluated by *ejection phase indices* (Starling stroke volume vs. end-diastolic pressure curves, stroke work vs. end-diastolic pressure, force–velocity curves, ejection fraction, velocity of circumferential fiber shortening), *preload recruitable stroke work*, *isovolumic phase indices* (rate of left ventricular pressure development at 40 mm Hg pressure, $[dP/dt]_{P_{40}}$; maximum dP/dt ; maximal velocity of contractile element shortening, V_{max} ; point of maximum, $dP/dt/P$ or V_{pm}), and *end-systolic indices* (pressure–volume or pressure–length relationship at end-systole). Many of these measurements are complicated and affected by preload or afterload as noted in Table 31-7.

| Index | Qualities |
|---|---|
| EJECTION PHASE INDICES | |
| Stroke volume versus EDP | Useful for acute contractility if ventricular function curve obtained |
| Stroke work versus EDP | Altered/variable |
| Ejection fraction (EF) | Not useful for basal contractility |
| Stroke volume versus EDP | Useful for basal contractility when EDP is known |
| Maximum acceleration of aortic blood flow | Altered/variable |
| Mean velocity of circumferential fiber shortening (V _c) | Altered/variable |
| Mean normalized aortic velocity rate | Not useful for basal contractility; may be useful for acute contractility changes |
| Maximum aortic distance | Not useful for basal contractility; may be useful for acute contractility changes |
| ISOVOLUMIC PHASE INDICES | |
| $dP/dt_{P_{40}}$, dP/dt_{max} | Useful for acute contractility changes |
| V_{max} | Not useful for basal contractility |
| V_{pm} | Dependent on timing of aortic valve opening |
| V_{c} | Useful for acute contractility changes |
| V_{c} | Not useful for basal contractility; may be useful for acute contractility changes |
| V_{c} | Dependent upon position of aortic valve |
| V_{c} | Not useful for basal contractility |
| V_{c} | Decreases with increased preload or afterload |
| V_{c} | Useful for basal contractility |

Table 31-7. MEASURES OF MYOCARDIAL CONTRACTILITY

Starling (Ventricular Function) Curve

If the cardiac muscle is stretched, it develops greater contractile tension because of changes in myofibril calcium sensitivity and alterations in the amount of activator calcium. This observation is the basis of Starling's law: “The law of the heart is therefore the same as that of skeletal muscle, namely, that the mechanical energy set free on passage from the resting to the contracted state depends . . . on the length of the muscle fibers.”⁷⁵ Atrial as well as ventricular muscle obeys Starling's law. Increased preload or initial fiber length increases resting tension, velocity of tension development, and peak tension. An increase in venous return stretches the muscle fibers to increase contractility and improve cardiac output. However, this process occurs only at subnormal filling pressures. In the upright position, ventricular filling pressures decrease to ~4 mm Hg, and the normal heart operates on the ascending limb of the ventricular function curve. Peak ventricular output occurs at filling pressures of ~10 mm Hg in normal humans.⁷⁶ Whether the heart can fall onto a descending limb of the length–stroke volume curve like skeletal muscle is unclear.⁷⁶ On the descending limb, the heart decompensates and further increases in end-diastolic volume decrease stroke volume, but disengagement of actin and myosin does not occur. In all probability, the heart moves to a different curve.

Ventricular function curves are influenced by afterload, although they incorporate the effects of preload alterations (Fig. 31-15). Starling curves are used clinically when weaning patients from cardiopulmonary bypass, to assess the effects of anesthetic agents on the heart, and to guide fluid and pharmacologic therapy in the perioperative period. The increased stretch and end-diastolic length produced by atrial (atrial kick) or early contracting ventricular fibers (idioventricular kick) increase ventricular stroke volume. Both of these effects are manifestations of Starling's law.

Figure 31-15. The ventricular function (Starling) curve of the normal left ventricle (*solid line*) is affected much more by changes in preload (left ventricular end-diastolic pressure) than it is by an increase in afterload (*dotted line*). The failing heart moves to a curve downward and to the right of the normal heart. Venodilator therapy decreases preload without increasing cardiac index (the heart moves to the left on the curve) while reduction of afterload increases cardiac index without a change in preload. Combined preload and afterload reduction decreases filling pressure and increases cardiac index.

Pressure–Volume Loops

Another index of contractility that is less affected by preload, afterload, or other conditions is the pressure–volume loop, an end-systolic index (Fig. 31-16). At end-systole, ejection ceases, and the aortic valve closes with the ventricle at minimum dimension and volume.

Figure 31-16. Pressure–volume loops. (A) The relationship of ventricular pressure and volume over the entire cardiac cycle. The loop begins on the bottom left with opening of the mitral valve and filling of the ventricle to end diastolic volume. When multiple pressure–volume loops are created, the slope of the individual end-systolic pressure–volume relations indicates myocardial contractility. An extension of the bottom portion of the loop (without ventricular systole) would give a diastolic pressure–volume relation for the ventricle. Isovolumetric contraction begins at the lower right portion of the curve with closure of the mitral valve. The aortic valve opens at the upper right portion of the loop and ventricular ejection begins. At the upper left of the loop, the aortic valve closes (end-systolic volume) and isovolumetric relaxation returns the loop to the starting point. Stroke volume is the difference between the volume at the end of diastole and the end of systole. The area of the loop is stroke work. (B) The effects of afterload reduction with sodium nitroprusside (SNP) on the pressure–volume loop. (C) The changes in the pressure–volume loop in a patient with aortic stenosis with a high peak systolic pressure and steep diastolic slope representing reduced ventricular compliance. (D) An ischemic heart has its pressure–volume shifted upward and to the right. (E) The effects of increasing the afterload of a normal heart with phenylephrine. (F) In a normal heart, an increase in heart rate markedly reduces left ventricular volume. See also Figure 31-17.

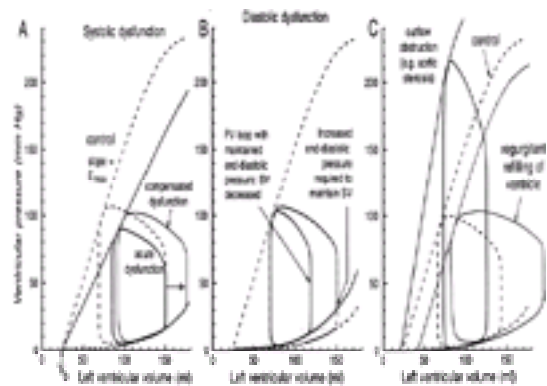

Figure 31-17. (A) The ventricular pressure–volume relationship in systolic dysfunction demonstrates depressed E_{max} and decreased stroke volume. With compensation, the stroke volume is restored by an increased end-diastolic volume. (B) With diastolic dysfunction, stroke volume is decreased unless end-diastolic pressure increases to maintain it. As in Figure 31-16C, ventricular outflow obstruction usually enhances systolic function because of ventricular hypertrophy, but associated diastolic dysfunction decreases stroke volume while increasing total ventricular work. With regurgitant ventricular filling, a compensatory increase in stroke volume occurs. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 119. Philadelphia, Churchill Livingstone, 2000.)

In such loops, the height and width of the loop are determined by the ventricular systolic pressure and stroke volume. The area subtended by the systolic portion of the curve provides a measure of stroke work during ejection, whereas the area of the diastolic limb is a measure of diastolic work performed during ventricular filling and distention. The volume between the systolic and diastolic portions of the loop is the stroke volume. Cardiac work, the product of pressure and volume, is the area of the pressure–volume loop, which is linearly related to myocardial oxygen consumption under various hemodynamic conditions.⁷⁷ In a given ventricle, all the end-systolic points are positioned on the same line, which represents the elastance of that ventricle (the change in end-systolic pressure/change in end-systolic volume, although elastance is actually the linear relationship between length and force). Contractility is directly proportional to elastance, with its slope becoming steeper with increased contractility and flatter with decreased contractility. The slope of the end-systolic pressure–volume relation is linear and correlates well with the ejection fraction.⁷⁸

Pressure–volume loops also reveal information about ventricular compliance. Compliance actually changes during each contraction. The normal relationship between diastolic pressure and volume is curvilinear. There is a relatively gentle slope at low end-diastolic pressures (*e.g.*, little change in pressure for large changes in volume). At end-diastolic pressures at the upper limits of normal (≈ 12 mm Hg), the curve becomes steeper, and pressure is almost exponentially related to end-diastolic volume. Ventricular compliance decreases under such conditions. The ventricular end-systolic pressure/volume relationship may be dependent on the type of loading intervention but can be used to assess left ventricular performance under various conditions.⁷⁹ (Fig. 31-16 and Fig. 31-17). However, one limitation of pressure–volume loops is that pressure may inaccurately reflect end-systolic afterload. The ratio of pressure to volume at end-systole can also be used as an index of contractile function. However, this assumes that at higher pressures there are larger volumes at a given inotropic state.

Pressure–Length Loops

Measurement of a pressure–length loop is a reproducible and sensitive method to evaluate total or regional systolic and diastolic myocardial function. However, it requires direct measurement of changes in myocardial length and intraventricular pressure. Ventricular segment length is plotted on the x-axis and ventricular pressure on the y-axis (Fig. 31-18). Normal loops are rectangular and include four segments: isovolumic contraction (*right*), ejection (*top*), isovolumic relaxation (*left*), and filling (*bottom*). The area of the loop represents ventricular stroke work.⁸⁰ Pressure–length loops are altered by changes in preload, afterload, inotropic state, and ischemia.

Ischemia increases postsystolic shortening and systolic lengthening, as depicted in [Figure 31-18 \(inset\)](#).⁸¹

Figure 31-18. The normal pressure–length loop (*thick black line*) is a rectangle whose area indicates total ventricular work. Ischemia (*thin solid line*) causes the loop to lean toward the right because of increased systolic lengthening and postsystolic shortening (*inset*). Increased afterload (*dotted line*) causes the loop to become taller at a similar preload. (Reprinted with permission from Lake CL (ed): *Clinical Monitoring for Anesthesia and Critical Care*. Philadelphia, WB Saunders, 1994.)

Force–Velocity Curve

Myocardial contractility can also increase when the myocardial fibers increase their developed force or velocity of shortening without a change in fiber length. Force–velocity curves evaluate contractility (velocity of shortening) at constant fiber length in a passively stretched muscle (preloaded), which is stimulated to contract against either no load or an afterload. Force–velocity curves are much more sensitive indicators of contractility than Starling curves and are based on the Hill model of isolated muscle.

As afterload is increased, the initial rate of shortening follows a hyperbolic relationship ([Fig. 31-19](#)). The force or tension developed during contraction is measured by dP/dt_{max} , the maximum rate of rise of intraventricular pressure during the isometric phase of ventricular contraction. The point of the curve where no shortening occurs, although the muscle develops maximal force, is termed P_0 . Extrapolation of the curve back to zero load where the maximal velocity of shortening occurs is termed V_{max} . Both preload and afterload affect dP/dt_{max} . As preload increases, the maximum isometric tension that the muscle develops increases, but the maximal velocity of shortening is unchanged. An increase in myocardial contractility increases both the developed tension and the maximum velocity of shortening, shifting the force–velocity curve upward and to the right.

Figure 31-19. A force velocity curve of cardiac muscle shows the point of maximal shortening with no load or V_{max} (point A). Point B is P_0 where no shortening occurs although tension development is maximal. Curve C is a force–velocity curve with increased preload. Curve D demonstrates increased myocardial contractility. On any curve, load (afterload) increases from left to right. (Reprinted with permission from Lake CL: *Cardiovascular Anesthesia*, p 10. New York, Springer-Verlag, 1985.)

Preload Recrutable Stroke Work (PRSW)

Stroke work is linearly related to left ventricular end-diastolic volume. A plot of end-diastolic volume against stroke work demonstrates that stroke work increases with increased preload and decreases with unloading. Thus, the PRSW is determined by plotting stroke work from successive pressure–volume loops during alterations in preload.

Cardiac Work

Because of the difficulties in obtaining the data for pressure–volume loops or force–velocity curves under clinical conditions, cardiac work is often measured as a substitute. Cardiac work describes pump function in terms of the load carried and the distance moved. Calculation of cardiac work standardized to body surface area (left and right ventricular stroke work indexes) is shown in [Table 31-4](#). Using cardiac work instead of cardiac output or stroke volume to describe pump function has several advantages: (1) calculation includes heart rate, preload, and afterload—the major variables affecting cardiac function; (2) the stroke work index defines the area of the pressure–volume loop; and (3) the stroke work index measures both systolic and diastolic performance.⁸²

Right Ventricular Function

The functional significance of the RV in normal circulatory homeostasis is minimal. Although the right ventricular spiral muscles contract during systole, direct left ventricular assistance to right ventricular contraction has been demonstrated.⁸³ Compared to the LV, intraventricular pressure develops more gradually in the RV and declines more slowly during diastole. Right ventricular pumping capability depends on (1) pressure against which it ejects, (2) filling volume, and (3) right ventricular contractility.⁸⁴ The RV obeys Starling's law except that its curve is upward and to the left of the left ventricular curve. At higher end-diastolic pressures, the RV response is flatter than that of the LV. Increases in filling volume increase right ventricular stroke volume up to the limit imposed by the restraint of the pericardium (normally, ~20% acute increase in cardiac volume).⁸⁵ The contractility of the RV depends upon sympathetic tone, myocardial structural integrity, and the chemical content of the coronary perfusate.⁸⁴ Normal right ventricular systolic pressures are only 30–40 mm Hg because the recruitable vasculature of the pulmonary circulation allows between 5 and 20 l of blood to flow within it. Peak ejection occurs later than in the LV and the ejection fraction is only 0.4. This difference in function results because the right ventricular free wall is flattened by the pull of the interventricular septum toward the LV during systole, giving a bellows-like action for expulsion of blood.⁸⁵ Because of this mechanism, right ventricular function is less likely to be impaired during right coronary arterial occlusion.⁸⁵

During systole, right ventricular stroke volume is more sensitive to afterload than left ventricular stroke volume. Factors that oppose blood flow from the RV (afterload) include the resistance of the pulmonary vascular bed, pulmonary arterial impedance, the mass of the pulmonary blood, blood viscosity, and pulse wave reflection altering pulmonary artery pressure. In diastole the RV is twice as distensible (more compliant) as the LV.⁸⁴

Under conditions of pressure overload, such as increased pulmonary vascular resistance or left ventricular failure, the RV hypertrophies to generate systemic pressures. Although acute right ventricular failure is compatible with life, the symptoms caused by increased venous pressure suggest that right ventricular function is important for maintenance of normal venous pressures.⁸⁵

Ventricular Interdependence

Because the ventricles are anatomically associated, alterations of volume and pressure in one ventricle affect these parameters in the other.⁸⁶ During normal

respiration with negative intrathoracic pressure, increased venous return increases right ventricular end-diastolic volume during inspiration, pulmonary vascular capacitance increases, left ventricular diastolic volume decreases, and left ventricular stroke volume increases but left ventricular transmural pressure is unchanged. Important factors in ventricular interdependence are septal position and deformability, pulmonary venous capacitance, right ventricular distensibility, the trans-septal pressure gradient, and the presence of the pericardium.

In vitro experimental animal models confirm that when left ventricular pressure increases, diastolic compliance and systolic ventricular function decrease in the RV and *vice versa*. The mechanisms are (1) the Frank–Starling effect caused by decreased ventricular diastolic volume and (2) decreased systolic ventricular function.⁸⁷ The etiology of the depressed systolic function is unclear.⁸⁷ Computer models confirm that hypertrophy from right ventricular pressure overload, which increases septal thickness and decreases septal compliance, decreases transfer of pressure and volume between the ventricles, limiting ventricular interdependence.

Myocardial Metabolism

An understanding of myocardial metabolism is essential to the preservation of the heart during conditions of stress, cardiac arrest, or elective asystole during cardiac surgery. Metabolism includes both substrate utilization and oxygen consumption.

Sources of Energy

The energy supply of the heart is derived primarily from lactate and fatty acids delivered by the coronary blood. Free or nonesterified fatty acids (palmitic and oleic acids) are the preferred fuel. Myocardial uptake of fatty acids is almost linear, with the plasma concentration above the threshold of $345 \mu\text{mol} \cdot \text{l}^{-1}$.⁸⁸ Fatty acid uptake by the heart from either fatty acid–albumin complexes or lipoprotein triglyceride occurs by passive diffusion or carrier-mediated transport. During fasting, free fatty acids are always used as fuel. The heart has a limited ability to synthesize fatty acids from acetyl coenzyme A, except for the formation of structural lipids. The oxidation of fatty acids and ketone bodies inhibits uptake of glucose, pyruvate oxidation, and glycolysis while facilitating glycogen synthesis.⁸⁸ Oxidation of nonesterified fatty acids accounts for 90% of myocardial oxygen consumption.

Fuel selection by the heart probably depends on regulatory enzymes controlled by factors other than substrate availability and product removal. Myocardial lactate utilization is regulated by the arterial lactate concentrations and pyruvate oxidation in the Krebs tricarboxylic acid cycle. Glucose, pyruvate, acetate, and triglycerides can also be used by the heart as energy sources. Utilization of glucose by the myocardium depends on the arterial glucose and insulin concentrations. Glucose is normally used postprandially. However, glucose use by the myocardium as the primary energy source occurs only with high glucose levels, insulin secretion, or hypoxia. Glucose is the only substrate used by the heart anaerobically. As long as the entry of acetyl coenzyme A into the Krebs cycle is not inhibited, the heart will use as much pyruvate as it is given. Substrates such as fructose, glycogen, or proteins are used for energy only during special circumstances, such as starvation, diabetic ketoacidosis, or anoxia.

Myocardial Oxygen Consumption

The heart has one of the highest metabolic rates of any organ. At rest it uses 8–10 ml of oxygen per 100 g of myocardium per minute. The subendocardium requires about 20% more oxygen than the epicardium. Myocardial oxygen consumption (MVO_2) is determined by heart rate, wall tension, and myocardial contractility. The relative importance of each of these factors is difficult to evaluate because they are interrelated through wall tension.⁸⁹ Less important factors include the oxygen costs of shortening of muscle fibers, electrical activation, and catecholamines as well as the basal oxygen requirements and the level of arterial oxygenation. Tension development constitutes about 50% of MVO_2 (Table 31-8).

Left ventricular end-diastolic pressure
Coronary artery diameter
Arterial oxygen content

Table 31-8. FACTORS INVOLVED IN MYOCARDIAL OXYGEN SUPPLY AND DEMAND

Myocardial wall tension is related to the tension–time index, left ventricular end-diastolic pressure, and ventricular size. Wall tension can be divided into its components: the rate of force development, the magnitude of force development, the interval during which force is generated and maintained for each contraction, and the frequency with which force is developed per unit time.⁸⁹ Wall tension is measured according to Laplace's law:

$$T = Pr/2h$$

where radius (r) is cardiac radius, T is cardiac tension, P is interventricular pressure, and h is ventricular muscle thickness. Increases in ventricular chamber pressure or volume increase both the magnitude of force development and the force maintained during ejection.

Myocardial Supply–Demand Ratio

A balance must always exist between oxygen consumption (demand) and myocardial oxygen supply if ischemia is to be avoided. Factors important to this relationship are shown in Table 31-8. Myocardial oxygen supply is dependent upon the diameter of the coronary arteries, left ventricular end-diastolic pressure, aortic diastolic pressure, and arterial oxygen content. In the normal heart, the coronary perfusion pressure is the difference between the aortic diastolic pressure and the left ventricular end-diastolic pressure. Myocardial blood flow is determined by the blood pressure at the coronary ostia, arteriolar tone, intramyocardial pressure or extravascular resistance, coronary occlusive disease, heart rate, coronary collateral development, and blood viscosity.

Myocardial blood flow is reduced by a low aortic diastolic pressure, increased pulmonary wedge pressure (both of which increase subendocardial tissue pressure), and tachycardia, which shortens diastole, reducing the duration of blood flow. Increasing preload or intracavitary pressure increases wall tension and oxygen demand while decreasing subendocardial perfusion.

Myocardial oxygen supply is also affected by the level of arterial oxygenation. Oxygen content resulting from PaO_2 , hemoglobin, 2,3-diphosphoglycerate (DPG), and pH , PCO_2 , or temperature effects on the oxyhemoglobin dissociation curve can be an important factor in patients with obstructive lung disease or severe anemia. Normal oxygen extraction by the heart is 60–70% and changes very little with increased cardiac work because coronary vascular resistance decreases. However, if the coronary vascular resistance response is limited, oxygen extraction can be increased to more than 90%.⁸⁹ An increase in oxygen extraction and coronary vasodilation constitutes the metabolic reserve of the heart in the case of increased demand.

Heart rate and diastolic ventricular volume are the two factors most likely to produce ischemia if either or both are increased. Increased myocardial contractility or afterload, by increasing arterial pressure and myocardial oxygen supply, offsets their tendency to increase myocardial oxygen consumption.

Distribution of Cardiac Output

The cardiac output is distributed to the systemic circulation as follows: brain 12%, heart 4%, liver 24%, kidneys 20%, muscle 23%, skin 6%, and intestines 8%. About 15% of the blood volume remains in the heart and pulmonary circulation, with the remainder in the systemic circulation. Of the blood in the systemic circulation, about 64% is in the veins. The total tissue blood flow in a given vascular bed is a function of the effective perfusion pressure and vascular resistance. Effective perfusion pressure is the difference between arterial and venous pressure across the vascular bed. Autoregulation maintains a constant blood flow in the face of changes in

perfusion pressure in the cerebral, renal, coronary, hepatic arterial, intestinal, and muscle circulations. Reflexes that alter circulatory distribution are in [Table 31-9](#).^{90,91,92,93,94,95,96} and [97](#) The carotid sinus, a dilated portion of the common carotid artery just before its bifurcation, contains two types of receptors that sense pressure in the carotid sinus, providing the most important aspect of reflex circulatory control.

Table 31-9. CARDIOVASCULAR REFLEXES

Peripheral Circulatory Physiology

The peripheral circulation consists of resistance and capacitance vessels. The majority of the resistance is in the arterial circulation, which consists of the Windkessel vessels, the precapillary resistance vessels, and the capillary exchange vessels. The Windkessel vessels are distensible elastic arteries such as the aorta and large muscular arteries that damp the pulsatile output of the ventricle. The arterioles, the precapillary resistance vessels, are muscular vessels that provide more than 60% of the peripheral resistance. At the most distal portion of the terminal arterioles are precapillary sphincters that regulate the flow of blood into specific capillary beds. The capillary exchange vessels contribute about one fourth of the total peripheral resistance, although most capillaries consist of a single endothelial cell layer without any surrounding smooth muscle. The systemic veins are the capacitance system.

Arterial Pulses and Blood Pressure

Arterial Pulse

The arterial pulse is a wave of vascular distention resulting from the impact of the stroke volume of each beat being ejected into a closed system. The wave of distention begins at the base of the aorta and passes over the entire arterial system with each heart beat. The pulse is not caused by the passage of the blood itself. The pulse waveform is the result of the combined effects of the forward-propagating pressure wave and its reflectance back toward the heart from various parts of the vasculature. Wave reflection may occur in high-resistance arterioles, branching points, or sites of changes in arterial distensibility, but the major source is the arteriole.⁹⁸ The velocity of the pulse wave depends on the elasticity of the vessel. The pulse wave velocity is most rapid in the least distensible arteries. In the aortic arch, the pulse wave travels $3\text{--}5\text{ m} \cdot \text{sec}^{-1}$, and the aortic pulse waveform precedes the brachial waveform by about 0.05 sec. In large distensible arteries such as the subclavian, the pulse wave travels $7\text{--}10\text{ m} \cdot \text{sec}^{-1}$, whereas in the small nondistensible peripheral arteries it travels about $15\text{--}30\text{ m} \cdot \text{sec}^{-1}$. Such differences become important when timing the counterpulsation of an intra-aortic balloon.

The arterial pressure waveform changes as it moves peripherally ([Fig. 31-20](#)). In central aortic waveforms, the closure of the aortic valve is indicated by a notch or incisura on the descending limb. By contrast, peripheral pulse waveforms have a greater amplitude, more pronounced diastolic wave, and lower mean pressure, and the foot of the wave is delayed.⁹⁸ The dicrotic notch, corresponding to the incisura, is more prominent. Systolic pressure is higher, whereas mean and diastolic pressures are slightly lower in the periphery. Such changes are best explained by a tubular model of the vascular system. In such a system, the contour of the pressure wave depends on the velocity of the pressure wave, the duration of the pulse, and the length of the tube.⁹⁸

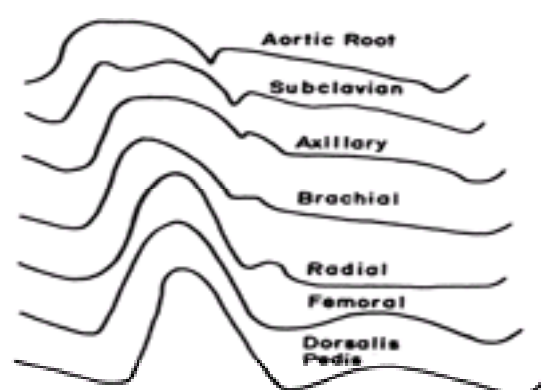

Figure 31-20. The change in the pulse waveform as it moves from the aortic root to the dorsalis pedis artery is dramatic. These changes result from both forward wave propagation and wave reflection at branch points in the circulation. The waveform has a greater amplitude, higher systolic pressure, lower diastolic pressure, and reduced mean pressure in the peripheral circulation. (Reprinted with permission from Bedford RF: Invasive blood pressure monitoring. In Blitt CD (ed): *Monitoring in Anesthesia and Critical Care Medicine*, p 100. New York, Churchill Livingstone, 1995.)

Pulse contour also changes with hemodynamic conditions. In children, wave reflection facilitates cardiac performance by a relative decrease in arterial pressure during systole and a relative increase during diastole. As aging occurs, wave reflection occurs earlier in the cardiac cycle, increasing systolic pressure and decreasing diastolic pressure. In shock, the pulse wave velocity is reduced by hypotension, increased heart rate reduces the duration of cardiac systole, and peripheral vasoconstriction increases the peripheral reflection coefficient. Pulse waveforms vary in atrial fibrillation, beats with short systolic durations demonstrating diastolic waves and those with long durations having accentuated systolic peaks. Patients with hypertrophic cardiomyopathy have double systolic pulse waveforms because the initial systolic wave of ventricular ejection occurs during the first half of systole and the reflected wave returns during the same systole.⁹⁸

Blood Pressure

Arterial pressure is the lateral pressure exerted by the contained blood on the walls of the vessels. Mean arterial pressure is the product of the cardiac output and the systemic vascular resistance. If a normal arterial waveform is present, mean pressure is about one third the difference between the systolic and diastolic pressures. However, mean pressure remains constant, whereas pulse pressure and systolic pressure increase as blood moves peripherally in the circulation.

Arterial pressure varies with the respiratory cycle. It normally decreases 6 mm Hg or less during inspiration because pulmonary venous capacitance increases during inspiration to a greater extent than the increase in right-sided heart venous return and output, thus causing a decrease in left ventricular stroke output and pressure. These changes are exaggerated in pericardial tamponade, causing pulsus paradoxus. Clinically, pulsus paradoxus is measured by auscultation of the blood pressure until the first heart sound is heard intermittently. Further deflation of the cuff to the pressure where all beats are heard yields the difference known as the paradoxical pulse.

Factors Controlling Peripheral Vascular Tone

Factors controlling blood pressure include central and autonomic nervous function, cardiac output, peripheral vascular resistance, and hormonal mechanisms including antidiuretic hormone, catecholamines, the renin–angiotensin system, and atrial natriuretic peptide.⁹⁹ Three medullary centers—the nucleus tractus solitarius, the caudal ventrolateral medulla, and the rostral ventrolateral medulla—are important in blood pressure control. Arteriolar tone is regulated by intrinsic and extrinsic mechanisms.

The intrinsic mechanism is the inherent myotonic activity of vascular smooth muscle cells and vascular endothelial cells. Extrinsic factors include neural (sympathetic) and humoral factors. Sympathetic neural activity provides rapid alteration of tone in response to a need for greater blood flow. [Figure 31-21](#) details the intracellular mechanisms for peripheral vasodilation and vasoconstriction. Nitric oxide and prostacyclin production and endothelin release from endothelial cells will produce vasodilation and vasoconstriction, respectively, in vascular smooth muscle cells.

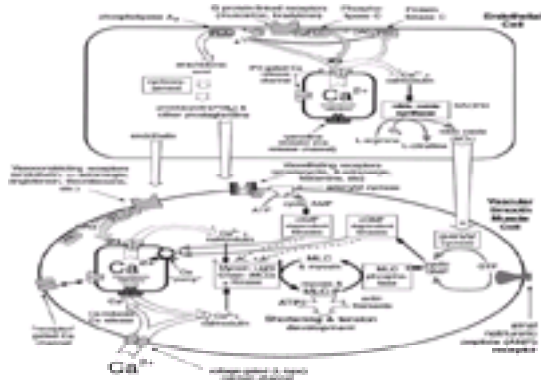

Figure 31-21. Vascular smooth muscle and endothelial function. Both endothelial cells and vascular smooth muscle cells have intracellular stores of calcium which can be released by the production of inositol triphosphate (IP_3). In both types of cells, agonist binding to specific receptors results in activation of phospholipase C (PLC) via guanine protein Gq (a). In the vascular smooth muscle cell, PLC activation results in IP_3 formation and release of intracellular calcium. Calcium binds to calmodulin, activating myosin light chain kinase (MLC), which then phosphorylates, causing myosin to interact with actin, producing shortening or tension generation. In contrast, in the endothelial cell, calcium binds to calmodulin to activate nitric oxide synthase, producing nitric oxide. Nitric oxide can diffuse to the vascular smooth muscle and modulate its behavior via activation of guanylate cyclase. Phospholipase A can be activated by G protein-linked pathways or by phosphokinase C and calcium, resulting in production of arachidonic acid. Arachidonic acid generates prostacyclin via the cyclooxygenase system, allowing relaxation of vascular smooth muscle. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 126. Philadelphia, Churchill Livingstone, 2000.)

Humoral factors such as endothelial-derived relaxing factor, antidiuretic hormones, or atrial natriuretic factors are less important in overall circulatory regulation.

Endothelium-Derived Relaxing Factor

Nitric oxide (NO), the endothelium-derived relaxing factor (EDRF), is a short-lived substance that activates soluble guanylate cyclase to increase intracellular cyclic guanosine 3',5'-monophosphate, causing relaxation of vascular smooth muscle. It is formed from L-arginine by the enzyme nitric oxide synthase (NOS) in various mammalian tissues, particularly vascular endothelium ([Fig. 31-22](#)). NOS is activated when intracellular calcium increases as a result of extracellular calcium entry or intracellular calcium release. Basal release of EDRF occurs in all except cerebral and coronary vessels. Atherosclerosis impairs endothelium-dependent relaxation. Decreased production of EDRF may also contribute to both systemic and pulmonary hypertension. Hypoxia impairs endothelium-dependent vasodilation owing to inhibition of EDRF production and decreased half-life.¹⁰⁰ Endothelium-derived relaxing factor also inhibits platelet adhesion and aggregation.

Figure 31-22. Endothelium-derived relaxing factor (EDRF) is produced from L-arginine by a process requiring calcium, calmodulin, nicotinamide adenine dinucleotide phosphate-dependent enzyme (NADPH), and EDRF synthetase. Increases in cytosolic calcium produced by agonists such as the calcium ionophore (A23187) or receptor-mediated agonists (acetylcholine, adenosine triphosphate [ATP], bradykinin) activate EDRF synthetase to produce EDRF. EDRF or other substances such as sodium nitroprusside (SNP), nitroglycerin (NTG), or nitric oxide (NO) produce vascular smooth muscle (VSM) relaxation by activation of adenylate cyclase. (Reprinted with permission from Johns RA: Endothelium-derived relaxing factor: Basic review and clinical implications. *J Cardiothorac Vasc Anesth* 5:71, 1991.)

Natriuretic Peptides

Atrial natriuretic peptide (ANP) is a peptide stored in the perinuclear granules of human atrial myocytes and to a lesser extent in the ventricle.¹⁰¹ Brain or B-type natriuretic peptide (BNP) is also produced primarily in atrium, while natriuretic peptide C is localized in the central nervous system. Natriuretic peptide receptors A, B, and C are receptor guanylyl cyclases, consisting of intracellular and extracellular domains. Atrial natriuretic peptide is released in response to increased vascular volume (atrial distention), epinephrine, vasopressin, morphine, and increased atrial pressure.¹⁰¹ Normal circulating plasma levels are $25\text{--}100\ \mu\text{g} \cdot \text{ml}^{-1}$.¹⁰²

The primary effects of ANP are direct peripheral vasodilation, suppression of antidiuretic hormone (ADH) release when the ADH is elevated by hemorrhage or dehydration, inhibition of aldosterone release, and direct renal effects such as increased glomerular filtration, natriuresis, and diuresis. Factors such as renal perfusion pressure and renal sympathetic nerve activity in conjunction with physiologic plasma concentrations of ANF produce natriuresis.¹⁰³ Kaliuresis does not occur. Atrial natriuretic factor affects not only blood pressure (by decreasing cardiac output and vascular resistance) but also water and electrolyte balance and blood volume. It has no direct inotropic or chronotropic properties.

Renin-Angiotensin System

Renin is a proteolytic enzyme produced in the granular juxtaglomerular cells of the kidney. Its release is governed by the macula densa, an intrarenal stretch-type receptor, circulating potassium, angiotensin II, epinephrine, and concentrations of antidiuretic hormone, and by the renal sympathetic nerves. Renin secretion is also inversely related to renal perfusion.¹⁰⁴ The half-life of renin is 4–15 min, during which it initiates the formation of angiotensin I from angiotensinogen, which is synthesized in the liver. Angiotensin I is biologically inactive until it is cleaved by angiotensin-converting enzyme in lung and other tissues to angiotensin II.¹⁰⁵ Angiotensin II and angiotensin III, formed by hydrolysis of angiotensin II, stimulate the secretion of aldosterone and inhibit renin release through a negative-feedback loop. The half-life of angiotensin II is about 30 sec.

Sympathetic Nervous System

Norepinephrine is the important agonist at the α_1 receptor mediating smooth muscle vasoconstriction in arteries and veins independently of neural supply. Epinephrine is more potent as a β_2 receptor agonist than is norepinephrine. β_2 receptors, located in both pre- and postsynaptic regions, dilate arteries by stimulation of adenylcyclase.

Specific Peripheral Circulations

Pulmonary Circulation

The pulmonary circulation is a low-pressure, high-flow system that has five principal functions: (1) metabolic transport of humoral substances and drugs¹⁰⁶; (2) transport of blood through the lungs; (3) reservoir for the left ventricle; (4) filtration of venous drainage; and (5) transport of gas, fluid, and solutes across the walls of exchanging vessels. Normally, all circulating blood passes through the pulmonary circulation at least once each minute, but only 500 ml is present at a given time.

Metabolic Transport

The pulmonary vascular endothelium is important for removal, biosynthesis, and release of various vasoactive hormones, including biogenic amines, prostaglandins, leukotrienes, and peptides. Norepinephrine is removed by the lung by a carrier-mediated, temperature- and drug-sensitive transport process. Epinephrine, histamine, vasopressin, and dopamine, however, are unaltered by transpulmonary passage.¹⁰⁶ Almost complete removal of 5-hydroxytryptamine, adenosine triphosphate, and monophosphate occurs in the lungs. Acetylcholine and bradykinin are inactivated by the lungs. Prostaglandins of the E and F series are also removed either by a carrier-mediated, energy-requiring process or by rapid degradation by 15-hydroxyprostaglandin dehydrogenase. Prostacyclin (PGI₂) is not inactivated in the lung. Many drugs such as propranolol, lidocaine, bupivacaine, captopril, and fentanyl are removed extensively during transpulmonary passage.

Intravascular Transport

The passage of blood and its distribution to various segments of the lung depend upon pulmonary blood flow, pulmonary vascular resistance or impedance, left atrial pressure, the transmural distending pressure, and the distensibility of the pulmonary vessel walls. Blood flow to the lung apex is less than that to the base because of regional differences in pulmonary venous, alveolar, and arterial pressures. However, the pulmonary circulation accommodates a large increase in flow with little change in pressure by a substantial decrease in resistance. Pulmonary resistance is about one fifth systemic and pulmonary impedance is about one half systemic; pulse wave reflections are stronger in the pulmonary beds—although the reflecting sites are similar, the vascular bed is smaller. Abundant vascular smooth muscle is present in pulmonary vessels, distributed evenly between arteries and veins. Muscular arterioles are absent in the lung.

Capillary endothelium, endothelial basement membrane, interstitial space, epithelial basement membrane, and alveolar epithelium form the alveolocapillary membrane, which separates the blood and gas phases in the lung. The pulmonary veins perform primarily a reservoir function, preventing pulmonary edema in the event of reduced left ventricular compliance.¹⁰⁷

Measurements of Pulmonary Tone

Measurements of pulmonary tone are essential to therapeutic investigations. However, the available measurement methods are either difficult or have significant limitations. Normal values for pulmonary vascular resistance are given in [Table 31-4](#).

Pulmonary artery pressures are clinically measured using flow-directed catheters. Wedging of the tip of these catheters in a small branch of the pulmonary artery measures the pulmonary artery wedge pressure or occluded pressure (PAoP) (see [Table 31-2](#)). As the pressure of the column of blood from the tip of the catheter (beyond the point of balloon occlusion) equilibrates with left atrial pressure, PAoP is achieved. Normally, left atrial pressure is similar to left ventricular end-diastolic pressure in the absence of mitral valvular stenosis. Other reasons for a PAoP that is greater than left ventricular end-diastolic pressure include increased airway pressures or the presence of an intra-atrial mass. Normally, the PAoP is 1–4 mm Hg lower than pulmonary end-diastolic pressure. However, with tachycardia or increased pulmonary resistance, the pulmonary wedge pressure may be the same or slightly higher than pulmonary end-diastolic pressure.

Pulmonary artery pressure is not linearly related to either flow or left atrial pressure. An increase in pulmonary flow or left atrial pressure is unaccompanied by a proportional increase in pulmonary arterial pressure. Therefore, calculated pulmonary vascular resistance decreases when either pulmonary flow or left atrial pressure increases. The nonlinearity results from distention or recruitment of vessels when flow or pressure increases. However, in Zone 3 of the lung (where left atrial pressure is greater than airway pressure), pulmonary artery pressure is the most important factor determining pulmonary blood flow.¹⁰⁸ Therefore, regardless of the effect on the pulmonary vascular tone, agents or manipulations that change pulmonary flow or left atrial pressure will change calculated pulmonary vascular resistance. Only if a particular intervention does not change pulmonary flow or left atrial pressure, or if the changes in pulmonary resistance can be explained only by active changes in pulmonary tone (e.g., a decrease in pulmonary artery pressure accompanied by an increase in pulmonary blood flow), is pulmonary vascular resistance unchanged. Even in these circumstances, however, reflex effects caused by the drug or maneuver cannot be eliminated.¹⁰⁹

Another major factor affecting indirect measurements is airway pressure, because the degree of lung inflation and the ventilatory pressure directly influence pulmonary pressure–flow relationships. Either increases or decreases in lung volume beyond normal functional residual capacity increase pulmonary resistance because of compression of small intra-alveolar vessels.

Effects of Drugs and Maneuvers on Pulmonary Tone

Baseline pulmonary tone, stimulation of pulmonary chemoreceptors, autonomic influences, bronchospasm, and other physiologic or nonphysiologic conditions actively or passively affect the pulmonary vasculature or modify its response to drugs. These factors are summarized in [Table 31-10](#).

| Factor | Changes |
|---|------------------------|
| ACTIVE CHANGES | |

Table 31-10. ALTERATIONS IN PULMONARY VASCULAR RESISTANCE

Alveoli in a poorly ventilated area of lung that contains hypoxic gas cause the precapillary arterial vessels supplying that area to constrict in order to divert blood away from the area. This process is termed hypoxic pulmonary vasoconstriction. Pulmonary hypertension does not occur because the hypoxia is localized. If hypoxia is generalized, pulmonary hypertension ensues.¹¹⁰ Metabolic acidosis slightly enhances hypoxic pulmonary vasoconstriction, whereas respiratory acidosis has no effect.¹¹¹ Metabolic and respiratory alkalosis decreases it.¹¹¹ Drugs such as nitroprusside, nitroglycerin, and the inhalation anesthetics decrease hypoxic pulmonary vasoconstriction, resulting in worsening of venous admixture and arterial PO₂.¹¹² However, increased pulmonary artery pressure from whatever mechanism inhibits hypoxic pulmonary vasoconstriction.

Bronchial Circulation

Bronchial flow depends upon the cardiac output and blood pressure and ceases at aortic pressures <40 mm Hg.¹¹³ It is increased by positive airway pressure and increased by hypoxia and hypercarbia.¹⁰ Sympathetic stimulation or epinephrine decreases bronchial flow, whereas parasympathetic or vagal stimulation increases it.¹¹³ Bronchial veins are more responsive to autonomic influences than are bronchial arteries.¹¹³ Histamine also increases bronchial flow, but prostaglandins decrease it.

Renal Circulation

Renal blood flow is well in excess of the amount needed for renal perfusion. It is autoregulated so that glomerular filtration remains relatively constant despite changes

in arterial pressure between 70 and 180 mm Hg. Theories proposed to explain renal autoregulation include the juxtaglomerular theory (vasoactive hormonal release from the juxtaglomerular apparatus in response to the quantity or quality of filtrate reaching the macula densa) and the myogenic theory (changes in afferent arteriole tone provide the autoregulation). Of these, the myogenic theory seems most likely.¹¹⁴

The main purpose of the excessive renal flow is to provide energy for active renal tubular reabsorption of sodium. Renal oxygen consumption is high, and the arteriovenous oxygen content difference is low. Of the blood delivered to the glomeruli, about 20% is filtered to form an ultrafiltrate of plasma. The main driving force is the glomerular hydrostatic pressure, which is essentially the systemic arterial pressure modified by the renal vasculature. Glomerular capillary pressure, about two thirds of systemic pressure, is increased by dilation of the afferent arteriole or constriction of the efferent arteriole.¹¹⁴ Renal arteriolar tone is also influenced by sympathetic stimulation, catecholamines, kinins, prostaglandins, and other vasoactive substances. Other factors affecting glomerular filtration include the total surface area available for filtration and the permeability of the glomerular membrane. The ultrafiltrate collects in Bowman's space before passing into the renal tubular system.

Hepatic Circulation

Hepatic arterial flow increases in response to decreased portal venous flow. The mechanisms for this alteration (the arterial "buffer response") include myogenic, metabolic, and neural controls as well as the quantity of the portal venous blood and the washout of some endogenous substance, probably adenosine, generated by hepatic tissue.¹¹⁵ Portal flow is controlled by preportal arterioles in the splanchnic organs from which the portal vein originates. Precapillary sphincters (presinusoidal) adjust portal flow to maintain an even distribution throughout the liver. The major site of resistance to portal flow is postsinusoidal, regulated by α -sympathetic receptors affecting venous smooth muscle.¹¹⁵ Normally, the liver contains about 15% of the blood volume. Sympathetic neural activation can mobilize one half of the hepatic blood volume. Like the systemic vasculature, the hepatic arteriole is the major site of resistance.

Physiology of the Venous System

Systemic veins have a conduit and a reservoir function. Since the smallest postcapillary venules lack muscular layers, and venules and small veins have only small amounts of muscle, the postcapillary resistance is usually small. However, postcapillary resistance is important because the ratio of precapillary to postcapillary resistance determines the capillary filtration pressure. The major capacitance vessels include medium and large veins as well as the venae cavae. About 60% of the systemic blood volume is in small veins and venules whose diameters range from 20 μ m to 2 mm.¹¹⁶

The term *vascular capacitance* is used for the vascular pressure–volume relationship at a given level of venous tone. Venous tone is normally at 70% of maximum in the erect human. Venodilation to accommodate as much as 70–75% of the systemic blood volume buffers sudden increases in arterial blood pressure by allowing sequestration of blood in systemic veins. The compliance of the venous system is regulated by venomotor tone, which is controlled by cerebral autonomic impulses. Sympathetically mediated venoconstriction adds about 1 l of blood to the circulation, but passive constriction from a reduction in venous pressure contributes about two thirds of the total volume mobilized. Individual organs contribute about 30–50% of their blood volume by sympathetically mediated venoconstriction.

Venous return (VR), the rate of flow of blood from the periphery to the heart, is a major determinant of cardiac preload. In a steady state, cardiac output is equal to venous return. It is determined by the pressure gradient from the peripheral vascular beds (P_{MS} or mean systemic pressure) to the right side of the heart (P_{RA}) and the resistance to venous return (R_v).^{116,117} This gradient is described by $P_{MS} - P_{RA}$ and the formula for venous return becomes

$$VR = (P_{MS} - P_{RA}) / R_v$$

The upstream driving pressure from the peripheral tissue to the right atrium is the mean circulatory filling pressure or mean systemic pressure. The term *mean systemic pressure* should not be confused with *mean arterial pressure*. The mean circulatory filling pressure, which is an equalization of pressures between the venous and arterial beds when flow is 0, is usually about 10 mm Hg, similar to the mean systemic filling pressure. It is increased by catecholamines or increased sympathetic activity.¹¹⁶ An increase in right atrial pressure decreases the pressure gradient and venous return. The resistance to venous return is primarily determined by large veins, such as the venae cavae and peripheral large and medium-sized veins, which are responsive to autonomic influences or vasoactive mediators. Factors which increase VR include redistribution of blood from vascular beds with low volume and high flows to those with high volume and low flow, polycythemia or conditions increasing blood viscosity, and venous constriction.¹¹⁷ Cutaneous venous tone is determined by thermoregulatory mechanisms rather than systemic pressure regulatory mechanisms.

Loss of venous tone, as in autonomic neuropathy or during anesthesia, limits the normal compensatory increases in venous tone to changes in posture, positive airway pressure, or decreased blood volume. If these factors are excessive, ventricular preload is adversely affected. Venoconstriction induced by hypovolemia, anxiety, or exercise augments intrathoracic blood volume and preload.

Physiology of the Pericardium

The pericardium has limited but important physiologic functions in the maintenance of biventricular systolic and diastolic function.¹¹⁸ As dilatation of the left ventricle occurs, intrapericardial pressure limits right ventricular filling and reduces forward flow to the lungs, possibly preventing pulmonary edema. Shifts of the left ventricular diastolic pressure–volume relationship are equal to changes in pericardial pressure and volume. During cardiac tamponade, increased intrapericardial fluid causes hypotension, decreased cardiac output, myocardial ischemia, and tachycardia. However, a vagally mediated depressive reflex is also operative, contributing further to the decreased cardiac output resulting from the presence of pericardial fluid.¹¹⁹ Increased intrapericardial pressure results in an underfilled ventricle, which operates on the ascending limb of Starling's curve.

Anesthetizing patients for open heart surgery is exciting, intellectually challenging, and emotionally rewarding. Competent and skillful clinical management requires a thorough understanding of normal and altered cardiac physiology; an intimate knowledge of the pharmacology of anesthetic, vasoactive, and cardioactive drugs; and a familiarity with the physiologic derangements associated with cardiopulmonary bypass and the surgical procedures themselves. This chapter presents a brief overview of the subject to familiarize the reader with the critical physiologic and technical considerations when caring for cardiac surgical patients. The initial discussions concerning coronary artery and valvular heart disease lay the physiologic and some of the pharmacologic groundwork upon which anesthetic planning and therapeutic decisions are based. First, we describe the balance of myocardial oxygen supply and demand, with particular reference to the patient with coronary artery disease. Next, we focus on those variables that regulate myocardial performance, specifically myocardial contractility, heart rate, and loading conditions (both preload and afterload). We then discuss the bells, whistles, and mechanics of cardiopulmonary bypass. Following this, we describe anesthetic considerations relevant to all adults undergoing cardiac surgery either with or without cardiopulmonary bypass (CPB), including preoperative evaluation, choice of monitoring techniques, selection of anesthetic drugs, and the actual conduct of the anesthetic before, during, and after bypass. The chapter concludes with some special topics as well as a brief introduction to the child with congenital heart disease. Some of the issues discussed are controversial because the field is continuously evolving. We have tried, whenever possible, to suggest what is the consensus about these topics, but, inevitably, our own preferences will be apparent. For the sake of brevity, numerous tables are included that summarize data and provide readily accessible guidelines for the various phases of the operative procedure. Many monographs are available for those who desire more detailed analysis of any aspect of cardiac anesthesia.^{1,2}

CORONARY ARTERY DISEASE

The prevention or treatment of ischemia before cardiopulmonary bypass in patients undergoing coronary artery bypass graft surgery reduces the incidence of perioperative myocardial infarction.^{3,4} The hemodynamic profile during the prebypass period, how the anesthetic is managed, and who does the managing are also important because the avoidance or treatment of factors known to increase myocardial oxygen demand ($M\dot{V}O_2$) reduces the frequency of precardiopulmonary bypass ischemic episodes.⁵ In addition, not only is control of $M\dot{V}O_2$ critical, but it is well recognized that many, if not most, ischemic events occur with minimal or no change in $M\dot{V}O_2$, suggesting that a primary reduction in oxygen supply is a major etiologic factor in intraoperative ischemia.^{5,6} and ⁷ Therefore, successful management of patients with coronary artery disease requires control of the factors determining $M\dot{V}O_2$ and, insofar as possible, optimizing oxygen delivery to the myocardium. The determinants of myocardial oxygen supply and demand are listed in [Table 32-1](#) and are also discussed in [Chapter 31](#).

| Demand | Supply |
|---------------|--------------------------------------|
| Wall tension | Coronary blood flow |
| Preload | Driving pressure (DBP - LVEDP) |
| Afterload | Diastolic time |
| Contractility | Coronary resistance |
| Heart rate | Collaterals |
| | Arterial O ₂ content |
| | Myocardial O ₂ extraction |

DBP = diastolic blood pressure; LVEDP = left ventricular end-diastolic pressure.

Table 32-1. MYOCARDIAL OXYGEN BALANCE

Myocardial Oxygen Demand

Wall tension and contractility are the principal determinants of $M\dot{V}O_2$.⁸ Laplace's law states that wall tension is directly proportional to both developed intracavitary pressure and ventricular radius and inversely proportional to wall thickness. Therefore, preventing or promptly treating ventricular distention is desirable in helping to control or reduce $M\dot{V}O_2$. Because contractility is also of major importance, myocardial depression is often beneficial so long as such depression does not result in an increase in wall tension, which itself may produce ischemia.

Myocardial Oxygen Supply

Any increase in myocardial oxygen requirements can be met only by raising coronary blood flow. Blood oxygen content (hemoglobin concentration \times O₂ saturation \times 1.34) is obviously important, as is oxygen extraction by the myocardium, but these are infrequently the basis of intraoperative ischemia. Oxygenation and blood volume are usually well maintained during anesthesia. Coronary sinus PO₂ is about 27 mm Hg (50% saturation), and although extraction can be increased somewhat under conditions of stress, this is inadequate to meet the continuously changing levels of demand. Therefore, the principal mechanism for matching oxygen supply to alterations in $M\dot{V}O_2$ is exquisite regulation and control of coronary blood flow.

Coronary Blood Flow

The critical factors that modify coronary blood flow are diastolic time available for perfusion (namely, heart rate), coronary perfusion pressure, coronary vascular tone, and the presence and severity of intraluminal obstructions. We are most concerned with flow to the subendocardial region of the left ventricle, the area most vulnerable to ischemia, because metabolic requirements are greater owing to greater systolic shortening and also because flow is restricted during systole.⁹

Perfusion of the left ventricular subendocardium takes place almost entirely during diastole, whereas the majority of right ventricular flow occurs during systole (in the absence of pulmonary hypertension) (Fig. 32-1). This temporal disparity is explained by the differences in intracavitary pressures during systole. Because left ventricular flow is diastolic, it is evident that not only is diastolic pressure important but duration of diastole is also critical in determining the volume of left ventricular subendocardial flow. The time available for diastole decreases with increasing heart rate.

Figure 32-1. Coronary artery blood flow during a single cardiac cycle. Left ventricular flow via the left coronary artery occurs primarily during diastole, whereas right ventricular perfusion is predominantly systolic. (Reprinted with permission from Berne FM, Levy MN: Cardiovascular Physiology, 5th ed, p 200. St. Louis, CV Mosby, 1986.)

Coronary perfusion pressure for the left ventricle is often defined as aortic diastolic pressure (AoDP) minus left ventricular end-diastolic pressure (LVEDP). This is an oversimplification because there is no single AoDP. Rather, it is likely that there is a range of pressures that drive blood to the subendocardium. In the presence of intraluminal obstruction or increased vascular tone, this pressure is reduced, as depicted in Figure 32-2. The precise degree of reduction is unknown to the clinician. Although the pressure at the end of the circuit is unknown and the subject of controversy, it is convenient and useful to consider ventricular filling pressure as this end pressure. Therefore, a low ventricular filling pressure is ideal both in terms of improving perfusion (higher pressure gradient) and of reducing $M\dot{V}O_2$ (decreased ventricular volume and wall tension). The consequences of altering systemic pressure are more difficult to predict because the cost of increasing perfusion pressure (afterload) is increased $M\dot{V}O_2$. It has been shown experimentally that at any given heart rate, hypotension is more likely to induce ischemia than is hypertension.¹⁰

Figure 32-2. The pressure relationships between the aorta (1) and the left ventricle (2) determine coronary perfusion pressure. In coronary artery disease, myocardial perfusion may be compromised by decreased pressure distal to a significant stenosis (1a) (not quantifiable clinically) and/or by an increase in left ventricular end-diastolic pressure (2a). (Reprinted with permission from Gorlin R: Coronary Artery Disease, p 75. Philadelphia, WB Saunders, 1976.)

Alterations in tone of the small intramyocardial arterioles regulate diastolic vascular resistance in the absence of flow, limiting obstructions in the epicardial vessels. These adjustments allow matching of oxygen supply and metabolic demand over a wide range of perfusion pressures. The difference between autoregulated supply and the amount available under conditions of maximal vasodilation is coronary vascular reserve, which is normally three to five times basal flow. As epicardial stenosis

becomes more pronounced, progressive vasodilation of these resistance vessels allows preservation of basal flow, but at the cost of reduced reserve. Whenever demand increases above available reserve, signs, symptoms, and metabolic evidence of ischemia develop (Fig. 32-3).

Figure 32-3. Schematic illustration of mechanisms producing myocardial ischemia. Myocardial oxygen demand is plotted on the left (as multiples of basal oxygen consumption) and oxygen supply on the right. In this example, maximal coronary flow reserve is reduced from 6 to 4 times basal levels by fixed intraluminal obstruction. As long as myocardial oxygen demand remains below this maximal limit, no ischemia occurs (A). Ischemia will develop, however, whenever oxygen demand exceeds maximal supply (B) or when supply is further compromised by coronary vasoconstriction (C). More pronounced coronary vasospasm may produce ischemia at rest (D). (Reprinted with permission from Maseri A, Chierchia S, Kaski JC: Mixed angina pectoris. *Am J Cardiol* 56:30E, 1985.)

Prinzmetal *et al*¹¹ first described angina and myocardial infarction in patients with angiographically normal coronary vessels. Subsequently, Maseri *et al* and others have emphasized repeatedly the frequency with which primary reductions in oxygen supply cause ischemia (Fig. 32-3).^{12,13} Small adjustments in coronary vascular tone at the site of previous obstructions can cause substantial reductions in luminal cross-sectional area. Alterations in stenosis diameter are possible because at least two thirds of plaques or atheroma are not concentric. Therefore, a certain portion of normal vessel wall, or at least reactive vessel wall, is present in the stenosis. It is now apparent that anesthesia is not protective against “supply” ischemia, which occurs frequently during surgery (Fig. 32-4).⁷ The etiology of this is unclear, but it may be caused by circulating catecholamines, local effects of blood components such as platelets at areas of atherosclerosis, or other as yet undetermined factors. It is not uncommon during anesthesia for a patient to show signs of ischemia without any change in heart rate, blood pressure, or ventricular filling pressure. Most ischemic episodes are unaccompanied by hemodynamic changes.^{7,14} Drugs such as nitroglycerin and the calcium entry blockers may be used to prevent and/or treat such episodes of coronary spasm¹⁵ although prophylactic use of these agents is usually ineffective.

Figure 32-4. Association of transesophageal echocardiographic (TEE) wall motion changes with hemodynamic indices of supply and demand from continuous monitoring of 50 patients undergoing coronary artery bypass surgery. (Reproduced with permission from Leung JM, O’Kelly BV, Mangano DT *et al*: Relationship of regional wall motion abnormalities to hemodynamic indices of myocardial oxygen supply and demand in patients undergoing CABG surgery. *Anesthesiology* 73:802, 1990.)

Hypotension, vasospasm, and acute thrombosis all decrease coronary perfusion pressure, reduce coronary blood flow, and limit oxygen delivery to the myocardium. Unstable angina pectoris and/or acute coronary thrombosis is a result of plaque rupture with ensuing platelet activation and thrombus formation. The presence of potentially hyper-reactive normal vessel wall adjacent to the thrombus may result in vasospasm and total occlusion of the vessel lumen in the presence of a previously nonocclusive eccentric plaque or thrombus. This type of acute thrombosis is thought to be the cause of acute myocardial infarction and sudden death (generally ischemia-induced cardiac dysrhythmias).

Hemodynamic Goals

Although the precise relationship between intraoperative ischemia and postoperative myocardial infarction remains controversial,^{16,17} there is consensus that a primary goal of a successful anesthetic is the prevention of myocardial ischemia.¹⁸ Failing that, the prompt identification and treatment of new episodes are essential. As is evident from the previous discussion and from the summary in Table 32-2, anesthetic decisions are designed to reduce and control those factors that increase myocardial oxygen demand, specifically, heart rate, contractility, and wall tension. At the same time, every attempt is made to optimize coronary blood flow, notably, maintaining coronary perfusion pressure and increasing diastolic time. The buzz words for patients with coronary artery disease are “slow, small, and well perfused.” Combinations of anesthetics, sedatives, muscle relaxants, and vasoactive drugs are selected to provide this hemodynamic milieu. Techniques to effectively prevent or treat alterations in coronary vascular tone—antiplatelet drugs, specific bradycardic agents, etc.—are still evolving and await further clinical trial before definitive recommendations can be made.¹⁸

| | |
|------------------|--|
| P | Keep the heart small; ↓ wall tension; ↑ perfusion pressure |
| A | Maintain; hypertension is better than hypotension |
| C | Depression is beneficial when LV function is adequate |
| R | Slow, slow, slow |
| Rhy | Usually sinus |
| MVO ₂ | Control of oxygen demand is frequently not enough; monitor for and treat “supply” ischemia |
| CPB | Elevated VFP is usually not needed after CABG |

P = preload; A = afterload; C = contractility; R = rate; Rhy = rhythm; MVO₂ = myocardial oxygen balance; CPB = postcardiopulmonary bypass; CABG = coronary artery bypass graft; VFP = ventricular filling pressure; LV = left ventricle.

Table 32-2. CORONARY ARTERY DISEASE—HEMODYNAMIC GOALS

Monitoring for Ischemia

Electrocardiogram

The ideal monitoring technique is not yet available. ST segment analysis in multiple leads (most commonly leads II and V₅) is currently the standard. Patients likely to

develop right ventricular ischemia¹⁹ or those with disease of the right coronary artery might benefit from monitoring of leads V_{4R} or V_{5R} . Computerized ST segment trending and interactive monitors that alarm when the ST segment deviates from the programmed algorithm aid in the detection of intraoperative events overlooked by even the most astute observer.

Heart Rate and Blood Pressure

Multiple attempts have been made to determine ischemic thresholds using commonly measured hemodynamic variables. Among the earliest of these was the rate–pressure product, obtained by multiplying heart rate by peak systolic pressure. For each patient, ischemia developed when a particular rate–pressure product was reached. The rate–pressure product was considered an easily determined index of $M\dot{V}O_2$. Although rate–pressure product may correlate with oxygen demand, especially during exercise, it is not a sensitive or specific indicator of intraoperative ischemia. Kissin *et al*²⁰ point out that identical rate–pressure products are possible from multiple combinations of heart rate and blood pressure. Improved conditions for oxygen balance are likely with a low heart rate and high blood pressure compared with the opposite, that is, hypotension and tachycardia.

In an effort to produce a more reliable predictor of ischemia, Buffington¹⁰ devised the pressure–rate ratio. Using a canine model, he observed the effects of 20 combinations of various blood pressures and heart rates and found that no single value of either blood pressure or heart rate or the rate–pressure product was predictive of ischemia. The ischemia threshold was mutually dependent on both the heart rate and coexisting blood pressure. No ischemia occurred if mean arterial pressure (MAP) exceeded heart rate, that is, if the pressure–rate ratio exceeded unity.

Leung *et al*,⁷ using transesophageal echocardiography to detect regional wall motion abnormalities suggestive of ischemia, found that neither the rate–pressure product nor the MAP/heart rate ratio was a sensitive predictor of ischemic changes and questioned their clinical usefulness. Furthermore, most (73%) of the ischemic episodes (detected by transesophageal echocardiography) in 50 patients undergoing coronary artery bypass graft surgery were not associated with acute changes in heart rate, blood pressure, or pulmonary arterial pressure, suggesting that most intraoperative ischemic episodes are related to decreased oxygen supply. Gordon *et al*, using the electrocardiogram as a monitor of ischemia, also demonstrated the lack of sensitivity and specificity of the pressure–rate ratio.²¹

Pulmonary Artery Catheter

Sudden elevations in pulmonary artery or capillary wedge pressure indicating systolic and/or diastolic dysfunction, large A waves reflecting decreased ventricular compliance, and V waves signaling the development of ischemia-induced papillary muscle dysfunction and mitral regurgitation are purported signs of ischemia that may be detected with a pulmonary artery catheter. Several studies contradict this long-held dogma and demonstrate that the pulmonary artery catheter is of little value as a monitor of myocardial ischemia. Leung *et al*²² found that only 10% of all regional wall motion abnormalities were associated with an acute rise in pulmonary capillary wedge pressure in 40 patients undergoing elective coronary artery bypass graft surgery. Haggmark *et al*²³ investigated 53 patients with coronary artery disease undergoing vascular surgery and compared several indicators of ischemia. They found that neither an increase in the pulmonary capillary wedge pressure nor the occurrence of an abnormal pulmonary capillary wedge pressure waveform was a sensitive indicator for myocardial ischemia. Van Daele *et al*²⁴ similarly found in 98 anesthetized patients prior to undergoing coronary artery bypass graft surgery that elevation of the pulmonary capillary wedge pressure was neither a sensitive nor a reliable indicator of ischemia. Furthermore, a large prospective study (1094 patients) by Tuman *et al*²⁵ showed that even high-risk cardiac surgical patients may be safely managed without routine use of a pulmonary artery catheter, and if a clinical need develops intraoperatively, delayed placement of a pulmonary artery catheter does not change outcome. Fontes *et al* assessed the limitations of pulmonary artery catheters in the management of critically ill patients in the intensive care unit. Comparing PA catheters to transesophageal echocardiography, the PA catheters predicted normal left ventricular function well, but performed poorly in judging preload and ventricular dysfunction.²⁶ Although pulmonary capillary wedge pressure changes are no longer considered a sensitive or reliable indicator of ischemia, the pulmonary artery catheter provides information regarding the patient's volume status and cardiac output.

Intraoperative Transesophageal Echocardiography

Since its introduction in the 1980s, two-dimensional transesophageal echocardiography (TEE) has become a vital, invaluable diagnostic and monitoring tool during cardiac surgery. TEE permits assessment of ventricular volume and regional wall motion, measurement of valve gradients, estimation and quantitation of valvular regurgitation, and visualization of the thoracic aorta as well as intracardiac air. It is of inestimable value in intraoperative decision making.

Basics. The TEE image is a two-dimensional slice of a three-dimensional object. Reconstructing the three-dimensional image requires the integration of anatomic references with the multiple image planes available in today's omniplane transducers. The American Society of Echocardiography (ASE)/Society of Cardiovascular Anesthesiologists (SCA) task force for intraoperative echocardiography has published guidelines for performing a comprehensive intraoperative echocardiographic examination.²⁷ These recommendations describe a series of 20 standard tomographic views of the heart and great vessels that should be included in all intraoperative echocardiographic examinations. With experience, a thorough examination can be completed in less than 10 minutes.

Evaluation of Ventricular Function. A variety of techniques have been employed in an attempt to quantify ventricular function with echocardiography. Nevertheless, qualitative assessment currently predominates in the clinical arena. The midpapillary short axis view of the left ventricle is the standard initial view for ventricular evaluation (Fig. 32-5). The presence of the papillary muscles assures that the same view is observed on repeated examinations. Because the left ventricle lies obliquely in the chest, its apex is directed away from the esophagus. The resulting image is a foreshortened ventricular long axis and the apex may not be well visualized.²⁸

Figure 32-5. The echo probe is advanced to obtain the transgastric midpapillary short axis view of the left ventricle. The illustration on the left depicts the anatomic relationship between the echo probe, the heart, and the ultrasound plane. The right side depicts the two-dimensional image of the ultrasound plane. (Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography: An Interactive Text and Atlas. New York, Churchill Livingstone, 1996.)

Qualitative assessment of left ventricular function is based on visual assessment of segmental excursion and myocardial thickening throughout the left ventricle. Segmental excursion is the systolic inward movement of a ventricular segment along an imaginary radius toward the center of the cavity.¹⁵ Evaluation of both excursion and thickening is necessary to account for the heart's normal systolic translation (lateral motion of the entire heart in the chest) and rotation (circular motion of the heart around the long axis of the left ventricle). Furthermore, an infarcted segment of myocardium will not thicken but may undergo excursion due to surrounding normal myocardium. This represents a segment of abnormal regional wall motion.

Ischemia. Although segmental wall motion abnormalities (SWMA) complicate both quantitative and qualitative assessment of global systolic ventricular function,²⁹ they provide information regarding coronary artery disease. The anatomy of the coronary blood supply to the ventricle is relatively constant; therefore, the location of segmental wall motion abnormalities often reflects the involved coronary artery. The level of the segmental wall motion abnormality (basal, midpapillary, or apical) often correlates with location of the coronary lesion on cardiac catheterization (proximal, mid, and distal). The ventricular distribution of the three main coronary arteries is depicted in Figure 32-6. Note that all three coronary arteries supply segments of the ventricle at the transgastric midpapillary short axis level, enhancing the utility of this view as a monitoring plane. The wall motion in these segmental ventricular wall segments is described as normal, hypokinetic, akinetic, or dyskinetic and assigned a corresponding numeric grade (Fig. 32-7; Table 32-3).

Figure 32-6. The distribution of the three main coronary arteries in relation to various two-dimensional TEE images. (Reproduced with permission from Thomas SJ (ed): Manual of Cardiac Anesthesia, 3rd ed. New York, Churchill Livingstone, 2001 [in press].)

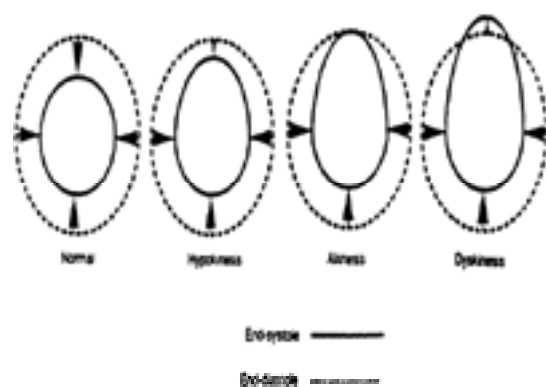

Figure 32-7. Segmental ventricular wall motion is evaluated for both excursion and thickening.

| Class of Motion | Wall Thickening | Change in Radius |
|-----------------------|-----------------|------------------|
| 1. Normal | Marked | >30% decrease |
| 2. Mild hypokinesis | Moderate | 10-30% decrease |
| 3. Severe hypokinesis | Minimal | <10% decrease |
| 4. Akinesis | None | None |
| 5. Dyskinesis | Thinning | Increase |

Table 32-3. DEFINITIONS FOR CHANGES IN REGIONAL WALL MOTION

The diagnosis of a new SWMA requires a change of two classes in the qualitative segmental level of function. The use of cine loop (side-by-side comparison of the ventricle over time) with the midpapillary short axis view of the ventricle improves the ability to recognize new wall motion abnormalities. In one study, however, the short axis midpapillary view detected only 17% of all SWMAs, emphasizing the importance of evaluating the ventricle in multiple planes with careful standardization of location and edge definition.³⁰ Training will increase the operator's ability to attain the required images and to recognize new SWMA in real time.¹⁶

Although ventricular wall motion is clearly very sensitive to coronary blood flow, the definition of ischemia is difficult. There is little agreement on a "gold standard" for the diagnosis of ischemia. Most studies have compared SWMA to changes in ST segments recorded on ECG. The concordance between SWMA and ECG evidence of ischemia is variable, ranging from 30% to 100%.^{31,32} This discrepancy may exist for a number of reasons. SWMAs are more sensitive to compromised coronary blood flow than are ECG changes. Animal models have demonstrated that a 50% decrease in coronary blood flow will produce a new SWMA on TEE, whereas ECG evidence of ischemia requires a 75% decrease in coronary blood flow.³³ In a similar study, when progressive coronary occlusion did generate ECG changes, they always occurred minutes after the appearance of SWMAs.³⁴ Thus, SWMAs on TEE can appear when the compromise in coronary flow is insufficient to produce ECG changes. If the compromise in coronary flow is enough to produce ECG evidence of ischemia, TEE SWMAs precede these ECG changes.

Not all SWMAs are indicative of ischemia. Nonischemic myocardium adjacent to ischemic or infarcted myocardium may be interpreted as SWMAs, a phenomenon known as "tethering." SWMAs also occur with pacing, bundle branch blocks, and myocarditis.³⁵ Tachycardia and hypovolemia may elicit new SWMAs. Although controversial, increased afterload has also been implicated as a cause for new SWMAs.^{36,37} Differentiating stunned myocardium from ischemia as the etiology for new SWMAs is important because treatment differs. Stunned myocardium requires supportive measures such as an inotropic infusion until function returns, while inadequate revascularization with ongoing ischemia requires a reassessment of graft patency and consideration of further revascularization. In the future, echocardiographic contrast agents that delineate coronary perfusion territories may refine this evaluation.^{38,39}

Quantification of Ventricular Function. Attempts to quantify global ventricular function have utilized linear measurements, geometric estimates of ventricular volume, and Doppler measurements of blood flow. Although useful, these methods all have clinical shortcomings.

LINEAR MEASUREMENTS. Fractional shortening (FS) and fractional area of change (FAC) are linear parameters that utilize the observation that the systolic decrease in ventricular volume occurs primarily along the short axis of the ventricle. Fractional shortening is the percentage change in the diameter of the ventricle from diastole to systole measured in M mode:

$$FS = \% \Delta \text{Diameter} = [(LVID_d - LVID_s) / LVID_d] \times 100$$

where LVID is left ventricular internal diameter, s is systole, and d is diastole.

TEE substitutes the percentage change in area obtained from planimetry (FAC = fractional area change) for the linear M-mode measurement. Both FS and FAC have demonstrated a linear correlation with ejection fraction (EF) determined by radionuclide angiography and cineangiography.^{40,41} Nevertheless, FAC still demonstrates an intraobserver variability of 10% and an interobserver variability of 6-23%.^{42,43 and 44}

Part of this variability may be attributed to difficulty in defining the endocardial border. The endocardial border is clearly delineated when it is perpendicular to the ultrasound beam. However, as the endocardial border becomes parallel to the ultrasound beam, the image becomes broad, blurred, and may even drop out. In the short axis midpapillary view, this occurs along the septal and lateral walls of the ventricle. Finally, the papillary muscles have been included as part of the endocardial border in some studies and as part of the chamber volume in other studies. Because the FAC method assesses global left ventricular function with a single short axis view, it is inherently inaccurate in the setting of an asymmetric ventricle. Such variability, coupled with the time required to manually trace the endocardial border, limits the clinical utility of the FAC method.

Automated border detection (ABD) overcomes some of these limitations. Improved computer software with ABD can provide real-time measurements of FAC.^{46,47} The

FAC determined by ABD has been clinically correlated with EF determined by radionuclide angiography.⁴⁸ Furthermore, the system remains accurate with serial changes in ventricular area.⁴² About 80% of the ABD values for EDA, ESA, and FAC are within the limits of expert offline analysis. A limitation of the ABD is that it cannot extrapolate the endocardial border.⁴²

Although EF has traditionally been used as an indicator of left ventricular function, it is dependent on preload, afterload, and contractility.⁴³ In an attempt to isolate and quantify left ventricular performance, the left ventricular area measurements obtained with ABD have been combined with left ventricular pressure measurements to generate pressure–area loops (Fig. 32-8). These pressure–area loops have been used to derive indices of contractility that are independent of the ventricle's loading conditions.^{44,45} and ⁴⁶ Routine application of this system is limited by its complexity and the necessity of a left ventricular pressure catheter.

Figure 32-8. Continuous pressure–area loops generated during preload reduction. The end-systolic points are shown as black diamonds. The slope of the line connecting these points, the end-systolic pressure–area relationship, is a measure of contractility. (Reproduced with permission from Declerck C, Hillel Z, Shih H *et al*: A comparison of left ventricular performance indices measured by transesophageal echocardiography with automated border detection. *Anesthesiology* 89:341, 1998.)

GEOMETRIC QUANTIFICATION. A more sophisticated and complex approach to determining ventricular function has utilized assumptions about ventricular shape to determine ventricular volume. The end-diastolic volume and end-systolic volume can then be used to calculate the EF. The simplest method assumes that the ventricle is a prolate ellipsoid (two short axes of equal diameter and a long axis that is twice the diameter of the short axis) (Fig. 32-9). The formula $V = D^3$ assumes that the ventricular volume can then be calculated from the measurement of the short axis midpapillary diameter. Measurements are made in systole and diastole and the corresponding values applied to a nomogram to obtain the EF (Table 32-4). Although a linear relationship of minor axis length to chamber volume has been demonstrated,⁴⁷ the “cubed formula” significantly overestimates ventricular volume in large ventricles. As a ventricle dilates, it becomes more spherical, dilating primarily along the minor axes.^{35,48} This increases the error associated with the assumptions of the cubed formula. In an attempt to account for this error, Teichholz⁴⁹ utilized regression formulas to modify the formula:

$$\text{Volume} = [7.0 / (2.4 + D)] \times D^3$$

Figure 32-9. A prolate ellipsoid model of the left ventricle with the two short axes (D1, D2) of equal diameter and the long axes (L) twice the diameter of the short axes. (Reproduced with permission from Weyman A: *Principles and Practice of Echocardiography*, 2nd ed. Philadelphia, Lea & Febiger, 1994.)

Table 32-4. A NORMOGRAM CALCULATING EJECTION FRACTION FROM THE FRACTIONAL SHORTENING MEASUREMENTS

The area–length ellipsoid formula and the modified Simpson's rule are more sophisticated geometric models that have been used in an attempt to increase the accuracy of the calculated EF. The ASE recommends that ventricular volumes be calculated with a modification of Simpson's rule. Simpson's rule states that the ventricular volume is equal to the summation of a series of disks from the ventricular apex to the base (Fig. 32-10). The intraoperative utility of these formulas is limited by the time required to perform the necessary measurements, the complexity of the calculations, and the inability of TEE to accurately measure the ventricular long axis.²⁸ Estimating ventricular volume with three-dimensional reconstruction from two-dimensional image planes is currently being evaluated.⁵⁰

SIMPSON'S RULE

Figure 32-10. Simpson's Rule: The ventricular volume is equal to the summation of a series of disks from the ventricular apex to the base. (Reproduced with

DOPPLER QUANTIFICATION. Stroke volume can be quantified using two-dimensional echocardiography with Doppler measurements of blood velocity:

$$\text{Stroke volume} = \text{CSA} \times \text{VTI}$$
$$\text{CSA} = \pi r^2$$

where CSA is cross-sectional area, r is the radius of the cylinder [$r = (\text{diameter of the cylinder})/2$], and VTI is velocity time integral.

Pulse wave Doppler (PWD) displays the velocity profile of blood at a specific location within the heart. It assumes that blood flow at this location is laminar and parallel to the ultrasound beam. Any deviation in the angle between the ultrasound beam and the blood flow will underestimate the VTI and consequently the stroke volume. Using a cursor, the VTI is calculated by tracing the PWD profile (Fig. 32-11). The CSA is then determined by measuring the diameter at this same location. Usually, these measurements are made at the left ventricle outflow tract, aortic annulus, or ascending aorta. These sites are assumed to be cylindrical so that the CSA can be calculated by the πr^2 formula. It is important that the diameter be accurately measured as any error in this measurement is subsequently squared.

Figure 32-11. The illustrated velocity profile is obtained by placing the sample volume of the pulse wave Doppler in the LVOT and then manually traced with the cursor. The computer integrates this to generate the velocity time integral of the LVOT. Multiplying this by the CSA of the LVOT will estimate the stroke volume of the LVOT. (LVOT = left ventricular outflow tract, CSA = cross-sectional area.)

Currently there is no echocardiographic measurement of global ventricular function that is both quick and accurate. Therefore qualitative assessment remains the most frequently used modality. With good endocardial definition and integration of the various cross sections of the ventricle, an experienced observer can reasonably estimate ejection fraction. One study found that 75% of the time qualitative estimates of ejection fraction were within 10% of offline quantified values.²⁹ Qualitative estimates of ejection fraction have also been found to be in agreement with ejection fraction determined by radionuclide angiography and contrast ventriculography.^{43,51}

Right Ventricle. The right ventricle is a complex anatomic structure draped over the anteriomedial portion of the left ventricle. There are no accepted three-dimensional representations of the right ventricle. Geometric models that have been employed include prism, triangular-based pyramid, and three-dimensional parallelogram.³⁵ In the transgastric short axis midpapillary view, the right ventricle appears crescent-shaped, with the septum forming the medial wall. The right ventricular border is irregular due to trabeculae carneae. Contraction of the right ventricle is also complex. It involves a shortening of the long axis and an inward movement of the free wall, which is primarily responsible for the ejection of blood. Collectively, these properties make it difficult to accurately evaluate right ventricular function.⁵²

The ability to qualitatively assess the right ventricle has been limited owing to its asymmetries and its decreased muscle mass relative to the left ventricle. For descriptive purposes, the right ventricle can be divided into three walls: anterior, lateral, and inferior (Fig. 32-12). The diagnosis of right ventricular infarct requires a change in right ventricular function from normal to akinesis or dyskinesis.^{53,54} and ⁵⁵ Quantitative measurements of the right ventricle with linear parameters have not been found to accurately reflect right ventricular function.³⁵ ABD has been applied to normovolemic right ventricles to generate pressure–area loops in order to evaluate right ventricular contractility.⁵⁶ It is not clear if this method is accurate with hypervolemic ventricles.⁵⁷ In the future, three-dimensional reconstruction of the right ventricle may allow improved evaluation.⁵⁸

Figure 32-12. Nomenclature of the right ventricle as seen in the transverse short axis at the level of the papillary muscles. (Reproduced with permission from Weyman A: Principles and Practice of Echocardiography, 2nd ed. Philadelphia, Lea & Febiger, 1994.)

If the right ventricle appears dilated, this should trigger an evaluation for an appropriate lesion such as an atrial septal defect, tricuspid regurgitation, or pulmonic regurgitation. Long-standing right ventricular pressure overload can result in right ventricular dilation; however, hypertrophy is more common. Right ventricular hypertrophy is diagnosed with a diastolic right ventricular free wall thickness greater than 0.5 cm.

Aorta. Neurologic dysfunction in cardiac surgical patients continues to be a devastating complication.^{59,60} Stroke, defined as a fixed neurologic deficit lasting longer than 24 hours, occurs with an incidence of 2–5% in patients undergoing CABG with CPB while more subtle neurologic dysfunction occurs in 30–60% of these patients.^{59,61} Risk factors that have been identified include a history of neurologic disease, older age, and the presence of aortic atherosclerosis.^{62,63} and ⁶⁴ Detecting aortic atherosclerotic disease allows surgical modifications that may decrease a patient's morbidity and mortality.^{65,66} and ⁶⁷ Prior to echocardiography, detection of aortic atherosclerotic disease relied on surgical palpation or radiographic evidence of its presence. Although successful for detection of severe aortic calcification, these techniques do not reliably predict aortic atheromas.^{63,68} TEE can accurately detect the presence of both aortic calcification and atherosclerosis.^{68,69} Because TEE is easy to perform, reproducible, quantifiable, and carries minimum risk, it has become the diagnostic method of choice for detecting aortic atheromas. The severity of aortic atherosclerotic disease is graded according to the scale depicted in Table 32-5.

| Aortic Atherosclerotic Grade | Description |
|------------------------------|------------------------------|
| 1 | Normal intimal thickening |
| 2 | Extensive intimal thickening |
| 3 | Sessile atheroma < 0.5 cm |
| 4 | Protruding atheroma > 0.5 cm |
| 5 | Mobile atheroma of any size |

Mild to moderate: grades 1-3; severe: grades 4-5.

Table 32-5. AORTIC ATHEROSCLEROTIC GRADING

TEE completely and accurately images the descending thoracic aorta. However, owing to the interposition of the trachea and/or the right mainstem bronchus between the esophagus and the ascending aorta, the distal ascending aorta and proximal aortic arch are much more difficult. Complete and accurate examination of this segment of the aorta requires direct examination with an epiaortic probe. The presence of a grade 3, 4, or 5 descending thoracic aorta is associated with an increased incidence of postoperative morbidity (stroke) and mortality.^{62,63,70} In a series of 189 patients who underwent a CPB/CABG and intraoperative TEE examination of the descending aorta, no strokes were noted in individuals with grades 1 and 2 aortas, whereas stroke rates of 5.5% (5/11), 10.5% (2/19), and 45% (5/11) were documented for descending aortas grades 3, 4, and 5⁶² (Fig. 32-13). In a subsequent study, an epiaortic examination of the ascending aorta was performed in all patients with a grade 4 or 5 descending thoracic aorta. If a grade 5 ascending thoracic aorta was documented, there was a 71% (5/7) incidence of stroke. It has been shown that if a complete TEE examination of the thoracic aorta is negative for atheromatosis, it is highly unlikely that there is significant atherosclerotic disease in the ascending aorta and proximal aortic arch. If the TEE examination reveals significant atheromatosis (>3 mm) in the aorta, there is a 34% chance of significant disease in the ascending aorta, and epiaortic scanning is applicable.⁶⁴ Thus, TEE is a very sensitive but only mildly specific method of determining the extent of atherosclerosis in the thoracic aorta.

Figure 32-13. Risk of perioperative stroke versus descending thoracic aortic grade. Numbers in parentheses represents the number of patients who suffered a stroke out of the total number of patients with that descending aortic grade. (Reproduced with permission from Hartman GS, Yao FS, Bruefach M *et al*: Severity of aortic arteromatous disease diagnosed by transesophageal echocardiography predicts stroke and other outcomes associated with coronary artery surgery: A prospective study. *Anesth Analg* 83:701, 1996.)

Despite TEE's shortcomings in imaging the thoracic aorta for atherosclerosis, it remains a primary tool for rapid and accurate evaluation of patients with suspected thoracic aortic pathology, especially aortic dissections. TEE has consistently demonstrated a 95–100% sensitivity and specificity in diagnosing an acute aortic dissection⁷¹ (Fig. 32-14). It is important to recognize that artifacts may appear as an aortic dissection.^{72,73} These artifacts can be classified as linear artifacts or mirror-image artifacts.⁷⁴ Linear artifacts may mimic intimal flaps. They frequently occur in the ascending aorta when the aortic diameter is greater than the left atrial diameter. Mirror-image artifacts are more common in the transverse and descending aorta and appear as a double-barrel aorta. These are produced by the aortic–lung tissue interface.⁷⁴ A number of methods can be used to decrease the risk of interpreting an artifact as a dissection. Performing a complete two-dimensional assessment of the aorta in multiple image planes will eliminate the majority. Applying color flow Doppler to the aorta may also distinguish a dissection from an artifact. Dissections will disrupt the blood flow pattern to produce a mosaic color flow image, a pattern not seen with artifacts. Finally, M-mode echocardiography can be used to demonstrate independent movement of the true aortic flap, a property not consistent with an artifact. Epiaortic evaluation of the ascending aorta should be performed if an acute dissection is suspected secondary to surgical cannulation of the aorta.

Figure 32-14. Color flow Doppler of the ascending aorta in a patient with aortic dissection. The turbulent color flow represented by the mosaic pattern illustrates blood flow between the true and false lumen.

Selection of Anesthetic

Numerous reports documenting the pattern of prebypass hemodynamics and the frequency of prebypass ischemia support the conclusion that there is no one “ideal” anesthetic for patients with coronary artery disease. Two large prospective outcome studies in coronary artery bypass graft patients addressed the question of anesthetic choice. Slogoff and Keats,⁷⁵ in a prospective randomized study using various anesthetics in 1012 patients, found a perioperative incidence of myocardial infarction of 4.1% and a mortality of 1.7%. Tuman *et al*,⁷⁶ in a prospective nonrandomized study of five anesthetic techniques in 1094 patients, similarly found a perioperative incidence of myocardial infarction of 4.1% and a mortality of 3.1%. In neither study did anesthetic choice influence outcome. Nearly every combination of anesthetic and vasoactive drug has both favorable studies and ardent zealots promoting its use. However, the choice of anesthetic should depend primarily upon the extent of pre-existing myocardial dysfunction and the pharmacologic properties of the drugs themselves. The fit patient who has angina only on heavy exertion and good ventricular function profits from having $M\dot{V}O_2$ decreased with a volatile-based technique. Conversely, the patient with severe congestive heart failure and a scarred myocardium might be better served by a less depressant technique. Clearly, there are patients who fall all along this spectrum. These examples illustrate the point that myocardial depression is harmful only in the patient whose heart cannot be further depressed without fear of precipitating overt heart failure. Most patients with mild or even moderate dysfunction may benefit from some degree of myocardial depression, decreasing oxygen demand and alleviating or at least decreasing episodes of ischemia.

Cost Containment

Cost containment permeates the practice of medicine today, and cardiac surgery and anesthesia have not been excluded. The high cost of cardiac surgery is due in part to the traditional modes of postoperative ICU care of these patients. Improvements in anesthetic, surgical, and perfusion techniques have reduced the need for prolonged ICU stays in many cardiac surgical patients. Thus, both clinical and economic factors have resulted in an evolving emphasis on “fast-track” recovery, which involves early postoperative awakening and extubation with an abbreviated ICU stay and a shortened overall hospitalization.^{77,78 and 79} Early extubation (1–8 hours) is only one of many components that contribute to the success of such an approach. Other key elements include appropriate patient selection, patient education, accelerated rehabilitation, a designated coordinator who maintains daily telephone contact, and adequate follow-up postoperative visits (at 1 week and 1 month). The fast-track recovery protocol has not been associated with an increase in either early or late morbidity or mortality.⁸⁰

There are multiple approaches to achieve early extubation in the cardiac surgical patient. The choice of anesthetic should be based on the known hemodynamic, pharmacologic, and pharmacokinetic effects of each drug as they apply to the particular patient, the experience of the anesthesiologist, and the relative cost–benefit of each agent. Volatile anesthetics with low-dose narcotics⁸¹ and total intravenous (iv) anesthesia with short-acting drugs (e.g., midazolam, alfentanil, remifentanil, propofol) have been utilized to effect early extubation. Another interesting approach is the combination of the opiates, sufentanil and morphine, instilled intrathecally before induction. This reduces postoperative analgesic requirements and, when combined with an appropriate anesthetic technique, allows extubation within 8 hours.⁸²

Opioids

The primary advantages of opioids are lack of myocardial depression, maintenance of a stable hemodynamic state, and reduction of heart rate (except for meperidine). Problems include hypertension and tachycardia during surgical stimulation (sternotomy and aortic manipulation), especially in patients with good ventricular function, predictable hypotension when combined with benzodiazepines, lack of titratability when used in high doses, and a low incidence of intraoperative recall. A primary opioid technique may be of value in the patient with severe myocardial dysfunction; in patients with normal ventricles, this may be inadequate as an anesthetic and may need to be combined with other anesthetics or vasoactive drugs. The planned time of extubation is now one of the major factors determining the selection and dosage of opioid.

Inhalation Anesthetics

The desirable features of volatile anesthetics include dose dependency, easy reversibility, titratable myocardial depression, amnesia, and suppression of sympathetic responses to surgical stress and cardiopulmonary bypass. Disadvantages include myocardial depression, systemic hypotension (whether induced by decreased contractility or vasodilation), and lack of postoperative analgesia. Combinations of opioids and volatile anesthetics may produce the advantages of each with minimal untoward effects. It is likely that any volatile anesthetic agent could be used as an adjuvant anesthetic if appropriate doses are used that minimize adverse cardiovascular effects. The known cardiovascular effects of a particular agent may be used to their advantage. For example, the vasodilation produced by isoflurane may be beneficial in reducing the afterload in a patient with a high systemic vascular resistance, or the myocardial depressant effect of enflurane—or, dare we say it, halothane—may be of value in a patient with hypertrophic cardiomyopathy. The use of any volatile agent in a patient with cardiac disease is predicated upon the anesthesiologist’s knowledge of the dose-dependent cardiovascular side-effects, the understanding of how such effects will affect a particular patient, and his/her experience in administering these agents.

Isoflurane is a coronary vasodilator, as are the other volatile anesthetics, although to a lesser degree.⁸³ This effect is dose-related and is clinically insignificant in doses less than 1 minimum alveolar concentration (MAC). Clinical studies using isoflurane to clinical rather than pharmacologic endpoints do not show increased episodes of ischemia or a worsened outcome.⁸⁴

Desflurane and sevoflurane have the advantage of faster recovery compared with the other volatile anesthetic agents. Desflurane has a rapid uptake and distribution, allowing it to be useful in cases where hemodynamic swings are dramatic. It has a cardiac profile similar to that of isoflurane. Of concern is the fact that a sudden increase in inspired concentration can lead to a marked increase in heart rate, mean arterial pressure, and plasma epinephrine levels, making it riskier for use in patients with coronary artery disease.^{85,86} Data relating the use of desflurane with myocardial performance have shown that its cardiac depressant effects and vasodilating properties are similar to those of isoflurane.^{87,88} In patients undergoing noncardiac surgery, desflurane does increase pulmonary artery pressure, wedge pressure, and pulmonary vascular resistance compared to isoflurane.^{88,90} Studying sympathetic nervous system activity, Helman *et al* found an increase in sympathetic activity and myocardial ischemia in patients anesthetized with desflurane as the sole anesthetic agent for coronary artery bypass surgery compared to patients anesthetized with sufentanil.⁹⁰ In contrast, Parsons *et al* found that a combination of low-dose fentanyl and desflurane had a similar incidence of ischemia when compared to midazolam–fentanyl as the anesthetic choice for coronary artery bypass surgery.⁹¹ The hemodynamic profile of sevoflurane also resembles that of isoflurane.⁹² Compared to isoflurane in a technique combining fentanyl with the inhalational anesthetic, sevoflurane had an acceptable cardiovascular profile prior to cardiopulmonary bypass and had similar outcome data to isoflurane.⁹³

Intravenous Sedative Hypnotics

An alternative adjuvant anesthetic to a reduced opioid technique is a titratable iv infusion of a short-acting sedative, such as midazolam or propofol, which can be continued postoperatively in the ICU and, after discontinuation, afford a predictable and fairly rapid awakening. Bell *et al* compared a propofol infusion with a low-dose fentanyl (15 $\mu\text{g} \cdot \text{kg}^{-1}$) technique to a high-dose fentanyl (60 $\mu\text{g} \cdot \text{kg}^{-1}$) anesthetic in cardiac surgical patients with a low cardiac output state.⁹⁴ They found that the patients in the propofol/reduced-dose fentanyl group awakened sooner and were extubated earlier than the patients in the high-dose fentanyl group. Comparison between the two sedatives shows both drugs to be effective and safe as anesthetics used in coronary artery bypass surgery with good control of intraoperative and postoperative ischemia.^{95,96}

Treatment of Ischemia

The use of anesthetics or vasoactive drugs that will enable the heart to return to the slow, small, perfused state is frequently required during anesthesia. The principal vasoactive drugs are nitrates, β blockers, peripheral vasoconstrictors, and calcium entry blockers. Clinical scenarios for their use are given in [Table 32-6](#). These drugs are discussed extensively in [Chapter 12](#) and are reviewed only briefly here. Volatile anesthetics can also be used to control blood pressure and reduce contractility.

| Demand | |
|-----------------|--|
| ↑ BP ± ↑ PCWP | NTG, ↑ anesthetic depth |
| ↑ HR | Treat usual causes, then β blocker |
| Supply | |
| ↓ BP | Vasoconstrictor, ↓ anesthetic depth |
| ↓ BP and ↑ PCWP | Phenylephrine + NTG, inotrope |
| NL hemodynamics | NTG, CCB |

BP = blood pressure; PCWP = pulmonary capillary wedge pressure; HR = heart rate; NL = normal; NTG = nitroglycerin; CCB = calcium channel blocker.

Table 32-6. TREATMENT OF INTRAOPERATIVE ISCHEMIA

Nitrates

Nitroglycerin is a venodilator and reduces venous return, lessening wall tension and $\dot{M}\dot{V}\text{O}_2$, and also a coronary arterial dilator, effective in coronary stenoses and in collateral beds.^{97,98} Nitroglycerin is the drug of choice for the acute treatment of coronary vasospasm. The evidence for the prophylactic use of nitroglycerin is unconvincing for the prevention of either intraoperative ischemic episodes or postoperative cardiac complications. Although nitroglycerin is primarily a systemic venodilator, it does dilate arterial beds and may cause systemic hypotension at higher doses.

Vasoconstrictors

Vasoconstrictors are useful adjuncts in the prevention and treatment of ischemia owing to their ability to increase systemic blood pressure. Administration of an α -adrenergic agent such as phenylephrine improves coronary perfusion pressure, albeit at the expense of increasing afterload and $M\dot{V}O_2$. In addition, concomitant venoconstriction increases venous return and left ventricular preload. In most situations, the increase in coronary perfusion pressure more than offsets any increase in wall tension. Peripheral vasoconstriction is indicated during episodes of systemic hypotension, especially those caused by reduced surgical stimulation or drug-induced vasodilation. Nitroglycerin is sometimes added to counteract any increase in preload. Similarly, phenylephrine can be administered to patients in whom nitroglycerin results in decreased ventricular filling pressures but unacceptably low arterial pressure.

Beta Blockers

β -Adrenergic blockade is often useful in improving myocardial oxygen balance by preventing or treating tachycardia as well as decreasing contractility. The use of atenolol has been shown to improve long-term survival in patients with heart disease undergoing noncardiac surgery.^{99,100} Myocardial depression can result in increased ventricular volume and wall tension; clinically, this is not usually a problem. Indications for β blockers include treatment of sinus tachycardia not resulting from the usual causes (e.g., light anesthesia, hypovolemia), slowing the ventricular response to supraventricular dysrhythmias, decreasing heart rate and contractility in hyperdynamic states, and control of ventricular dysrhythmias. Intravenous preparations include propranolol, metoprolol, labetalol, and esmolol. Propranolol is a nonselective β blocker with an elimination half-life of 4–6 hours. Metoprolol is similar to propranolol but has the purported advantage of β_1 selectivity. Labetalol combines α -blocking properties with those of β blockade and is useful in treating hyperdynamic situations and in controlling hypertension. Esmolol is a short-acting β blocker that is cardioselective, with a half-life of only 9.5 minutes. It is often useful in treating momentary increases in heart rate owing to episodic sympathetic stimulation.

Calcium Channel Blockers

Calcium channel blockers are useful in slowing the ventricular response in atrial fibrillation and flutter, as coronary vasodilators, and in the treatment of postoperative hypertension. *In vitro*, all calcium entry blockers depress contractility, reduce coronary and systemic vascular tone, decrease sinoatrial node firing rate, and impede atrioventricular conduction. Unlike the β blockers, which are similar both in structure and pharmacodynamic effect, the calcium entry blockers vary remarkably in their predominant pharmacologic action. The negative inotropic effect is greatest with verapamil and less with nifedipine, diltiazem, and isradipine (in decreasing order).¹⁰¹ Verapamil is useful in the treatment of supraventricular tachycardia and slowing the ventricular response in atrial fibrillation and/or flutter; however, its myocardial depressant effects may limit its usefulness in some patients. In patients with reduced myocardial function, iv diltiazem is effective in the treatment of atrial fibrillation and flutter by slowing atrioventricular conduction with minimal myocardial depression. It is also useful in decreasing sinus rate. Nifedipine and diltiazem are coronary vasodilators and are used as anti-anginal agents and in the prevention of coronary vasospasm. It has been shown that continuous infusion of diltiazem during coronary bypass surgery is associated with fewer ischemic episodes, a lower incidence of atrial fibrillation and preservation of myocardial function.¹⁵

Nifedipine, isradipine, amlodipine, and nicardipine are prominent peripheral vasodilators. Owing to their systemic vasodilatory effects, intravenous isradipine and nicardipine have been shown to be effective in the treatment of postoperative hypertension in cardiac surgical patients, with minimal side-effects.^{102,103} Magnesium has use in the treatment of myocardial ischemia. It has coronary artery vasodilating properties, reduces the size of myocardial infarction in the setting of acute ischemia, and decreases mortality associated with infarction.^{104,105,106} and ¹⁰⁷ Additionally, it is an anti-arrhythmic and minimizes myocardial reperfusion injury.^{108,109}

VALVULAR HEART DISEASE

Alterations in loading conditions are the initial physiologic burdens imposed by valvular heart lesions, both stenotic and regurgitant. For example, the left ventricle is pressure-overloaded in aortic stenosis and volume-overloaded in aortic insufficiency and mitral regurgitation. In mitral stenosis, however, the left ventricle is both volume- and pressure-underloaded, whereas the right ventricle faces progressively increasing left atrial and pulmonary artery pressure. The mechanisms used to compensate for these additional stresses consist of chamber enlargement, myocardial hypertrophy, and variations in vascular tone and the level of sympathetic activity. These mechanisms in turn induce secondary alterations, including altered ventricular compliance, development of myocardial ischemia, chronic cardiac dysrhythmias, and progressive myocardial dysfunction. Myocardial contractility is often transiently depressed but may progress to irreversible impairment even in the absence of clinical symptoms. This is especially true in mitral regurgitation and aortic insufficiency, in which markedly reduced afterload favors ejection and forward flow.¹¹⁰ Conversely, the patient with aortic stenosis may complain of dyspnea, not because of impaired systolic function, but because of reduced ventricular compliance, increased left ventricular end-diastolic pressure, and increased pulmonary pressures.

When a decision for valve replacement or repair is made, the anesthesiologist is often presented with a patient with pulmonary hypertension, severe ventricular dysfunction, and chronic rhythm disorders. Anesthetic management is predicated on understanding the altered loading conditions, preserving the compensatory mechanisms, maintaining circulatory homeostasis, and anticipating problems that may arise during and after valve surgery. In this section, we briefly describe the pathophysiology, the desirable hemodynamic profile, and other pertinent anesthetic considerations for each valvular lesion.

TEE has become the standard of care in the perioperative management of patients undergoing valve surgery.¹¹⁰ TEE can further refine the preoperative diagnosis, identify valvular pathology and the mechanism of disease, and quantify the degree of stenosis and/or regurgitation. Studies have shown a change in the perioperative plan regarding valve surgery in as many as 19% of cases as a result of the prebypass echocardiographic exam.^{110,111,112} and ¹¹³ TEE's ability to immediately evaluate the surgical results also affects the operative course. Depending on the surgical intervention, 5–18% of the time TEE reveals findings that result in an immediate return to CPB.^{113,114} However, detailed assessment of valve function pre- and post-CPB is complex. Two-dimensional echocardiography and color flow Doppler can provide a gross evaluation of valve function, but complete assessment requires Doppler evaluation of blood flow velocities. Comprehensive reviews of these topic can be found in standard textbooks of echocardiography. Ultimately, the decision to intervene surgically for valve pathology is clinical and must take account of the patient's individual situation. Both valve replacement and repair result in a level of valve pathology that may or may not be in the best interest of the patient.

Aortic Stenosis

Pathophysiology

Progressive calcification and narrowing of the aortic valve orifice are degenerative processes affecting a normal or congenitally bicuspid valve. This results in chronic obstruction to left ventricular ejection. Increased intraventricular systolic pressure with concomitant increase in wall tension is required to maintain forward flow. "Concentric" ventricular hypertrophy, in which the wall gradually thickens but the chamber size remains unchanged, is the compensatory response normalizing wall tension. Contractility is preserved and ejection fraction is maintained at a normal range until late in the disease process (Fig. 32-15). The normal valve area is about 3 cm²; signs and symptoms of aortic stenosis occur when this is reduced to 0.8 cm².

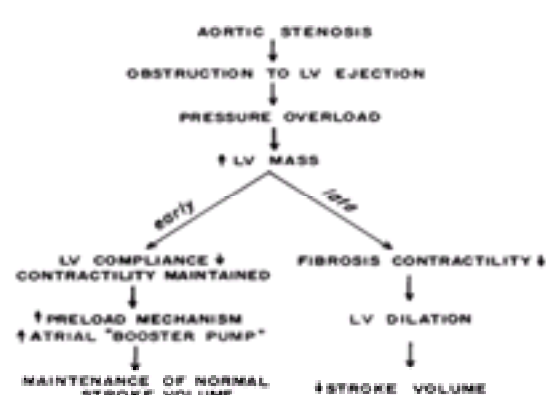

Figure 32-15. The physiologic consequences of aortic stenosis. (Reprinted with permission from Thomas SJ, Lowenstein E: Anesthetic management of the patient with valvular heart disease. *Int Anesthesiol Clin* 17:67, 1979.)

The cost of this concentric hypertrophy is decreased diastolic compliance and a precarious balance between myocardial oxygen supply and $M\dot{V}O_2$. The clinical implications of the low-compliance ventricle are summarized in [Table 32-7](#). Because the ventricle is so stiff, atrial contraction is often critical for maintaining ventricular filling and stroke volume. The “atrial kick” may account for up to 30–40% of left ventricular end-diastolic volume. Hypertrophy-induced impairment of diastolic relaxation can further impede left ventricular filling. Ventricular filling pressure, as reflected by pulmonary capillary wedge pressure, is sometimes difficult to interpret, because it may vary widely yet reflect only small changes in ventricular volume.

Sensitive to volume depletion
 Dependent upon atrial kick for adequate ventricular filling
 Wide swings in ventricular filling pressure
 PCWP underestimates LVEDP
 ↑ LVEDP reduces coronary perfusion pressure

PCWP = pulmonary capillary wedge pressure; LVEDP = left ventricular end-diastolic pressure.

Table 32-7. CLINICAL AND PHYSIOLOGIC IMPLICATIONS OF A LOW-COMPLIANCE VENTRICLE

Hypertrophied myocardium is susceptible to ischemia, even in the absence of concurrent coronary artery disease. The enlarged muscle mass increases basal myocardial oxygen requirements while demand per beat rises owing to the elevated intraventricular systolic pressure. Simultaneously, supply may be impaired, perfusion pressure is reduced (aortic diastolic pressure is decreased, ventricular filling pressure is increased), capillary density is often inadequate in the hypertrophic muscle, and total vasodilator reserve may be impaired.¹¹⁵ This situation is compounded in the presence of coronary obstruction.

Anesthetic Considerations

The ideal hemodynamic environment for the patient with aortic stenosis is summarized in [Table 32-8](#). Maintenance of adequate ventricular volume and sinus rhythm is crucial. Hypotension must be prevented if at all possible and treated early if it develops. Anticipation of likely hemodynamic changes is essential (*e.g.*, expected decreases in blood pressure following spinal anesthesia). Coronary perfusion pressure must be maintained to prevent the catastrophic cycle of hypotension-induced ischemia, subsequent ventricular dysfunction, and worsening hypotension. Bradycardia is a common clinical etiology for hypotension in the patient with aortic stenosis. Slowing the heart rate and increasing diastolic time will not increase stroke volume. Therefore, bradycardia will induce a fall in total cardiac output and systemic arterial pressure. This is especially pertinent in the elderly patient, in whom sinus node disease and reduced sympathetic responses may predispose to significant bradycardia. Tachycardia must be avoided.

| | |
|---------------|---|
| F | Full; adequate intravascular volume to fill noncompliant ventricular chamber |
| A | Already elevated, but relatively fixed; coronary perfusion pressure must be maintained |
| C | Usually not a problem; inotropes may be helpful; preinduction in end-stage aortic stenosis with hypotension |
| R | Not too slow (↓ CO), not too fast (ischemia) |
| Rhy | Sinus ! Cardioversion: if hemodynamic instability from supraventricular dysrhythmia |
| $M\dot{V}O_2$ | Ischemia is an ever-present risk; tachycardia and hypotension must be avoided |

Abbreviations are defined in [Table 32-2](#).

Table 32-8. AORTIC STENOSIS—HEMODYNAMIC GOALS

Ischemia may be difficult to detect because the characteristic changes are often obscured by the electrocardiographic signs of left ventricular hypertrophy and strain. Unfortunately, an ideal alternative is not available. Elevated left ventricular filling pressures, although not necessarily reflecting increased volume, often require treatment to optimize coronary perfusion pressure. Nitroglycerin is useful in this regard, but it must be remembered that minimal reductions in ventricular volume are required; therefore, very low doses of nitroglycerin should be used and titrated to effect.

TEE in Aortic Stenosis

In a normal adult the aortic valve is composed of three semilunar cusps attached to the wall of the aorta. The normal annular diameter is 1.9–2.3 cm with an aortic valve area (AVA) of 2–4 cm². The outpouchings of the aortic wall immediately above the valve cusps define the sinuses of Valsalva. The cusps and the corresponding sinuses are named according to their relation with the coronary ostia: left, right, and noncoronary. The sinuses of Valsalva should be symmetric, with a diameter that is 0.2–0.3 cm greater than the aortic valve annular diameter. On the ventricular side of the aortic valve is the cylindrical outflow tract. Its borders are the inferior surface of the anterior leaflet of the mitral valve, the interventricular septum, and the left ventricular free wall. The normal diameter of the left ventricular outflow tract (LVOT) is 2.2 cm ± 0.2 cm.

The short axis view of the aortic valve during systole can provide both a diagnosis and the mechanism of aortic stenosis. All three cusps of the aortic valve should be identified during systolic excursion. In degenerative calcification, the systolic orifice becomes smaller as the leaflet cusps become calcified, thickened, and deformed, resulting in a decreased ability to separate ([Fig. 32-16](#)). In contrast, rheumatic valve calcification is along the commissures, resulting in fusion and a progressive decrease in the valve orifice area. Although the rheumatic process usually involves the mitral valve, it can simultaneously or in isolation affect the aortic valve. A bicuspid aortic valve occurs in 2% of the population and predisposes the individual to aortic stenosis as well as aortic regurgitation and endocarditis. Frequently, the bicuspid valves have a raphe in the large cusp, which may be mistaken as a commissure during diastole. Trileaflet valves, if heavily calcified and fibrotic, may be indistinguishable from bicuspid valves.

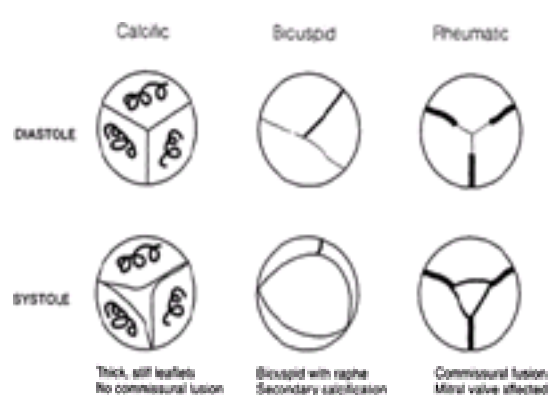

Figure 32-16. Diagram illustrating the three most common causes of aortic stenosis. See text for further discussion. (Reproduced with permission Otto MC, Pearlman AS: *Textbook of Clinical Echocardiography*. Philadelphia, WB Saunders, 1994.)

The systolic aortic valve arc (AVA) can be accurately estimated by planimetry. In the midesophageal aortic valve long axis view, a systolic leaflet separation >1.3 cm reliably excludes severe aortic stenosis.¹¹⁶ Associated two-dimensional findings with aortic stenosis may include concentric hypertrophy of the left ventricle, left ventricular diastolic dysfunction, and a post-stenotic aortic root dilatation that can become severe enough to require surgical correction.

Doppler interrogation across the stenotic aortic valve permits determination of the pressure gradient and AVA. Color flow Doppler across a stenotic aortic valve will show a mosaic of aliased turbulent flow. In about 90% of patients, the deep transgastric long axis view allows excellent alignment of the ultrasound beam with aortic blood flow (angle < 30°).^{117,118} If this view cannot be obtained, rotation to an angle between 60° and 90° from the transgastric midpapillary short axis view may align the ultrasound beam with the aortic blood flow. Utilizing the modified Bernoulli equation, the peak and mean aortic valve gradients can be determined from the peak and mean blood flow velocities across the stenotic valve. It is important to note that the cardiac catheterization data frequently report the left ventricular peak to aortic peak pressure gradient. These pressures occur at different times in the cardiac cycle and the gradient is consistently less than the peak instantaneous gradient measured by Doppler.¹¹⁹ However, the mean gradients measured by echocardiography and catheterization should be the same. The pressure gradient is dependent on the flow through the orifice. The severity of the stenosis may be underestimated if the cardiac output is reduced; conversely, it is overestimated if flow is increased from aortic regurgitation or inotropic support. If one of these scenarios is suspected, the AVA should be calculated utilizing the continuity equation. The continuity equation assumes that the flow across any two orifices is the same. In this case, left ventricular outflow tract flow equals aortic valve (AV) flow. Doppler-derived flow measurements are the product of the VTI and the area of the orifice. The VTI of the LVOT is measured with pulsed Doppler, while the LVOT diameter is measured with two-dimensional echocardiography. Continuous-wave Doppler can measure the peak velocity through the stenotic lesion. The AVA is then calculated from the continuity equation:

$$VTI_{AV} \times area_{AV} = VTI_{LVOT} \times area_{LVOT}$$

$$Area_{AV} = VTI_{LVOT} \times area_{LVOT} / VTI_{AV}$$

The severity of aortic stenosis can be estimated by employing these echocardiographic modalities and the grading criteria outlined in [Table 32-9](#).

| | Normal | Mild | Moderate | Severe |
|------------------------|---------|---------|----------|--------|
| AVA (cm ²) | 3.0-5.0 | 1.2-2.0 | 1.1-0.8 | <0.8 |
| Peak gradient (mm Hg) | <10 | 16-34 | 35-75 | >75 |

AVA = aortic valve area.

Table 32-9. GRADING FOR AORTIC STENOSIS

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy, also known as idiopathic hypertrophic subaortic stenosis or asymmetric septal hypertrophy, is a genetically determined disease characterized by histologically abnormal myocytes and myocardial hypertrophy developing *a priori* and not in response to pressure or volume overload in a nondilated chamber.¹²⁰

Pathophysiology

The physiologic consequences of hypertrophic cardiomyopathy are depicted in [Figure 32-17](#). Some degree of subvalvular obstruction is present in 20–30% of patients. During systole, the left ventricular outflow tract is narrowed by apposition of the hypertrophic interventricular septum to the anterior leaflet of the mitral valve ([Fig. 32-18](#)). Blood is ejected rapidly through this area, creating a Venturi effect, pulling the mitral valve leaflet even closer to the septum (SAM, systolic anterior motion).¹²¹ The timing and duration of septal–leaflet contact determine the severity and clinical significance of the obstruction. Early prolonged contact can generate pressure gradients of 100 mm Hg. If the apposition occurs later, although a pressure gradient may exist, it is of little importance because most of the stroke volume has already been ejected. This obstruction is dynamic and is accentuated by any intervention that reduces ventricular size, facilitating septal–leaflet contact. Therefore, increases in contractility or heart rate or decreases in either preload or afterload are detrimental in this regard. Another hypothesis proposed for systolic anterior motion of the mitral valve is abnormally displaced mitral apparatus.¹²²

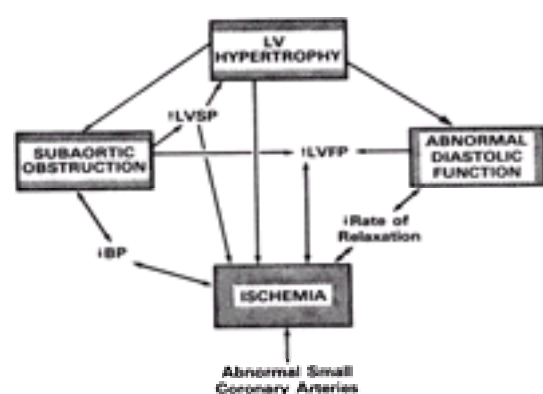

Figure 32-17. The physiologic interrelationships of primary left ventricular hypertrophy in hypertrophic cardiomyopathy. (LVSP = left ventricular systolic pressure; LVFP = left ventricular filling pressure.) (Reprinted with permission from Maron BJ, Bonow RO, Cannon RO *et al*: Hypertrophic cardiomyopathy: Interrelations of clinical manifestations, pathophysiology, and therapy. *N Engl J Med* 316:344, 1987.)

Figure 32-18. Proposed mechanism for outflow tract obstruction in hypertrophic cardiomyopathy. (A) The normal outflow tract is ample and offers no impedance to ejection. (B) The outflow tract is narrowed by the hypertrophic ventricular septum in hypertrophic cardiomyopathy. A Venturi effect is produced as blood is ejected

rapidly through this area, drawing the anterior mitral leaflet toward the septum. Obstruction to forward flow (owing to mitral–septal contact) as well as mitral regurgitation can occur. (Reprinted with permission from Wigle ED, Sasson Z, Henderson ME *et al*: Hypertrophic cardiomyopathy: The importance of the site and the extent of hypertrophy. A review. *Prog Cardiovasc Dis* 28:1, 1985.)

The histologically abnormal muscle demonstrates impaired diastolic relaxation and reduced ventricular compliance. The clinical and hemodynamic implications are similar to those detailed for aortic stenosis.

The ventricles are hypertrophic, even in the absence of a pressure gradient. In addition, there is evidence of alterations in the small intramyocardial vessels. Therefore, as expected, myocardial oxygen balance is tenuous, and the development of ischemia is an ever-present possibility.

Anesthetic Considerations

Anesthetic management focuses on maintenance of ventricular filling and reduction in the factors predisposing to outflow tract obstruction or ischemia (Table 32-10). Myocardial depression is desirable, and volatile anesthetics are useful, although their tendency to cause junctional rhythm is of some concern. Because of the exquisite sensitivity of preload to atrial contraction, these patients will benefit from atrial pacing if junctional rhythm occurs. Methods to achieve this include transesophageal pacing or use of a pulmonary artery catheter with pacing capability. This permits the administration of volatile anesthetics without fear of compromising sinoatrial conduction. In addition, control of atrial rate and rhythm is beneficial during the prebypass period.

| | |
|------------------------------|---|
| P | Full, full, full: volume is first prescription for hypotension |
| A | Up, up, up: a pure vasoconstrictor is next prescription for hypotension |
| C | Depression is fine |
| R | Not too slow, not too fast |
| Rhy | Sinus, sinus, sinus; consider pacing pulmonary artery catheter to better control atrial mechanism |
| MV _O ₂ | Usual precautions apply |
| CPB | Avoid inotropes post-CPB; the myocardial disease is still present; try vasoconstrictors first |

Abbreviations are defined in Table 32-2.

Table 32-10. HYPERTROPHIC CARDIOMYOPATHY— HEMODYNAMIC GOALS

Although infrequent, hypertrophic cardiomyopathy occasionally coexists with valvular aortic stenosis and may explain unanticipated difficulties in separating from bypass following seemingly uncomplicated aortic valve replacement. If this is suspected, measurement of the gradient between the left ventricle and the outflow tract will resolve the dilemma. In addition, dynamic left ventricular outflow obstruction is occasionally observed following mitral valve repair. Anterior septal motion of the mitral valve is observed echocardiographically. Pharmacologic management of hypotension is with volume replacement and vasoconstrictors rather than inotropes and vasodilators.

Aortic Insufficiency

Rheumatic disease, endocarditis, or processes that dilate the aortic root such as ascending aortic aneurysms or collagen vascular diseases are the primary causes of aortic insufficiency.

Pathophysiology

The fundamental physiologic derangement is chronic volume overload (Fig. 32-19). Chamber size increases gradually, sometimes to massive proportions, increasing wall stress and inducing mural hypertrophy. This pattern of chamber enlargement and increasing ventricular wall thickness is termed *eccentric hypertrophy*. Despite these enormous increases in end-diastolic volume, end-diastolic pressures are usually within the normal range, evidence of a significant increase in chamber diastolic compliance. In contrast to aortic stenosis, considerable alterations in left ventricular volume can occur with only minimal changes in left ventricular filling pressure.

Although the ventricle may pump three to four times the normal cardiac output, $M\dot{V}O_2$ does not increase extraordinarily because the oxygen cost for muscle shortening is low. The contractile state of the myocardium is often difficult to discern from clinical signs and symptoms. Ventricular afterload is chronically reduced because of the low diastolic pressure, reflecting continuing diastolic runoff as well as a moderately vasodilated state. This will allow patients to be relatively symptom-free even in the presence of reduced contractility. This is important in terms of planning the anesthetic, but perhaps even more so with respect to timing of aortic valve replacement. Ideally, the valve should be replaced just prior to the onset of irreversible myocardial damage. Therefore, continued follow-up of these patients emphasizes repeated noninvasive measurements of contractility, usually after some form of afterload stress, either pharmacologic- or exercise-induced.

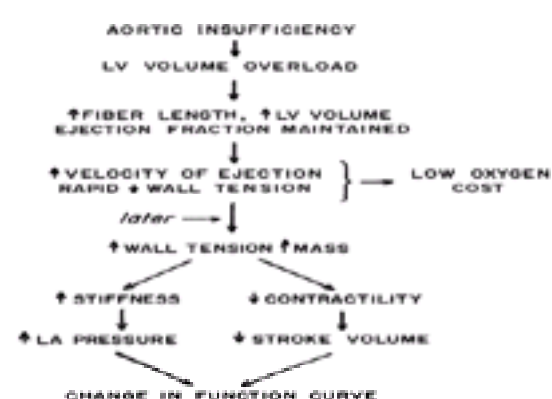

Figure 32-19. The physiologic consequences of aortic insufficiency. (Reprinted with permission from Thomas SJ, Lowenstein E: Anesthetic management of the patient with valvular heart disease. *Int Anesthesiol Clin* 17:67, 1979.)

In contrast to chronic aortic insufficiency, acute aortic insufficiency subjects a ventricle with normal diastolic function to sudden volume overload; severe congestive heart failure dominates the clinical picture. The previously normal-sized left ventricle, with limited distensibility, is presented with large regurgitant volumes, rapidly elevating left ventricular end-diastolic pressure (along the steep portion of the diastolic pressure–volume relation). Left ventricular end-diastolic pressure increases to alarming levels, and myocardial contractility becomes impaired. Compensatory mechanisms include tachycardia and peripheral vasoconstriction, but occasionally hypotension and low cardiac output ensue (Table 32-11). Some patients are so acutely ill that emergency aortic valve replacement is required, whereas in less severe circumstances, mild systemic vasodilation and inotropic support can return hemodynamics toward normal.

| | Chronic | Acute |
|---|---------|-------|
| Left ventricular size | ↑ | — |
| Left ventricular compliance | ↑ | — |
| Left ventricular end-diastolic pressure | — | ↑ |
| Effective cardiac output | Normal | ↓ |
| Systemic vascular resistance | — | ↑ |
| Pulmonary edema | No | Yes |
| Pulse pressure | ↑ | ↑/— |
| Heart rate | — | ↑ |

Table 32-11. ACUTE VERSUS CHRONIC AORTIC INSUFFICIENCY

Anesthetic Considerations

Full, mildly vasodilated, and modestly tachycardic describe the optimal cardiovascular state for patients with aortic insufficiency (Table 32-12). Vasodilation promotes forward flow, although additional intravascular volume may be necessary to maintain preload. The ideal heart rate is somewhat controversial.¹²⁴ It is likely that changes in rate alone will not alter net forward or regurgitant flow; each will be proportionately reduced. Tachycardia does reduce diastolic ventricular volume and wall tension, and also increases diastolic blood pressure, which should improve coronary perfusion and offset the increase in oxygen demand secondary to an increased heart rate. Bradycardia should be avoided because it predisposes to ventricular distention, which causes elevations in left atrial pressure and pulmonary congestion.

| | |
|------------------------------|--|
| P | Normal to slightly ↑ |
| A | Reduction beneficial with anesthetics or vasodilators; increases aortic regurgitant flow |
| C | Usually adequate |
| R | Modest tachycardia reduces ventricular volume, raises aortic diastolic pressure |
| Rhy | Usually sinus; not a problem |
| MV _O ₂ | Not usually a problem |
| CPB | Observe for ventricular distention (↓ HR, ↑ VFP) when going onto CPB |

Abbreviations are defined in Table 32-2.

Table 32-12. AORTIC INSUFFICIENCY—HEMODYNAMIC GOALS

Ventricular distention may occur with the onset of cardiopulmonary bypass if the heart slows or if there is unexpected ventricular fibrillation. Monitoring of the appearance of the heart, the rate and rhythm, and ventricular filling pressure if available are especially important in these patients. If distention occurs, the insertion of a left ventricular vent or the immediate application of an aortic crossclamp should relieve the problem.

TEE in Aortic Insufficiency

Annular dilatation or abnormal leaflet motion are the mechanisms that result in aortic insufficiency. Annular dilatation can occur with ascending aortic aneurysms, aortic dissections, and eccentric hypertrophy of the left ventricle. Because the aortic cusp area is 40% greater than the cross-sectional area of a normal aortic root, small increases in the diameter of the aortic annulus can be accommodated before the valve becomes incompetent. Abnormal leaflet motion and coaptation can be noted with calcific degeneration, rheumatic disease, and bicuspid aortic valves. Postinflammatory disease of the aorta is the most common cause of isolated aortic regurgitation. Other two-dimensional echocardiographic findings associated with aortic regurgitation include fluttering and reverse doming of the anterior mitral leaflet, premature closure of the mitral valve, aortic vegetations, leaflet perforations, and eccentric hypertrophy of the left ventricle.

Application of color flow Doppler will identify the aortic regurgitant jet, localize the site of regurgitation, and help grade the severity of the aortic insufficiency.¹²⁵ Unlike mitral regurgitation, neither the length nor area of the regurgitant jet correlates with the angiographic grade of aortic insufficiency.¹²⁶ Rather, the severity of aortic insufficiency is most reliably graded by comparing the diameter of the regurgitant jet at the level of the aortic valve with the diameter of the LVOT.¹²⁷ As in mitral regurgitation, it is important to recall that the size and shape of the color flow jet are dependant on the Nyquist limit. Continuous-wave Doppler across an aortic regurgitant jet will typically demonstrate a pandiastolic flow signal. The peak velocity in early diastole corresponds to the peak aortic to left ventricular diastolic pressure gradient as defined by the modified Bernoulli equation. The slope of the decay in this pressure gradient reflects the severity of aortic insufficiency. With severe aortic insufficiency, there is a rapid equilibration of pressure between the aorta and the left ventricle. This results in a steep slope of decay and a short pressure half-time (PHT). If the aortic insufficiency is mild, there is a slow equilibration of the pressure between the aorta and the left ventricle that results in a relatively flat slope of decay and a long PHT. Interpretation of the slope of decay as an index of regurgitation is complicated by factors that increase the equilibration of the pressure gradient between the aorta and left ventricle. These factors include the compliance of the left ventricle and the filling from the mitral valve. The severity of aortic insufficiency (AI) can be graded by employing these echocardiographic modalities and the criteria outlined in Table 32-13.

| | Mild | Moderate | Severe |
|--------------------------|------|----------|--------|
| Jet width at origin (mm) | <2 | 3-5 | >5 |
| Jet width/LVOT width | <30% | 30-60% | >60% |
| Jet length (cm) | <2 | 3-5 | >5 |

LVOT = left ventricle outflow tract.

Table 32-13. GRADING FOR AORTIC INSUFFICIENCY

The presence of moderate to severe AI affects the surgeon's approach to cardiopulmonary bypass. An incompetent aortic valve may prevent the delivery of cardioplegia to the coronary system to produce the diastolic arrest of the heart. After application of the aortic crossclamp, the cardioplegia is normally injected into the aortic root, delivering this solution to the coronary system, producing a diastolic arrest of the heart. If moderate to severe aortic insufficiency is present, the cardioplegia will fill and distend the left ventricle, increasing the ischemic insult incurred during cardiopulmonary bypass. As a result, in the presence of aortic insufficiency the surgeon may elect to arrest the heart by injecting cardioplegia directly into the coronary ostia or into the coronary sinus.

Accurate evaluation of aortic insufficiency is essential in determining the feasibility of performing an aortic repair. Successful aortic valve repairs are routinely performed with aortic dissections, and have been reported with aneurysms and bicuspid aortic valves.^{128,129,130} and ¹³¹ About 70% of type A dissections lend themselves to repair with an 80–90% freedom from valve replacement 10 years out from the surgery. Repairing aortic valves in patients with bicuspid valves or aortic aneurysms secondary

to tissue disorders is controversial.

Mitral Stenosis

Stenosis of the mitral valve is usually of rheumatic origin, with clinical disease becoming manifest within 3–5 years following initial infection. Debilitating symptoms such as fatigue and dyspnea on exertion do not begin for another decade or two.

Pathophysiology

The spectrum of physiologic disruption in patients with mitral stenosis is presented in [Figure 32-20](#). This complicated pathophysiologic profile may be simplified by grouping the changes as either proximal or distal to the obstructing mitral valve.

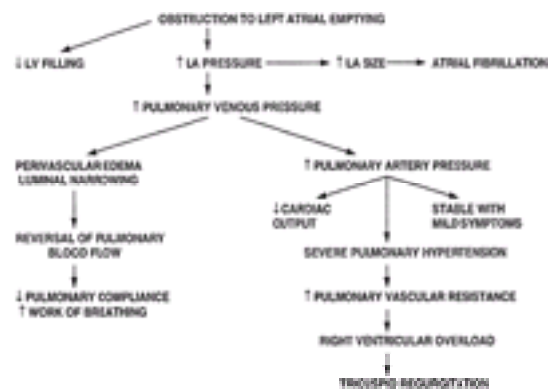

Figure 32-20. The cardiovascular and pulmonary effects of mitral stenosis.

In mitral stenosis, unlike other valvular lesions, the left ventricle is not subject to either pressure or volume overload. It is often relatively underloaded owing to the obstruction preventing left ventricular filling. The left ventricle may be small, but ventricular function is usually maintained, although one third of patients may demonstrate contractile abnormalities on angiography, presumably as a result of rheumatic carditis or involvement of the subvalvular apparatus.¹³² The diminished ventricular volume precludes effective use of vasodilators to improve left ventricular flow.

Increased left atrial pressure (LAP) and volume overload are inevitable consequences of the narrowed mitral orifice. The relationship between left atrial pressure and the size of the valve orifice is expressed in the formula derived by Gorlin and Gorlin:

$$\text{Valve area} = \text{flow} / K \cdot \sqrt{(\text{pressure gradient})}$$

where flow = (cardiac output)/(diastolic filling time); pressure gradient = (left atrial pressure) – (left ventricular end-diastolic pressure), or LAP – LVEDP; and *K* is the hydraulic pressure constant. This calculation assumes no regurgitant flow. If we assume a constant valve area, rearrange terms, and eliminate the constant, we have a more useful expression of the clinical variables determining atrial and ventricular pressures:

$$\text{LAP} - \text{LVEDP} = [(\text{cardiac output}) / (\text{diastolic time})]^2$$

Therefore, whenever cardiac output increases or the diastolic filling period decreases, the gradient across the mitral valve is altered by the square of the original changes. This explains why tachycardia or increases in forward flow, seen classically with pregnancy, thyrotoxicosis, or infection, can precipitate pulmonary edema. As LAP increases, left ventricular filling pressure may actually decrease. Thus, the development of atrial fibrillation causes hemodynamic embarrassment, not so much because of the loss of atrial kick but because of the rapid rate that ensues. We are left with the paradoxical situation of a patient in pulmonary edema with a relatively empty left ventricle. The treatment in this situation is therefore not inotropic or vasodilator therapy, but rather attempts to reduce the heart rate or diagnose and treat the cause responsible for the increased flow. The pulmonary capillary wedge pressure can be used as an index of left ventricular filling, keeping in mind that it is higher than the true left ventricular end-diastolic pressure, at least by the amount of the pressure gradient. During episodes of tachycardia or increased flow, the wedge pressure continues to reflect left atrial pressure; however, this is no longer indicative of left ventricular filling pressure.

Persistent elevations in LAP are reflected back through the pulmonary circulation, leading to right ventricular pressure overload with compensatory right ventricular hypertrophy and strain. The progression and severity of pulmonary hypertension are variable and reflect further narrowing of the valve orifice and irreversible reactive changes in the pulmonary vasculature. Right ventricular dysfunction may develop in response to the afterload stress. Tricuspid annular dilatation and insufficiency may climax this hemodynamic nightmare.

Chronically elevated left atrial pressure causes perivascular edema in the lung, increased vascular pressure in the dependent portions of the lung, redistribution of blood to the upper lung fields, and a somewhat increased work of breathing.

Anesthetic Considerations

Preventing trouble is the cornerstone of prebypass anesthetic management ([Table 32-14](#)) because treatment of hemodynamic derangements is sometimes difficult. Avoiding tachycardia precludes episodes of left atrial and pulmonary hypertension with potential right ventricular dysfunction as well as inadequate left ventricular filling with concomitant systemic hypotension. Preoperative maintenance of digitalis and b-blocking drugs, selection of anesthetics with no propensity to increase heart rate, and attainment of anesthetic levels deep enough to suppress autonomic responses are methods to achieve these goals. Episodes of pulmonary hypertension and potential right-sided heart failure stemming from pulmonary vasoconstriction must also be prevented. Hypoxia, hypercarbia, and acidosis are the classic offenders. It is wise, then, to follow the ancient internist's classic nostrum: Avoid them.

| | |
|-----------------|---|
| P | Enough to maintain flow across stenosis |
| A | Avoid ↑ right ventricular afterload (pulmonary vasoconstrictors) ↑ inotropes for systemic hypotension |
| C | LV usually OK until after CPB; right ventricle may be impaired if there is long-standing pulmonary hypertension |
| R | Slow to allow time for ventricular filling |
| Rhy | Often atrial fibrillation; control ventricular response |
| MV ₂ | Not a problem |
| CPB | Vasodilators may help post-CPB right ventricular failure; control of ventricular response may be difficult |

Abbreviations are defined in [Table 32-2](#).

Table 32-14. MITRAL STENOSIS—HEMODYNAMIC GOALS

Treatment of hypotension in patients with mitral stenosis can present a challenging dilemma. Although these patients normally take diuretics, hypovolemia is not usually the cause; hence the response to volume administration is often disappointing. Use of a vasoconstrictor to offset mild peripheral vasodilation is acceptable, bearing in mind the risk of pulmonary vasoconstriction and possible accentuation of right ventricular dysfunction. It is often prudent to select a drug with some inotropic effect such as ephedrine or epinephrine instead of relying on a pure vasoconstrictor. In separating from cardiopulmonary bypass, much is made of right ventricular failure (discussed subsequently); more commonly, however, it is the left ventricle that is dysfunctional. This may be because intraoperative injury or sudden increase in

flow to and distention of the chronically underloaded left ventricle. After bypass, prominent V waves may be present in the left atrial pressure curve. This almost always reflects increased left atrial filling from the right side rather than mitral regurgitation because cardiac output is increased after bypass when compared with preinduction values.

TEE in Mitral Stenosis

The mitral valve area in a normal adult ranges from 4 to 6 cm². It is composed of the funnel-shaped atrioventricular membrane, which is divided into two leaflets (anterior, posterior), and the suspensory tensor structures. The anterior mitral leaflet is triangular, covering about 60% of the valve orifice. It occupies about 40% of the annular circumference and is contiguous with the noncoronary and left coronary cusps of the aortic valve. The broad, crescent-shaped posterior leaflet comprises three scallops. Although equal in surface area, the posterior leaflet occupies about 60% of the annulus and, as a result, is shorter and less mobile (Fig. 32-21). The leaflets are tethered like parachutes by the subvalvular tensor apparatus, which consists of chordae tendineae and their muscular insertions into the anterolateral and posteromedial papillary muscles. Both leaflets receive chordae from each papillary muscle. These fibrous tendons, along with the coordinated contraction of the supporting muscles, prevent the leaflets from prolapsing into the left atrium when high pressures are exerted on the leaflets during left ventricular systole. Doppler interrogation across a normal mitral valve reveals a biphasic filling pattern composed of two waves. Early passive filling of the ventricle during diastole is represented by the E wave while the atrial contribution to ventricular filling generates the A wave (Fig. 32-22). Normal blood flow velocities measured at the tips of the mitral valve leaflets are between 0.50 and 0.80 m · sec⁻¹.¹¹⁴

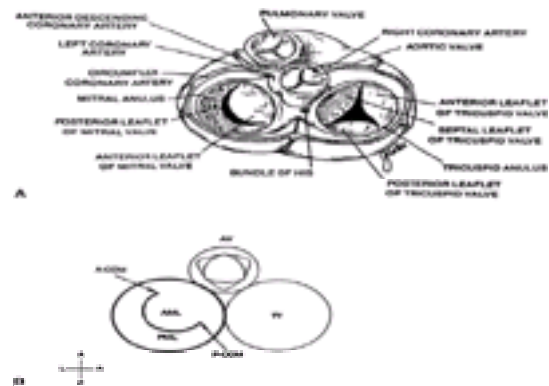

Figure 32-21. (A) Diagram illustrating the anatomic position of the mitral valve within the heart as viewed in cross-section looking inferiorly toward the cardiac apex. (B) Note that the anterior mitral leaflet originates from only 40% of the annular circumference but accounts for 60% of the orifice. (Reproduced with permission from Oka Y, Goldiner PL: Transesophageal Echocardiography. Philadelphia, JB Lippincott, 1992.)

Figure 32-22. Normal Doppler flow velocity profile across the mitral valve. Early passive filling of the ventricle during diastole is represented by the E wave while the atrial contribution to ventricular filling generates the A wave. Normal blood flow velocities measured at the tips of the mitral valve leaflets range between 0.50 and 0.80 m · sec⁻¹.

Mitral stenosis results from insufficient opening of the valve leaflets during diastole. The valve leaflets become fibrous and thick while the chordae are shortened. The diastolic excursion of the leaflets is limited, resulting in a characteristic doming or hockey stick deformity of the anterior mitral leaflet that is best seen in the midesophageal four-chamber or long axis view. Calcium deposits begin in the valve commissures and extend to the leaflet bodies, the valve annulus, and the subvalvular apparatus. The extent of calcification is variable and inversely related to the size of the stenotic orifice. Planimetry of the cross-sectional area of the narrowest opening in a two-dimensional short axis view of the mitral valve can be used to directly measure the orifice area. Although reproducible and accurate for transthoracic echocardiography, it has not yet been validated for TEE. Associated two-dimensional findings with mitral stenosis may include an enlarged left atrium (>4 cm) with bowing of the interatrial septum toward the right atrium, occurrence of spontaneous echocontrast, and the presence of atrial thrombi. Spontaneous echo contrast is the result of blood cell aggregation and occurs in areas of low flow. It is seen in more than 50% of patients with mitral stenosis and is associated with an increased risk of thromboembolism.⁹⁷

Doppler interrogation across the stenotic mitral valve permits determination of the pressure gradient and the mitral valve area (MVA). Color flow Doppler across a stenotic mitral valve reveals laminar flow acceleration into the stenotic orifice and a turbulent jet emerging into the ventricle. Bernoulli's equation explains the relationship between a pressure drop across a stenotic valve and the corresponding velocity of flow. Simplification of his formula assumes negligible contributions from blood viscosity, viscous friction, and flow acceleration. With these assumptions, a peak instantaneous transvalvular pressure gradient can be estimated. The peak blood flow velocity is measured and applied to the following equation:

$$P = 4V^2$$

where P is pressure, and V is velocity.

The mean pressure gradient can be determined by tracing and integrating the diastolic spectral blood flow velocity profile. The pressure half-time (PHT) method is utilized to calculate the MVA. The PHT is generated from the rate of decline of the E wave of the diastolic spectral blood flow profile. This permits calculation of the MVA by the following equation:

$$\text{MVA}(\text{cm}^2) = 220/\text{PHT}$$

where PHT is the time interval (milliseconds) between the maximum early diastolic transmitral pressure gradient and the time point where the pressure gradient is one half the maximum value. This number is calculated by the computer when the slope of the E wave is entered (Fig. 32-23). When analyzing the transvalvular blood flow velocity profile, one must recall that it is a function not only of the size of the mitral valve orifice, but also of the amount of flow through the orifice, the chamber compliance, and the presence of aortic regurgitation.¹³⁴ These are variables that affect the transvalvular pressure gradient. Aortic regurgitation results in a rapid equalization of pressure between the left atrium and the left ventricle. This generates a rapid PHT which overestimates the MVA by the PHT equation. The severity of mitral stenosis can be estimated by employing these echocardiographic modalities and the criteria outlined in Table 32-15.

Figure 32-23. The MVA is calculated by the pressure half-time method. Note the decreased slope of the deceleration of the E wave as a result of the prolonged presence of a pressure gradient between the left atrium and left ventricle secondary to the stenotic mitral valve.

| | Normal | Mild | Moderate | Severe |
|------------------------|---------|---------|----------|--------|
| MVA (cm ²) | 4.0-6.0 | 1.5-2.0 | 1.0-1.5 | >1.0 |
| PHT (ms) | <100 | 100-150 | 150-200 | >220 |
| Mean gradient | <2 | 2-6 | 6-12 | >12 |

MVA = mitral valve area; PHT = pressure half-time.

Table 32-15. GRADING FOR MITRAL STENOSIS

Mitral Regurgitation

Mitral valve prolapse, chronic ischemic heart disease, rheumatic heart disease, endocarditis, and annular dilation are causes of mitral regurgitation. Acute mitral regurgitation occurs with papillary muscle dysfunction or chordal rupture following myocardial infarction and may require emergency surgical repair.

Pathophysiology

Chronic volume overload similar to that described with aortic insufficiency is the cardinal feature of mitral regurgitation. The left atrium acts as a low-pressure vent for left ventricular ejection. Total stroke volume consists of the forward flow via the aorta and backward flow into the left atrium. There is no period of isovolumetric contraction because blood is immediately ejected retrograde with the onset of ventricular systole. Despite decreased contractility, patients may be minimally symptomatic despite progressive myocardial damage because of this reduced afterload. The additional oxygen cost is low, needed only for additional muscle shortening because there is little pressure development. Ventricular compliance increases; thus, the large end-diastolic volume does not cause striking increases in left ventricular end-diastolic pressure. Atrial and ventricular chamber enlargement, ventricular wall hypertrophy, and increased blood volume are the compensatory responses. The volume of regurgitant flow is related to the size of the regurgitant orifice, the time available for retrograde flow, and the pressure gradient across the valve. Regurgitant orifice size, in turn, is dependent upon ventricular size. Therefore, both increases in heart rate and preload reduction decrease the amount of regurgitant flow by diminishing ventricular volume. Arteriolar dilators, in contrast, are effective by reducing the ventriculoatrial pressure gradient.

Other similarities of mitral regurgitation to aortic insufficiency include increases in ventricular chamber compliance and difficulty in evaluating left ventricular contractile function. The latter is particularly troublesome because in mitral regurgitation the left ventricle is maximally unloaded. The incompetent valve acts as a low-pressure vent for left ventricular ejection. There is no period of isovolumic contraction because blood is immediately ejected retrograde with the onset of ventricular systole. This explains why many patients have minimal symptoms despite progressive myocardial damage. This reduced afterload also explains why ejection fraction, a measure heavily afterload-dependent, can be misleading in patients with mitral regurgitation. Normal or minimally reduced ejection fractions can be present even with severe impairment of contractile function.¹¹⁰ Repairing or replacing the valve increases afterload, and often the dysfunctional myocardium becomes apparent. Administration of inotropes and/or vasodilators may be necessary to successfully separate from bypass.

When mitral regurgitation is of acute onset, the hemodynamic picture is different. Volume overload of the left atrium and ventricle occurs in the absence of compensatory ventricular enlargement. Ventricular filling pressures increase dramatically, as do pulmonary pressures. Cardiac output decreases, and pulmonary edema develops. If this occurs in the setting of acute myocardial infarction, cardiac performance may be inadequate despite pharmacologic support. Intra-aortic balloon assistance as well as emergency surgery may be lifesaving.

Anesthetic Considerations

Selection of anesthetics that promote vasodilation and tachycardia is ideal in the patient with mitral regurgitation (Table 32-16). Active pharmacologic intervention is usually unnecessary because most patients are not teetering on the brink of myocardial failure. However, in some patients, especially those with acute myocardial regurgitation, aggressive pharmacologic management may be required. In the absence of acute deterioration, difficulties in management are usually limited to the postbypass period.

| | |
|-----------------|--|
| P | Usually pretty full; may need to keep that way, although preload reduction may reduce regurgitant flow |
| A | Decreases are beneficial; increases augment regurgitant flow |
| C | Unrecognized myocardial depression possible; titrate myocardial depressants carefully |
| R | A faster rate decreases ventricular volume |
| Rhy | Atrial fibrillation is occasionally a problem |
| MV _o | Only if mitral regurgitation is a complication of coronary artery disease, then be careful |
| CPB | Newly competent valve post-CPB increases afterload; vasodilators may be helpful; inotropes are frequently required |

Abbreviations are defined in Table 32-2.

Table 32-16. MITRAL REGURGITATION—HEMODYNAMIC GOALS

The problem of unmasking depressed myocardial contractility has already been discussed. Paradoxically, after the administration of vasodilators and inotropes, a patient occasionally deteriorates even further. As mentioned earlier, in these patients, the physiologic and clinical picture is exactly that of hypertrophic cardiomyopathy. It is seen after valve repair, not replacement. Systolic anterior motion of the anterior mitral leaflet is demonstrable by echocardiography. If this scenario is suspected, a trial of volume expansion and vasoconstrictors is indicated.

TEE in Mitral Regurgitation

The presence and severity of mitral regurgitation are major determinants of outcome in cardiac surgical patients. If the mitral regurgitation is severe enough to require surgical intervention, a decision must be made regarding the feasibility of performing a mitral valve repair as opposed to replacement. The etiology of the regurgitation and accurate localization of the site of mitral regurgitation are two important factors in this decision. In the suitable patient population, a repair has become the treatment of choice. It avoids the morbidity associated with valvular prostheses and long-term anticoagulation while providing significantly lower hospital mortality, late valve-related events, and better long-term survival.^{135,134,135,136,137,138} and ¹³⁹ Mitral disease localized to the posterior leaflet or to a focal portion of the anterior leaflet is most amenable to repair. Conversely, mitral repair is more difficult when there is heavy calcification of the annulus or extensive disease of the anterior leaflet of the mitral valve. This has resulted in the desire for increasingly sophisticated TEE evaluation of mitral regurgitation.

Mitral regurgitation results from incomplete coaptation of the mitral leaflets, permitting blood to flow from the left ventricle to the left atrium during systole. Mechanical etiologies of mitral regurgitation include (1) annular dilatation, (2) leaflet prolapse, (3) restricted leaflet motion, (4) and leaflet perforation.

1. **Annular dilatation:** The mitral annulus is contiguous with the fibrous skeleton of the heart anteriorly, while the posterior portion of the annulus is composed of the atrioventricular membrane of the free wall of the heart. It is the posterior portion of the mitral valve annulus that is susceptible to the dilatation that can occur with myocardial infarctions and myopathies. In this setting leaflet appearance and motion are frequently normal. Since normal mitral valve coaptation occurs on the left atrial surface of the leaflets, small increases in the diameter of the mitral annulus are possible before the mitral valve becomes incompetent.
2. **Leaflet prolapse:** Redundant leaflet tissue and chordae may be present when there are connective tissue disorders or myxoid degeneration of the mitral valve. This results in excessive leaflet motion with coaptation occurring in the left atrium beyond the plane of the mitral valve annulus. Occasionally, there is complete rupture of the chorda or papillary muscle that anchor the mitral valve leaflets. This can produce extreme leaflet mobility known as a "flail leaflet" where the tip of the flail leaflet is freely mobile in the left atrium (Fig. 32-24).

Figure 32-24. Mitral regurgitation due to "flail" posterior leaflet of the mitral valve.

3. **Restricted leaflet motion:** Tethering of the leaflets, calcification of the chordae, and scarring of the papillary muscles can restrict leaflet mobility, resulting in an incompetent mitral valve owing to a failure of the leaflets to adjoin.
4. **Leaflet perforation:** Leaflet perforation can occur with endocarditis.

A systematic approach is necessary for accurate localization of the site of mitral regurgitation.^{135,136} Maintaining spatial orientation is crucial. The mitral valve lies posterior, inferior, and lateral to the aortic valve. The posterior leaflet forms the lateral edge of the mitral valve and contains three scallops labeled P1, P2, and P3, with P1 located anterior and lateral while P3 is inferior and medial. The anterior leaflet is the medial portion of the valve; although not clearly scalloped, it is likewise subdivided into sections A1, A2, and A3, with A1 anterior and A3 posterior (Fig. 32-25). In the four-chamber view at a rotational angle of 0°, the image plane transects the mitral valve across the middle scallops (A2, P2). If the probe is withdrawn and/or flexed, the most anterior portion of the mitral valve will be imaged (A1, P1). However, if the TEE is advanced and/or retroflexed from the four-chamber view, the posterior medial portion of the mitral valve will be transected (A3, P3) (Fig. 32-26). If the image plane is rotated 45–90° from the four-chamber view, it will align with the major axis of the mitral valve. Clockwise rotation (toward the patient's right) will place the image plane across the anterior leaflet, and counterclockwise rotation will allow complete transection of the posterior leaflet by the image plane. These views can be used to confirm the location of valve pathology delineated at a rotational angle of 0°. Agreement of the location of mitral regurgitation with TEE and direct surgical observation is excellent.^{135,136} Other two-dimensional echocardiographic findings associated with mitral regurgitation include an enlarged left atrium (>4 cm) and eccentric hypertrophy of the left ventricle. The left atrium will be akinetic if atrial fibrillation is present; however, when mitral regurgitation is severe, spontaneous contrast and atrial thrombi are not likely to be present owing to a lack of blood stasis.

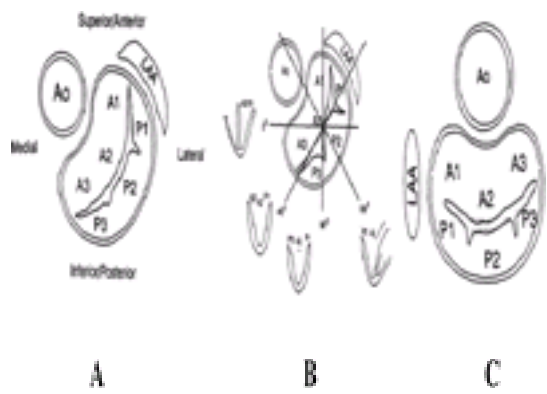

Figure 32-25. (A) View from the left ventricular apex demonstrating the anatomic relationship of the mitral valve to the aorta (Ao) the left atrial appendage (LAA). (B) Reference view demonstrating the relationship of the transesophageal echocardiographic imaging planes (0, 45, 90, and 135 degrees) to the mitral valve with the probe positioned in the standard midesophageal position. (C) Surgical view of the mitral valve as seen from left atrium. A1, A2, A3 = anterior leaflets sections; P1, P2, P3, = posterior leaflet sections. Figure 32-26. (A) Effect of flexion and retroflexion (*top left*) or advancement of the TEE probe tip with no flexion (*bottom left*) on the imaging plane in relation to the mitral valve. The transducer rotational angle is 0°. (B) Effect of clockwise and counterclockwise probe rotation on the imaging plane in relation to the mitral valve. The transducer rotational angle is adjusted to the major axis of the mitral orifice (typically 45–90°). Ao = aorta; A1, A2, A3 = anterior leaflet sections; P1, P2, P3 = posterior leaflet sections. (Reproduced with permission from Foster GP, Isselbacher EM, Rose GA *et al*: Accurate localization of mitral regurgitant defects using multiplane transesophageal echocardiography. *Ann Thorac Surg* 65:1025, 1998.)

Application of color flow Doppler will identify the mitral regurgitant jet and can be used to help localize the site of regurgitation¹⁴⁰ (Fig. 32-27). It is important to recall that the size and shape of the color flow jet are dependent on the Nyquist limit. The Nyquist limit is a color visualization of blood flow velocity which is determined by a number of machine variables including sector scan width, depth of the sector, and density of the scan lines. If the Nyquist limit is low ($<40 \text{ cm} \cdot \text{s}^{-1}$), color Doppler can overestimate the extent of regurgitation. The type of regurgitant jet also affects the extent of the color flow area depicted. Eccentric jets, common with isolated individual leaflet abnormalities, frequently impinge on the atrial wall and produce smaller color Doppler areas than central jets of similar regurgitant volumes.^{108,109 and 110}

Figure 32-27. The application of color flow Doppler to a regurgitant mitral valve. Note the mosaic pattern in the left atrium during systole.

The effect of mitral regurgitation on left atrial pressure and the pulmonary circulation is evaluated by analysis of the pulse wave Doppler pattern in the pulmonary veins. Mitral regurgitation increases the left atrial pressure during systole. As mitral regurgitation increases in severity, the pressure gradient from the pulmonary vein to the left atrium decreases. This results in attenuation of the systolic component of the pulmonary vein flow pattern. If severe mitral regurgitation is present, the left atrial pressure may exceed the pulmonary vein pressure during systole, resulting in reversal of the S wave. This is illustrated in Figure 32-28. Although systolic reversal of pulmonary vein blood flow is a marker of severe mitral regurgitation, eccentric jets of moderate grade may produce isolated systolic reversal in a pulmonary vein blood flow.⁹⁷

Figure 32-28. The change in the left upper pulmonary vein Doppler flow velocity profile as the left atrial pressure increases. (A) Normal profile; note that a normal pulmonary vein flow pattern should have the peak of the S-phase (systolic) wave at least equal to the peak of the D-phase (diastolic) waveform. (B) Blunted systolic filling; note the pronounced blunting of the peak of the S-phase waveform relative to the D-phase waveform. (C) Systolic reversal; note the inversion of the S-phase waveform. (Reproduced with permission from Rafferty TD: Basics of Transesophageal Echocardiography. New York, Churchill Livingstone, 1995.)

The pulmonary vein flow pattern is one measure that has been used to grade mitral regurgitation. Other commonly used criteria to grade mitral regurgitation are outlined in Table 32-17. When grading mitral regurgitation, a thorough examination with multiple techniques is essential. The severity of mitral regurgitation is very dependent on afterload. If moderate mitral regurgitation is present, the afterload should be increased and the severity reassessed.

| | Mild | Moderate | Severe |
|--------------------------|-----------------|-----------------|---------------------------|
| Jet width at origin (mm) | <2 | 3-5 | >5 |
| Jet area/LA area | <30% | 30-60% | >60% |
| Jet length/LA length | 2-6 | 6-12 | >12 |
| Pulmonary vein doppler | Blunting S wave | S wave < D wave | Systolic reversal of flow |

LA = left atrium.

Table 32-17. GRADING FOR MITRAL REGURGITATION

CARDIOPULMONARY BYPASS

Circuits

Although there are multiple configurations used for cardiopulmonary bypass, they all incorporate essential components, including large catheters for venous drainage, an oxygenator/heat exchanger, and a pump and tubing and cannula for arterial return (Fig. 32-29). In many institutions, additional components are added to this elementary circuit. These include a filter on the arterial return cannula and often on the suction catheters, alarms to detect low levels of blood in the oxygenator to prevent pumping of air, in-line pressure and/or blood gas monitors, and a separate circuit for infusion of crystalloid or blood cardioplegia. Vaporizers can be positioned in the gas inflow circuit so that volatile anesthetics can be administered during the bypass period.

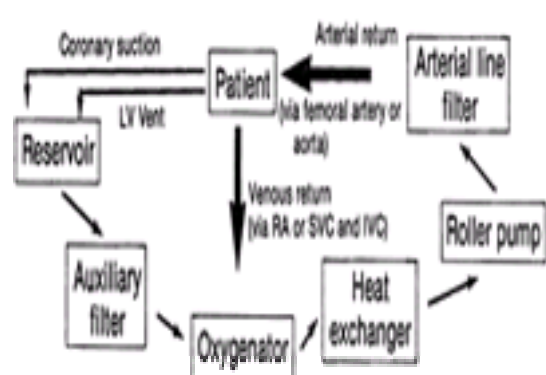

Figure 32-29. The basic circuit for cardiopulmonary bypass. (Reprinted with permission from Thomson IR: Technical aspects of cardiopulmonary bypass. In Thomas SJ [ed]: Manual of Cardiac Anesthesia, 2nd ed, p 480. New York, Churchill Livingstone, 1993.)

Blood is drained into a reservoir from either a large single two-stage cannula (drains the right atrium and the inferior vena cava) inserted into the right atrium or from two separate smaller cannulas placed in the superior and inferior vena cavae. The rate of venous return is dependent upon intravascular volume, the height of the patient above the reservoir, and proper placement of the cannulas. Flow can be reduced by partially or completely clamping these lines either by the surgeon or the perfusionist. Additional blood is carried to the venous reservoir from the operative field with suction generated by two small roller pumps. The first is the coronary suction that scavenges blood from the operative field, and the other is the vent suction used either to decompress the left ventricle or as an additional "coronary sucker." When used to decompress the left ventricle, this suction line is connected to a catheter inserted across the mitral valve *via* the left superior pulmonary vein, to a metal or plastic tube inserted directly into the apex of the left ventricle, or to the aortic cardioplegic cannula. Many surgeons choose not to routinely vent the left ventricle during coronary artery bypass operations.

Most commonly, oxygenated blood is returned to the patient through a cannula placed in the ascending aorta. If this proves technically difficult, if emergency cannulation is necessary, or if partial bypass is used during surgery on the descending thoracic aorta, the femoral artery is usually selected. The axillary artery is also an acceptable site for arterial inflow.

Oxygenators

Bubble

Bubble oxygenators utilize direct contact between fresh gas and blood to affect transfer of oxygen (O₂) and carbon dioxide (CO₂). It is far more difficult to transfer O₂ than CO₂ because the solubility ratio is 1:25. Foaming is an extremely efficient method of oxygenation and, in combination with high oxygen tensions, alleviates this problem. Gas is passed through a ceramic manifold to create bubbles small enough to provide sufficient total surface area for gas exchange but not so small as to preclude easy removal. The smaller the bubbles, the greater the surface-to-volume ratio and the greater the oxygen transfer. In bubble oxygenators, CO₂ transfer is proportional to total gas flow, whereas oxygen transport is chiefly dependent upon bubble size. Gas flows do affect oxygen transport, and, at higher flows, CO₂ is sometimes added to the gas mixture to prevent unacceptable levels of hypocarbia. Critical to the function of the bubble oxygenator is the ability to reconstitute the perfusate ("defoaming") by passage through spongy polypropylene mesh impregnated with a charged silicon-containing polymer.

Bubble oxygenators are associated with time-dependent trauma to blood because of the direct blood-gas interface. Hemolysis develops with potential capillary plugging and organ damage from red blood cell debris. Platelet activity is impaired secondary to platelet destruction, induction of aggregation, and adherence to parts of the oxygenator. Decreases in leukocyte counts have also been reported. Additional problems associated with bubble oxygenators include activation of complement *via* the alternate pathway, formation of particulate and gaseous microemboli, and denaturation of blood proteins (including those of the coagulation cascade).¹⁴⁴

Membrane

To eliminate or attenuate the problems associated with the blood-gas interface, the membrane oxygenator separates the two phases by a thin, gas-permeable membrane of silicon, Teflon, or polypropylene. Blood flows in a thin film along the membrane while gas slowly diffuses across it. The oxygen tension is controlled by the FIO₂ of the inspired gas, and CO₂ is regulated by total gas flow.

Studies comparing membrane with bubble oxygenators demonstrate less blood trauma with membranes and, in some cases, improved postoperative hemostasis.¹⁴⁵ However, other investigators report that these differences are clinically insignificant as long as perfusion time is less than 2 hours. Differences in performance of the two types of oxygenators are also obscured by the amount of blood scavenged from the operative field because these cells are the most severely damaged from direct mechanical trauma as well as from the turbulent blood-gas interface.

Pumps

Roller

Two types of pumps are used to generate the pressure required to return the perfusate to the patient (or, in the case of a membrane, to drive blood through the oxygenator and then to the patient). The first is a roller pump. A roller pump consists of a central housing with two arms extending 180° in opposite directions with smooth-faced rollers on each end. Flow is generated by compression of a heavy walled section of Silastic tubing by the rollers. Contact between one arm of the roller and the tubing begins where contact between the second roller ends, thus preventing retrograde flow. Shearing forces that would disrupt cells are minimized by ensuring that contact between the roller and tubing is nonocclusive. The roller pump head is driven by an electric motor designed to maintain constant speed, and therefore flow, despite variations in arterial inflow line resistance or power line voltage. If the motor or its power supply fails, the pump can be hand-cranked to provide adequate flow rates and systemic pressures. In many centers, the roller pump has been replaced with the centrifugal pump as the primary pump driving blood to the patient. It is still universally used for cardiotomy and vent suction and for delivering cardioplegia.

Centrifugal

Centrifugal pumps are conical, hardened-plastic housings containing rapidly rotating cones that impart momentum to the blood. This mechanism is pressure-sensitive, and flow is determined by both inflow and outflow pressures as well as by pump head speed. An in-line electromagnetic flow meter is necessary to indicate forward flow because, in contrast to a roller pump, direct conversion from revolutions per minute (rpm) to flow rate is inaccurate. The maximal pressure generated with this pump is lower than that with a roller pump, and the likelihood of disconnects following inadvertent cannula obstruction is reduced.

Pulsatile Flow

Roller pumps generate a sine wave pattern of flow, which, after damping during transit through the inflow tubing and cannulas, results in a nonpulsatile arterial pressure wave. Selection of a different pump or insertion of additional components into a circuit allows the production of a pulsatile waveform. This is both theoretically attractive and intuitively more physiologic, but whether or not it is beneficial is controversial.¹⁴⁶ Pulsatile flow is thought to provide improved perfusion at the capillary level and is associated with lower systemic vascular resistance during bypass, improved oxygen extraction, and lower production of pyruvate and lactate. A decrease in the need for pharmacologic or mechanical support after bypass has also been reported, as well as improved mortality. Some investigators advocate converting to pulsatile perfusion, especially in patients with severe preoperative impairment of ventricular function. Until noncontroversial studies demonstrate beyond doubt the superiority of pulsatile flow, the convenience and simplicity of nonpulsatility continue to make it the overwhelming choice for almost all procedures requiring cardiopulmonary bypass, even though some suggest that pulsatile perfusion is beneficial in high-risk patients.¹⁴⁷

Heat Exchanger

A heat exchanger adjusts the temperature of the perfusate to provide moderate systemic hypothermia during the period of cardiac repair. Metabolic requirements are reduced approximately 8% per degree centigrade decrease in body temperature (about 50% of normal at 28°C). Deliberate hypothermia provides protection during periods of hypoperfusion and potential tissue ischemia. In addition, adequate tissue oxygenation is achieved at lower flow rates, reducing trauma to the blood. Lower systemic flow also decreases flow to the heart *via* noncoronary collaterals (vessels arising from pericardial reflections), diminishing the rewarming and the rate of washout of cardioplegic solution. Also, by cooling the tissues surrounding the heart, reducing the rate of cardiac rewarming, hypothermia acts as an adjunct to myocardial protection.

Prime

The prime for most adult perfusions contains a balanced salt solution because such a solution resembles plasma in terms of osmolality and electrolyte composition. Individual recipes add albumin or hetastarch (to increase oncotic pressure), mannitol (to promote diuresis), additional heparin, bicarbonate, calcium, and so on. Although albumin is commonly added to prime solutions to increase oncotic pressure, it has not been shown to provide any clinical benefit in terms of outcome. Blood

is infrequently used except in neonates, children, and adults with significant preoperative anemia in whom profound hemodilution might decrease oxygen-carrying capacity below acceptable levels. After mixing of the patient's blood volume with 1500–2500 ml (depending upon oxygenator and circuitry) of prime, acute normovolemic hemodilution to hematocrits of 20–30% is normal. This offsets the increase in viscosity associated with systemic hypothermia. Retrograde arterial prime allows for part of the asanguinous prime to be siphoned off in favor of autologous blood that is slowly bled back into the circuit. Not only can this reduce the incidence of red cell transfusion, it can also minimize the hemodynamic changes associated with the abrupt change in viscosity at the beginning of cardiopulmonary bypass.¹⁴⁸

Anticoagulation

Prior to cannulation, systemic anticoagulation is mandatory to prevent catastrophic thrombus formation triggered by contact between the blood and oxygenator. Heparin, a polyanionic mucopolysaccharide extracted from bovine lung or porcine intestinal mucosa, accelerates the velocity of the reaction between antithrombin III and the activated forms of Factors II, X, XI, XII, and XIII, effectively neutralizing these factors. A tertiary complex is formed between heparin, antithrombin III, and these serine proteases. The half-life of heparin's anticoagulant effect is approximately 90 minutes in a normothermic patient, the rate of decay decreasing with hypothermia.

Anticoagulant activity varies among samples of commercially prepared heparin, as does patient response to a given dose. Patients receiving heparin in the period immediately prior to surgery and those with reduced levels of antithrombin III are notably resistant to normal precardiopulmonary bypass doses. It seems prudent to assess the adequacy of heparinization prior to starting cardiopulmonary bypass because of the lack of correlation among heparin dosage, blood levels, and clinical effect, as well as to ensure that heparin has in fact been given and distributed. Controversy exists as to whether this is best done by measuring heparin levels or the effect of heparin on the coagulation process. The former utilizes a manual or automated protamine titration test or other assays for heparin level; the latter utilizes a thrombin time (not usually available) or an activated clotting time. Because heparin levels do not always correlate with effect, many centers choose the more functional test, especially since it is easier and less costly. The activated clotting time is the most commonly used test for the adequacy of anticoagulation. It is performed either manually or automatically and indicates the time required for thrombus formation, detected visually or magnetically, when blood is mixed with one of a variety of clotting accelerators. The exact activated clotting time value necessary before initiation of cardiopulmonary bypass to ensure absolute anticoagulation remains controversial. Many use 400 s, a value derived from a study in primates that found no fibrin monomer, an indicator of coagulation, as long as activated clotting time was above that level.¹⁴⁹

The interpatient relationship between heparin concentration and activated clotting time is not linear, nor is the sensitivity of the activated clotting time (*i.e.*, the change in activated clotting time per unit increase in heparin level). However, the association between the dose of heparin administered and activated clotting time in an individual patient before cardiopulmonary bypass is somewhat linear. There are advocates of such a dose–response curve to determine heparin and protamine requirements.¹⁵⁰ However, this is often too time-consuming; moreover, it overestimates protamine needs because hemodilution and hypothermia alter inpatient activated clotting time sensitivity.¹⁵¹ Heparin is usually given in an initial dose of 300–400 U · kg⁻¹; an activated clotting time is measured 5 minutes later, and additional heparin is given as required. The activated clotting time should be rechecked periodically, especially if the interval following initial administration is unduly protracted or if the rewarming period on cardiopulmonary bypass is prolonged. The rate of heparin decay increases during rewarming.

In patients allergic to heparin, alternative anticoagulants can be administered. They range from snake venom derivatives to platelet inhibitors.^{152,153} and ¹⁵⁴ Occasionally, patients exhibit resistance to the anticoagulating effects of heparin resulting from anti-thrombin III deficiency. FFP or antithrombin III concentrate can be administered to achieve the needed level of anticoagulation from heparin administration. Additionally, bypass circuits can be heparin-coated or bonded to minimize the amount of heparin required to accomplish CPB successfully.^{155,156} and ¹⁵⁷

Myocardial Protection

A wide variety of methods are used to maintain myocardial cell integrity and energy stores while the coronary circulation is interrupted. Although techniques utilizing cold cardioplegia are the most common, other techniques used include hypothermic fibrillation,¹⁵⁸ intermittent crossclamping interspersed with periods of reperfusion, and continuous warm blood cardioplegia. The two critical elements with respect to cold cardioplegia are hypothermia (10–15°C) and hyperkalemia to ensure diastolic electrical arrest. Individual formulas add a variety of other ingredients, including, but not limited to, glucose as an energy substrate, buffering agents, albumin or mannitol for osmotic activity, citrate to reduce the calcium concentration, and nitroglycerin to improve distribution of the cardioplegic mixture. This solution is mixed with either crystalloid or oxygenated blood and is infused into the aortic root after the crossclamp is applied. The cardioplegia may be injected via a separate circuit on the bypass machine or manually, using a pneumatic infusion device. Direct injection into the aortic root is not feasible in patients with aortic insufficiency. The aorta must be opened and the cardioplegia injected directly into the coronary ostia with small perfusion cannulas. Cardioplegia can also be injected retrograde *via* the coronary sinus. This is particularly helpful in patients with severe coronary ostial stenosis or multiple severe lesions preventing adequate distribution, but is often used routinely in both coronary and valve operations. An additional site of cardioplegic injection is directly down newly constructed bypass grafts. During the period of cardioplegic arrest, the anesthesiologist should monitor the electrocardiogram for return of electrical activity, the pulmonary artery pressure (if available) and/or the appearance of the heart for evidence of ventricular distention, and the operative field for return of contraction. The atria are often first to show return of contractile activity. Depending upon the duration of ischemia necessary, periodic reinjection may be necessary to maintain hypothermia and diastolic arrest and to wash out metabolic products. The variations of cardioplegic recipes and techniques are staggering. Several reviews discuss the physiologic and technologic details of cardioplegia; the interested reader is urged to consult them.^{159,160,161} and ¹⁶²

Blood Conservation in Cardiac Surgery

Postoperative bleeding contributes to the morbidity, mortality, and economic costs of cardiac surgery. Cardiopulmonary bypass itself results in platelet activation and coagulation defects. Given the inherent risks and costs associated with blood transfusions and the general public's fear of receiving blood, considerable attention is being paid to perioperative blood conservation techniques. Such techniques include intraoperative autologous hemodilution, administration of antifibrinolytics, red blood cell scavenging, and attention to surgical hemostasis. Intraoperative hemodilution, which involves the removal of one or more units of whole blood prebypass, is used in those patients who are stable with an adequate initial hematocrit. The autologous blood, which has thus been spared the damaging effects of the bypass circuit, is then reinfused postbypass for volume and red blood cell replacement. Red blood cells may also be salvaged from the field and bypass tubing, washed, and retransfused throughout the procedure.

Pharmacologic measures include antifibrinolytics (ε-aminocaproic acid, tranexamic acid, aprotinin, and desmopressin (DDAVP)).^{163,164,165} and ¹⁶⁶ Aprotinin, an antifibrinolytic and serine protease inhibitor with platelet protective effects, has been shown to significantly decrease blood loss in high-risk patients (*e.g.*, reoperation, known coagulopathy, Jehovah's Witness, sepsis) with a low incidence of adverse events. It inhibits trypsin, kallikrein, and activation of complement, thereby acting as an anti-inflammatory agent as well. Disadvantages of aprotinin include a risk of anaphylaxis on re-exposure (because it is an animal-derived protein, from bovine lung) and its high cost. However, the added direct cost of the drug may be offset by the cost savings owing to the reduction in transfusion requirement, operating room time, and the need for mediastinal re-exploration. ε-Amino caproic acid and tranexamic acid are other antifibrinolytics, which have also been shown to decrease blood loss in cardiac surgery patients. These agents should be administered both before and during bypass to afford optimal results, *i.e.*, to mitigate the effects of the systemic inflammatory response due to the initiation of cardiopulmonary bypass. DDAVP has been shown to benefit a subgroup of cardiac surgical patients who have abnormal platelet function.^{167,168} and ¹⁶⁹

PREOPERATIVE EVALUATION

The preoperative visit appropriately concentrates on the cardiovascular system but should also focus on the assessment of pulmonary, renal, hepatic, neurologic, endocrine, and hematologic functions. Equally important is a discussion with the patient of the projected events on the day of surgery, including transport to the operating room, preoperative routines (O₂ mask, vascular cannulation, anesthetic induction), and, finally, the awakening process in the recovery room or intensive care unit. The importance of communicating to the anesthesiologist any symptoms such as chest pain, shortness of breath, or the need for nitroglycerin during transport or the preinduction period should be stressed. The depth and detail of the explanation depend upon the patient's emotional state and desire to know.

Data from the history, physical examination, and laboratory investigations are used to delineate cardiovascular anatomy and functional state. Of critical importance is the assessment of severity of left and/or right ventricular failure. Pertinent findings suggestive of dysfunction are described in [Table 32-18](#). Increases in the severity or frequency of anginal attacks or the presence of ischemia-induced ventricular dysfunction suggest that there are large areas of myocardium at risk. A history of previous arrhythmias should be obtained, including the type, severity, associated symptoms, prior intervention, and successful treatment. Integration of this information leads to appropriate selection of monitoring devices and anesthetic techniques.

| |
|--|
| History |
| History of MI, intermittent or chronic CHF |
| Symptoms of CHF (fatigue, DCE, orthopnea, PND, ankle swelling) |
| Physical Examination |

| Ventriculography—low EF, multiple areas of hypokinesis, akinesis, or dyskinesis |

MI = myocardial infarction; CHF = congestive heart failure; DCE = dyspnea on exertion; PND = paroxysmal nocturnal dyspnea; LVEDP = left ventricular end-diastolic pressure; EF = ejection fraction; CI = cardiac index.

Table 32-18. PREOPERATIVE FINDINGS SUGGESTIVE OF VENTRICULAR DYSFUNCTION

Conditions commonly associated with heart disease such as hypertension, diabetes mellitus, and cigarette smoking must also be evaluated. The last is extremely important and may be useful in differentiating whether episodes of intraoperative pulmonary hypertension are caused primarily by pulmonary or cardiac factors. Higher systemic arterial pressures may be desirable throughout surgery in patients with a history or other evidence of carotid artery disease. Evidence for renal dysfunction must be sought because the most common cause of postoperative renal failure is pre-existing renal insufficiency. If renal reserve is reduced, intraoperative measures such as diuretics or dopamine may be used, although no data showing an improved outcome are available.

Current Drug Therapy

Almost without exception, cardiovascular drugs, including cardiac antidysrhythmics, beta or calcium channel blockers, and nitrates are continued until the time of surgery. Interactions between these drugs and anesthetics are rarely detrimental; rather, they are more often beneficial in maintaining hemodynamic control during periods of surgical stress.

The b-blocking drugs are similar in structure and differ in degree of cardioselectivity, mode of excretion, and duration of action. The calcium entry blockers have shorter elimination half-lives and somewhat different pharmacologic actions. Concern about intraoperative hypotension and increased requirement for vasopressor support seems unwarranted. In patients receiving calcium channel blockers without concomitant b blockade, increases in heart rate and contractility may occur during surgical stimulation. Indeed, it has been shown that such patients have more perioperative ischemic electrocardiographic changes than patients receiving b-blocking drugs alone or in combination with calcium channel-blocking drugs. Vasodilation following CPB has been observed in patients taking ACE inhibitors.

Digoxin is prescribed to suppress cardiac dysrhythmias, control the ventricular response to atrial fibrillation, and improve contractility in patients with congestive heart failure. The efficacy of this last indication is sometimes difficult to discern clinically, so that discontinuation of digoxin to avoid digitoxic dysrhythmias seems appropriate. However, in those patients in whom it is being used for rate or rhythm control, continuation until the time of surgery seems advisable. Signs or symptoms of digoxin excess, including ventricular ectopy, atrial tachydysrhythmias, and variable degrees of atrioventricular block, should be sought. The latter is typically manifested by slowing and regularization of the ventricular response to atrial fibrillation. This represents digoxin-induced atrioventricular blockade with a regular junctional escape rhythm. Noncardiac symptoms include gastrointestinal distress or visual disturbances. Toxicity is more common in patients concomitantly receiving drugs that increase digoxin levels (e.g., nifedipine, verapamil, amiodarone) or reduce potassium levels (e.g., diuretics). Most cardiac antidysrhythmics should also be continued to the time of surgery. Their pharmacology is well known (see [Chapter 12](#) and [Chapter 21](#)), and they usually present little problem with anesthetic management.

Physical Examination

As mentioned previously, the physical examination seeks to elicit signs of cardiac decompensation such as an S₃ gallop, rales, jugular venous distention, or pulsatile liver. Routes for vascular access should be assessed, and the status of peripheral arteries should be evaluated. As always, the airway should be carefully evaluated with respect to ease of mask ventilation and intubation of the trachea. Other pertinent points are described in [Table 32-19](#).

| |
|---|
| Vital Signs |
| Current values and range while hospitalized |
| Height, Weight |
| For calculation of drug dosages, group fitness, cardiac index |
| Airway |
| Anatomic features that could make mask ventilation or intubation difficult |
| Neck |
| Current jugular distention (JVD) |
| Carotid bruits (aortic/aortic valve disease) |
| Carotid bruits (subcarotid/arterial disease) |
| Heart |

CHF = congestive heart failure; LVEDP = left ventricular end-diastolic pressure; S₃ = third heart sound; P₂ = point of maximal intensity; COPD = chronic obstructive pulmonary disease.

Table 32-19. PREOPERATIVE PHYSICAL EXAMINATION

Premedication

Even the most thorough preoperative psychological preparation is often inadequate to assuage the anxieties and apprehensions of a patient facing cardiac surgery. Premedication will assist in providing a calm, anxiety-free, but arousable and hemodynamically stable patient who is prepared for surgery. Selection of drug and dosage is predicated on the patient's age, cardiovascular state, and level of anxiety. Heavy premedication is ideal for the fit person scheduled for coronary artery bypass grafting. Inadequate sedation may predispose to hypertension, tachycardia, or coronary vasospasm, all potential causes of myocardial ischemia. The frail, 50-kg cachectic patient with severe valvular dysfunction fares better with light premedication to avoid possible respiratory depression or loss of endogenous catecholamine support. Additional sedation can always be given in the operating room under direct observation by the anesthesiologist.

Premedication for cardiac surgery often combines the sedative and analgesic properties of an opioid (morphine, 0.1–0.2 mg · kg⁻¹) with the sedative and amnestic properties of scopolamine (0.006 mg · kg⁻¹) or a benzodiazepine (diazepam 0.05–0.1 mg · kg⁻¹, midazolam 0.03–0.05 mg · kg⁻¹, or lorazepam 0.04 mg · kg⁻¹). The possibility of oversedation, hypercarbia, or hypoxia following premedication is always of concern. However, Hensley *et al*¹⁷⁰ have shown that morphine and scopolamine, when administered in standard doses, do not produce hypoxia. Rather, if hypoxia does occur after this combination, it is secondary to the additional supplementation administered in the operating room.

The choice of premedication may also affect the hemodynamic response to anesthetics. Thomson *et al*¹⁷¹ administered a standard high-dose fentanyl anesthetic to patients premedicated with either morphine and scopolamine or lorazepam. In general, the patients receiving lorazepam were hemodynamically less responsive in that they had less hypertension, more hypotension, and a greater requirement for vasoactive drugs. This suggests that premedication may have a previously unappreciated but profound effect on intraoperative hemodynamics. Clonidine has also been used as a premedication with similar intraoperative effects. The difficulty with premedication currently is that the patients arrive in the operating room after just getting off the bus! Same-day admission does make the job more difficult.

Monitoring

We will emphasize only those aspects of monitoring particularly relevant to cardiac surgery. The subject is discussed extensively in [Chapter 25](#), and we have already reviewed techniques for identification of myocardial ischemia and for evaluation of valve function.

Pulse Oximeter

The need for multiple vascular cannulations and applications of numerous monitoring devices often prolongs the preinduction period. The pulse oximeter should be positioned prior to catheter insertion to detect clinically unsuspected episodes of hypoxemia, especially if additional iv sedation has been administered. Attention must be focused on the entire patient, even during the hunt for successful vascular access.

Electrocardiogram

Simultaneous observation of both a precordial lead V_5 and an inferior lead II or lead III for the presence and location of ischemia has been emphasized. Regional ischemia may be localized by appropriate lead monitoring. Lead II can be monitored to interpret arrhythmias and detect ischemia in the inferior wall of the left ventricle (leads II, III, AVF = right coronary artery). Lead V_5 is monitored to detect ischemia in the anterior wall of left ventricle (left anterior descending artery). Leads I and AVL can be monitored to detect ischemia in the lateral wall of the left ventricle (circumflex artery). If the standard leads prove inadequate for cardiac dysrhythmia detection and analysis, esophageal or epicardial leads may be used. Occasionally, intraoperative myocardial injury causes substantial reductions in QRS voltage. Monitoring an electrocardiogram via a surgically placed ventricular pacing wire provides adequate voltage to facilitate dysrhythmia analysis or to trigger an intra-aortic balloon pump, if this is necessary. A strip-chart recorder documents and facilitates detailed analysis of both ST segment alterations and complex dysrhythmias.

Temperature

Central temperature can be measured with esophageal, tympanic, or Foley catheter probes or with a thermistor from a pulmonary artery catheter. Obviously, this last method is not reliable during the period of aortic crossclamping when there is no flow through the heart. Rectal and toe probes record peripheral temperatures, which lag behind central measurements during both cooling and rewarming.

Arterial Blood Pressure

Systemic arterial pressure is always monitored invasively. The radial or femoral artery is usually cannulated, although the brachial and axillary arteries may also be used. The exact site is often a matter of personal or institutional preference. Criteria include convenience, selection of the fullest or most bounding pulse, and avoidance of the dominant hand. In addition, during dissection of the internal mammary artery, the ipsilateral radial or brachial artery pulse may be transiently occluded; therefore, an artery opposite a planned internal mammary artery is selected. Occasionally, the site of surgery dictates appropriate placement; for example, the right radial artery should be used for any procedure involving the descending thoracic aorta because the left subclavian artery may be included in the proximal aortic clamp. Following cardiopulmonary bypass, radial artery pressure is often misleading and may be as much as 30 mm Hg lower than central aortic pressure.¹⁷² The mechanism is thought to be peripheral vasodilation during rewarming. Whenever such a discrepancy is suspected, aortic pressure can be estimated by palpation by the surgeon, or if direct measurement is needed, a needle may be placed directly into the aorta. The gradient between aortic and radial pressure usually disappears within 45 minutes of separation from bypass.

Central Venous Pressure/Pulmonary Artery Catheter

Access to the central circulation is mandatory for infusion of cardioactive drugs. In addition, right atrial or central venous pressure accurately reflects right ventricular filling pressure and is of critical importance whenever right ventricular dysfunction is suspected. In patients with unimpaired left ventricular function, transduced right atrial pressure is often assumed to be a reliable guide of left-sided filling. This relationship is less predictable in the presence of severe left ventricular dyssynergy, pulmonary hypertension, or reduced left ventricular compliance. In these instances, insertion of a pulmonary artery catheter for measurement of pulmonary capillary wedge pressure provides a somewhat better index of left ventricular filling. In addition, determination of cardiac output and calculation of derived hemodynamic indices offer additional information to guide hemodynamic and anesthetic management.

Indications for pulmonary artery catheterization vary greatly among institutions. In some, these catheters are used routinely, whereas in others, they are limited to patients with specific disease states such as severe left ventricular dysfunction or pronounced pulmonary hypertension. Additional indications include combined procedures (valvular plus coronary) or those that require prolonged intraoperative time (cardiac reoperations or use of one or both internal mammary arteries). Insertion of a pacing pulmonary artery catheter can be helpful whenever exact control of rate and rhythm is desirable, for example, in patients with hypertrophic cardiomyopathy or those with significant bradycardia secondary to b blockade.

When pulmonary artery catheters are used, disagreement still exists as to whether they should be placed before or after the induction of anesthesia. In some patients, early insertion of the catheter and determination of baseline hemodynamic values can beneficially influence anesthetic selection and guide the induction sequence. However, the anxious and uncomfortable hypertensive patient is better served by a smooth induction of anesthesia followed by catheter placement. Incremental sedation followed by preinduction placement is a suitable alternative associated with minimal, if any, hemodynamic change.

It must be remembered that the catheter often migrates toward the periphery of the lung with cardiac manipulation before and during cardiopulmonary bypass. Therefore, it seems prudent to pull the catheter back a few centimeters prior to the initiation of bypass to prevent permanent wedging or possible pulmonary artery rupture. Despite the controversy concerning the routine use of these catheters, there is no disagreement that the capability to measure both cardiac output and ventricular filling pressures must be available in any institution performing cardiac surgery. Whether this is done with a pulmonary artery catheter, direct cannulation of the left atrium and dye dilution techniques, or TEE is immaterial. The critically ill patient requires these measurements to determine the effectiveness of vasoactive drugs, to adjust dosage, and to evaluate the need for further pharmacologic or mechanical intervention.

Echocardiography

Two-dimensional transesophageal echocardiograph (TEE) is the newest, most complex, and most expensive diagnostic device. Detection of ischemia by on-line evaluation of new regional wall motion abnormalities and its utility in assessing valvular lesions, both before and after repair, and the ascending aorta have been mentioned. Other applications specific to cardiac surgical patients are also useful. It is well known that, following cardiopulmonary bypass, ventricular filling pressure, irrespective of site of measurement (left ventricular end-diastolic pressure, left atrium, pulmonary capillary wedge pressure), is a poor and often misleading indicator of ventricular volume status.^{173,174} Direct estimation of left ventricular volume with two-dimensional TEE more appropriately directs fluid infusion and selection of vasoactive drugs in patients who are difficult to wean from bypass. In addition, residual valve lesions, intracardiac air, or new areas of ischemia are readily identified. Global dysfunction suggesting residual crossclamp effect, inadequate cardioplegia, or reperfusion injury can be detected.

Central Nervous System Function and Complications

Monitoring of the brain during extracorporeal bypass is difficult, with a lack of standardized equipment or criteria. Neurologic complications after cardiac surgery can be devastating to patients and their families, significantly affecting their quality of life while exponentially increasing the economic cost of recovery after cardiac surgery. Thus, many investigators have recently focused on methods to determine the etiology and improve the detection, prevention, and treatment of postoperative neurologic complications in patients undergoing cardiac surgery.

The incidence of stroke after coronary artery bypass graft (CABG) surgery is approximately 3% (1–5%). There is a much higher incidence (60–70%) of subtle cognitive deficits that can be elicited by detailed neuropsychometric testing. It is known that the neuropsychiatric deficits do improve over the initial 2–6 months after cardiac surgery; however, a significant percentage of patients (13–39%) have residual impairment. The etiology of perioperative neurologic complications is thought to be predominantly secondary to emboli (air, atheroma, other particulate matter) and less importantly to hypoperfusion in susceptible patients (e.g., pre-existing cerebrovascular disease). Most overt strokes after cardiac surgery are focal and likely due to macroemboli, whereas the cognitive changes are subtle and probably result from microemboli (e.g., air, platelet aggregates).

Risk factors for neurologic complications include advanced age (70 years), pre-existing cerebrovascular disease (e.g., carotid artery stenosis 80%), history of prior stroke, peripheral vascular disease, ascending aortic disease, and diabetes. Operative factors include the duration of CPB and intracardiac procedure (e.g., valve replacement). Intraoperative hyperglycemia, which could theoretically result in worsened neurologic damage, has not been associated with poorer neurologic outcome.¹⁷⁵

Historically, intracardiac (e.g., valvular) procedures are associated with a greater risk of neurologic complications (presumably secondary to greater risk of air emboli) than closed cardiac (i.e., CABG) procedures. As discussed earlier, TEE has given both anesthesiologists and surgeons an appreciation for the adequacy of the de-airing process after intracardiac procedures. From studies using transcranial Doppler to detect cerebral emboli, it is now known that the time points of maximal risk

for embolization are at aortic cannulation, onset of CPB, weaning from CPB, and decannulation.¹⁷⁶

The role of TEE in evaluating the ascending and descending aorta is described above. There are several management options undergoing investigation for patients with severely diseased aortas, especially those with mobile atheromas who are at increased risk of stroke. These include hypothermic fibrillatory arrest with left ventricular vent and no crossclamp, single crossclamp (*i.e.*, distal and proximal grafts performed during same crossclamp), relocation of proximal grafts to area of nondiseased aorta, no proximal grafts (internal mammary arteries only), and hypothermic ischemic arrest with resection and graft replacement of diseased aorta, off bypass if possible.

Cerebral protection is rather limited. Hypothermia is excellent in that it decreases cerebral metabolic rate and prolongs ischemic tolerance; however, profound hypothermia is not practical for routine cardiac surgery. Unfortunately, during routine CPB the patient is normothermic at most points when there is the highest risk of embolization. There is some laboratory evidence that mild hypothermia (34–36°C) may confer some benefit.^{177,178} Thus, patients at increased risk for neurologic complications may benefit from remaining mildly hypothermic upon separation from CPB and in the immediate postoperative period. Sodium thiopental has been shown to be cerebroprotective in intracardiac procedures,¹⁷⁹ but not in CABG surgery.¹⁸⁰ This difference may be a result of the “reversible” neurologic impairment secondary to gas emboli, which is more likely during intracardiac procedures than CABG surgery.

Selection of Anesthetic Drugs

The task confronting the anesthesiologist is to render the patient undergoing cardiac surgery analgesic, amnesic, and unconscious while simultaneously suppressing the endocrine and autonomic responses to intraoperative stress. Equally important is preservation of compensatory cardiovascular mechanisms and prevention of perioperative episodes of myocardial ischemia. Although these goals are not unique to the cardiac surgical patient, they are sometimes a bit more difficult to accomplish because of the severity of ischemic and/or valvular disease. Notwithstanding institutional and personal bias with respect to choice of anesthetic, there are no data that document superiority of any anesthetic for either coronary or valvular surgery. The large outcome studies of Tuman *et al* and Slogoff and Keats indicate that the choice of anesthetic has no effect on outcome in CABG patients. As was previously emphasized, the most critical factor governing anesthetic selection is the degree of ventricular dysfunction. Anticipated difficulties during the tracheal intubation sequence, the expected length of surgery, and the anticipated time until extubation of the trachea also influence choice of anesthetic. It is desirable to be able to alter anesthetic depth to accommodate the varying intensity of surgical stress. During intubation of the trachea, incision, sternotomy, pericardiotomy, and manipulation of the aorta, there is intense stimulation and sympathetic response. The period of prepping and draping following intubation of the trachea requires minimal levels of anesthetic, as does the period of hypothermic bypass.

There is no one best technique. Familiarity with all anesthetics and their physiologic and pharmacologic effects in the patient with severe cardiac disease allows great flexibility in anesthetic selection. In addition, it provides numerous options applicable to the cardiac patient undergoing noncardiac surgery.

Potent Inhalation Anesthetics

These drugs are useful both as primary anesthetic drugs and as adjuvants to treat or prevent “breakthrough” hypertension associated with high-dose opioid techniques. The balance of myocardial oxygen supply and $M\dot{V}O_2$ is usually altered favorably by reduction in contractility and afterload. Deleterious declines in perfusion must be prevented or treated, and the possibilities of increases in wall tension must be considered. These agents have been used successfully in all types of valve surgery without untoward effects, although they are sometimes associated with more hemodynamic variability than is seen with opioids. Use of these drugs involves no more hemodynamic intervention than upfront loading with opioids, and the ability to rapidly increase and decrease concentrations permits easy adjustment to variable levels of surgical stimulation. Volatile anesthetics can be administered during bypass through a vaporizer mounted on the pump; they are also appropriate in the postbypass period, assuming that cardiac function is adequate. Volatile anesthetics seem to be more important now, in combination with short-acting opiates or hypnotics, since the volume of off-bypass procedures is increasing and the urge to fast-track continues.

Opioids

The opioids lack negative inotropic effects in the doses used clinically and have thus found widespread use as the primary agents for cardiac surgery. This era began in 1969 when high doses of morphine were used to anesthetize patients for aortic valve replacement.¹⁸¹ However, hypotension, histamine release, increased fluid requirements, and, often, inadequate anesthesia resulted in a decline in the use of morphine in favor of the more potent fentanyl derivatives. Aside from bradycardia, fentanyl and its analogs are relatively devoid of cardiovascular effects and have proved to be effective anesthetics. As a primary anesthetic agent, fentanyl (50–100 $\mu\text{g} \cdot \text{kg}^{-1}$) or sufentanil (10–20 $\mu\text{g} \cdot \text{kg}^{-1}$) and oxygen provide hemodynamic stability, although they do not consistently prevent a hypertensive response to periods of increased surgical stimulation. In patients with good ventricular function, although high doses of opioids produce unconsciousness and characteristic electrocardiographic slowing, patient recall of intraoperative events remains a potential problem. Adjuvant agents are frequently used to supplement the opioids—benzodiazepines to provide amnesia, and volatile anesthetics or vasodilators to control hypertension. Superiority of any one opioid has not been demonstrated for either coronary or valvular surgery. The use of high-dose opioids prolongs the time until emergence and extubation when compared with techniques primarily based on volatile anesthetics and is no longer in fashion. Alfentanil, with an elimination half-life shorter than that of fentanyl or sufentanil, is suitable for infusion techniques and may provide optimal conditions for early extubation of the trachea. Remifentanil, an ultrashort-acting opioid, is 30 times more potent than alfentanil and undergoes hydrolysis by nonspecific esterases in minutes.¹⁸² Its predictable and rapid elimination is unaffected by hepatic or renal disease, making it an optimal drug for infusion techniques.

Combinations of the fentanyl-type drugs and benzodiazepines, whether given concomitantly or as premedication, result in hypotension secondary to a fall in systemic vascular resistance.¹⁸³ The use of any opioid in high doses can produce excessive bradycardia. Vecuronium or cisatracurium may magnify this problem, whereas pancuronium is often useful in preventing it. Abdominal and chest wall rigidity commonly occurs with rapid injection of high doses of opioids and can be severe enough to render ventilation impossible. A low-dose (priming) of nondepolarizing muscle relaxant should be given prior to opioid administration.

Nitrous Oxide

In many centers, nitrous oxide is not used at all during cardiac surgery. Increases in pulmonary vascular resistance associated with nitrous oxide have been demonstrated, with the greatest response in patients with pre-existing pulmonary hypertension.¹⁸⁴ The drug is also a mild myocardial depressant and elicits a compensatory sympathetically mediated increase in systemic vascular resistance.¹⁸⁵ These minimal changes may not be well tolerated in patients with minimal cardiovascular reserve.

It is well known that nitrous oxide increases the size of any air-filled cavity. The possibility of expansion of air introduced into the circulation either before or during bypass should preclude its use immediately before, during, or after bypass.

Induction Drugs

The benzodiazepines, the barbiturates, and etomidate can be used as supplements to either inhalation or opioid anesthetics and, more importantly, are excellent as sole induction drugs in patients with cardiac disease. Obviously, dosage requirements must be altered to fit the clinical situation, but these are excellent drugs with which to begin an anesthetic.

Neuromuscular Blocking Drugs

Muscle relaxants are part of an anesthetic plan for cardiac surgery. Although they are not essential to surgical exposure of the heart, muscle paralysis facilitates intubation of the trachea, prevents shivering, and attenuates skeletal muscle contraction during defibrillation. In addition, muscle relaxants are necessary to prevent or treat opioid-induced truncal rigidity. The chief criteria for selection are the hemodynamic and pharmacokinetic properties associated with each relaxant, the patient's myocardial function, presence of coexisting disease, current pharmacologic regimen, and anesthetic technique. This translates into what is a desirable heart rate and blood pressure for any particular patient.

Intraoperative Management

In this section, we describe the anesthetic management of a patient undergoing a cardiac surgical procedure from the time of arrival in the operating room until care is transferred to intensive care unit personnel. Because the physiologic and pharmacologic rationales for anesthetic selection have previously been discussed, this is rather a sequential description of what happens and what is required during surgery. Anticipation of needs specific to each stage of the procedure and ready availability of necessary equipment and drugs prevent untoward hemodynamic aberrations as well as last-minute scrambling and potentially avoidable delays.

Preparation

The operating room must be readied prior to arrival of the patient. Check the anesthesia machine, and have available all supplies necessary for management of a normal airway or any additional equipment if a difficult intubation of the trachea is anticipated. Anesthetic drugs, emergency drugs, and medicated infusions should be prepared and ready for use. Heparin must be drawn up prior to induction of anesthesia in the unlikely event of the need to “crash” onto bypass. All monitoring equipment should be switched on, working, and calibrated. Confirm that typed and cross-matched blood is available in the operating suite. [Table 32-20](#) is a checklist to aid in proper preoperative preparation of the operating room.

Table 32-20. ANESTHETIC PREPARATION FOR CARDIAC SURGERY

Preinduction Period

A brief conversation outside the operating room serves to evaluate the patient's general status and level of anxiety and to assess the effectiveness of premedication. Remind the patient to inform you if chest pain, shortness of breath, or other symptoms occur. Angina should be promptly treated with oxygen, sublingual or iv nitroglycerin, additional sedation, or perhaps if related to anxiety-induced hypertension or tachycardia, the prompt induction of general anesthesia. Supplemental oxygen via nasal cannula should be given to all patients once they have been transferred to the operating table, and peripheral oxygen saturation should be monitored with a pulse oximeter during line placement. Electrocardiographic leads and blood pressure cuff are placed, and initial vital signs are recorded.

One or two large-bore iv cannulas are inserted following local anesthesia (additional routes for infusion are desirable in patients undergoing repeat cardiac surgery). In some centers, anesthesia is then induced, and following intubation of the trachea, arterial and central venous cannulas are inserted. In other centers, however, these additional lines are inserted prior to anesthesia. Preinduction or postinduction insertion of central venous or pulmonary artery catheters has been discussed previously. Once they are inserted, however, initial values for all pressures and cardiac output should be recorded, and baseline determinations of arterial blood gases, hematocrit, and activated coagulation time should be obtained.

Throughout the preinduction period, the anesthesiologist must never let preoccupation with placement of iv and pressure monitoring catheters divert his or her attention from the patient. In addition to continuously monitoring vital signs, careful observation of the patient with periodic verbal contact facilitates detection of increased anxiety, excessive response to iv sedation, and hemodynamic or electrocardiographic abnormality.

Induction and Intubation

The exact choice and sequence of drugs are a subtle combination of art and science. The dose, speed of administration, and specific agents selected (*e.g.*, sedative, opioid, volatile drug, muscle relaxant) depend primarily on the patient's cardiovascular reserve and desired cardiovascular profile. A smooth transition from consciousness to blissful sleep is desired without untoward airway difficulties (*e.g.*, coughing, laryngospasm, truncal rigidity) or hemodynamic responses (either hypotension, too much drug, loss of sympathetic tone, myocardial depression; or hypertension, insertion of airway, “tugging” on the jaw). A “slow cardiac induction” sometimes creates rather than alleviates these potential problems. However, a slow, sedated, awake intubation of the trachea may be most appropriate in a bull-necked, obese patient who appears difficult to intubate and ventilate. These examples re-emphasize the necessity for an individual approach to each patient.

Deep planes of anesthesia, brief duration of laryngoscopy, and innumerable pharmacologic regimens have been proposed for eliminating the hypertension and tachycardia associated with intubation of the trachea. None is uniformly successful, and all drug interventions carry some degree of risk, small though they may be. In addition, in some patients, especially those with a slow heart rate prior to induction of anesthesia, the reflex response to intubation of the trachea is primarily vagal, and severe bradycardia and rarely sinus arrest can occur. Furthermore, recent evidence suggests that intubation of the trachea is a strong stimulus for coronary vasoconstriction irrespective of the anesthetic, because left ventricular blood flow is dramatically altered in the absence of hemodynamic changes. Therefore, the response to tracheal intubation may be varied, although it is usually short-lived. Nevertheless, evidence for persistently abnormal hemodynamics or ischemia should be sought and treated.

After documented successful intubation of the trachea, the tube is then secured, an esophageal stethoscope is inserted, and the eyes and all pressure points are protected. The importance of frequent checks of all monitors during these busy minutes cannot be overemphasized.

Preincision Period

The period of time from intubation of the trachea until skin incision is one of minimal stimulation as the surgical team attends to insertion of a bladder catheter, temperature probe, positioning, prepping, and draping. Hypotension often occurs during this period, regardless of the anesthetic technique used. It may be necessary to reduce anesthetic depth or alternatively support systemic pressure with a vasoconstrictor. The potential risks of vasoconstriction in patients with poor left or right ventricular performance must be remembered. Deeper planes of anesthesia are obviously necessary immediately prior to incision and sternotomy.

Incision to Bypass

As previously emphasized, the prebypass period is characterized by periods of intense surgical stimulation that may cause hypertension, tachycardia, or ischemia. Anticipating these events and deepening the anesthetic may be effective, but often a vasodilator or other adjuvant is required. This is particularly true in patients with good ventricular function when an opioid-oxygen technique is used. Hypotension can occur during the less stressful moments before bypass, but it is more commonly associated with cardiac manipulation in preparation for and during atrial cannulation. This may interfere with venous return or produce episodic ectopic beats or sustained supraventricular dysrhythmias. Atrial fibrillation is not uncommon. Depending upon the blood pressure and heart rate response, appropriate treatment may range from nothing at all to vasoconstrictors, cardioversion, or rapid cannulation and institution of bypass. Maintenance of adequate intravascular volume may attenuate the extent of blood pressure decrease. This is a critical time; continual observation of the surgical field is essential.

Prebypass, ST segment analysis is extremely important in identifying and localizing new ischemia, and if it does occur, it should be treated appropriately and the surgeon notified. During all cardiac procedures (perhaps more so than with any other type of surgery), hemodynamic change must be immediately correlated with events in the surgical field. Retracting, lifting, and in general, “mugging” the heart are sometimes necessary; the hemodynamic consequences are unpredictable. This is particularly true following cardiopulmonary bypass when grafts and suture lines are inspected and repaired if necessary. This is also true during reoperations, when dissection may be difficult, tedious, and time-consuming and when continuous retraction of the heart is often necessary. Bleeding, sometimes unexpectedly profuse, will compound the problem. In rare cases in which a cardiac chamber is entered and bleeding is uncontrollable, heparin is administered, the femoral vessels are cannulated, and cardiopulmonary bypass is begun using coronary suction from the field as a major source of venous return. Communication between the anesthesiologist and the surgeon is necessary to keep both apprised of the situation and to ensure that the heart gets a periodic “rest.”

Cardiopulmonary Bypass

After heparin has been administered, the cannulas are inserted, and adequate levels of anticoagulation are checked to ensure that the patient is ready for the institution of cardiopulmonary bypass ([Table 32-21](#)). Attention is focused on adequacy of venous drainage, oxygenation, unobstructed arterial return, and provision of necessary

anesthetics and muscle relaxants. Anesthetic requirements decrease if systemic hypothermia is used.

| Laboratory Values | |
|--|--|
| ACT | as measure of adequate heparinization |
| Electrolytes | |
| Anesthesia/Recovery | |
| Adequate analgesia and muscle relaxation | green |
| Patent airway (if intub) | |
| Monitor | |
| Arterial pressure | initial hypotension and then normo |
| CVP | indicator of inadequate venous drainage |
| PCWP | LV indicator—adequate drainage, AB—pull back pressure artery catheter 3–2 cm |
| Patent/Drain | |
| Canulae in place | no air locks, clamps, or kinks; no bubbles in arterial canulae |
| Facial appearance | |
| Swallowing (adequate SVC drainage) | |
| Unobstructed drainage (decompressive artery cannulation) | |
| Heart | |
| Signs of distention (especially in AI, ischemia) | |
| Support | |
| Usually not required | |

The major categories for this table and Tables 32-15 and 32-16 are organized using the mnemonic LAMP: L = laboratory values; A = anesthesia/monitoring; M = mechanical ventilation; P = patency of drainage. ACT = activated clotting time; CVP = central venous pressure; PCWP = pulmonary catheter pressure; LV = left ventricle; SVC = superior vena cava; AB = aortic insufficiency.

Table 32-21. CHECKLIST BEFORE INITIATING CARDIOPULMONARY BYPASS

Once full cardiopulmonary bypass is established, it is no longer necessary to continue ventilation of the lungs. There is complete agreement on this point. However, there is no such consensus about what exactly to do with the lungs during the period of bypass. Some anesthesiologists completely disconnect the patient from the anesthesia machine; others maintain the lungs slightly inflated with low levels of positive end-expiratory pressure using 100% oxygen or various mixtures of room air. No specific method is associated with superior postoperative pulmonary function.

During the initial minutes of bypass, systemic pressure initially drops to 30–40 mm Hg as pulsatile flow ceases and the effect of the dilute prime becomes apparent. Once adequate mixing is obtained, blood pressure increases to levels primarily determined by flow rate (Table 32-22). There is no consensus as to what constitutes the ideal blood pressure or flow rate during bypass for maintenance of adequate vital organ perfusion, especially of the brain. Commonly, flow rates are maintained at approximately 50–60 ml · kg⁻¹, with systemic blood pressures in the 50–60 mm Hg range. Alternatively, some institutions believe that lower flows are beneficial (less hematologic damage, less rewarming of the heart through noncoronary collaterals) and that the need for higher flows or pressures has not been conclusively demonstrated. Some surgeons believe that a higher perfusion pressure affords better myocardial protection when surgery is performed on the cold fibrillating heart rather than with cardioplegia.

| Laboratory Values | |

The major categories for this table and Tables 32-15 and 32-16 are organized using the mnemonic LAMP: L = laboratory values; A = anesthesia/monitoring; M = mechanical ventilation; P = patency of drainage. ACT = activated clotting time; CVP = central venous pressure; PCWP = pulmonary catheter pressure; LV = left ventricle; SVC = superior vena cava; AB = aortic insufficiency.

Table 32-22. CHECKLIST DURING CARDIOPULMONARY BYPASS

Monitoring and Management During Bypass

The common etiologies of blood pressure changes during cardiopulmonary bypass are listed in Table 32-22. Of primary importance is continuous observation of the surgical field and cannulas to ensure that nothing mechanical is awry. Attention can then be directed to other causes of hypotension or hypertension and their appropriate treatment. Other areas that require periodic monitoring and occasional intervention during bypass are also described in Table 32-22. Maintenance of adequate depths of anesthesia is obviously important during the bypass run, although clinical signs are few. Anesthetic requirements are decreased during the period of hypothermia but return toward normal when the patient is rewarmed.

Arterial pH and mixed venous oxygen saturation are often used to assess the adequacy of perfusion. Urine output is also monitored, but so many variables influence this, such as arterial and venous pressure, flow rate, temperature, and diuretic history, that it is difficult to draw meaningful conclusions from this measurement. In addition, postoperative renal failure develops from either aggravation of pre-existing renal dysfunction or persistent low cardiac output following bypass. Although many institutions administer diuretics routinely, they are just as assiduously avoided elsewhere.

Rewarming

When surgical repair is nearly complete, gradual rewarming of the patient begins. A gradient of approximately 10°C is maintained between the patient and the perfusate to prevent formation of gas bubbles. Patient awareness becomes a possibility as the potentiation of anesthetic effects due to hypothermia dissipates. Volatile anesthetics are often avoided because of residual myocardial depression present at the time of separation from bypass. If adequate doses of anesthetics have not been given, administration during rewarming should be considered to prevent recall of intraoperative events. Upon completion of the surgical repair, a variety of maneuvers are performed to remove any residual air in the ventricles. The anesthesiologist is called upon to vigorously inflate the lungs to remove air from the pulmonary veins and aid in filling the cardiac chambers. TEE is particularly useful in assessing the effectiveness of the de-airing process. The heart is defibrillated and allowed to beat and replace some of its oxygen debt. The field is tidied up, and preparations are made to separate from cardiopulmonary bypass.

Discontinuation of Cardiopulmonary Bypass

Prior to discontinuing cardiopulmonary bypass, the patient should be warmed, the surgical field dry, appropriate laboratory values checked, pulmonary compliance evaluated, and ventilation of the lungs begun (Table 32-23). If necessary, heart rate and rhythm can be regulated either pharmacologically or electrically with appropriate pacing. The venous cannulas are then incrementally occluded as bypass flow is slowly decreased and sufficient pump volume is transfused into the patient. During this time, cardiac function is continually evaluated from monitoring data and direct inspection of the heart; the need for vasoactive or cardioactive drugs is assessed. The potential disparity, previously alluded to, between radial artery and aortic pressures must be kept in mind. Contractility, rhythm, and ventricular filling can all be estimated by careful observation of the beating heart. For example, a low blood pressure but a vigorously contracting, relatively empty ventricle suggests that volume and perhaps a vasoconstrictor are all that is needed to wean the patient from bypass, whereas adequate blood pressure in the presence of a sluggish and overdistended heart may be treated with a vasodilator and/or a small dose of an inotrope. See Figure 32-30 for a general approach to termination of cardiopulmonary bypass.

Inadequate cardiac performance must prompt a search for possible etiologies (Table 32-24); structural defects require more than mere regulation of inotropes or vasodilators. If the clinical picture is suggestive of coronary air emboli with diffuse ST segment elevation and a hypocontractile heart, continuous support on cardiopulmonary bypass with a high perfusion pressure and an empty ventricle is indicated.

| |

| Cardiomyopathy |

Table 32-24. ETIOLOGY OF RIGHT OR LEFT VENTRICULAR DYSFUNCTION AFTER CARDIOPULMONARY BYPASS

If pharmacologic support is required, an integration of cardiac physiology (Chapter 31) and pharmacology (Chapter 12) will lead to the rational selection of an appropriate drug or drugs. Numerous algorithms are available to guide decision-making; one is described in Figure 32-31. This algorithm uses arterial pressure, ventricular filling pressure (central venous pressure, pulmonary artery pressure, direct left atrial measurement), and cardiac output. After integrating available data, a diagnosis is made and appropriate treatment is begun. Continual reassessment of the situation is necessary to document the efficacy of treatment or to suggest new diagnoses and therapeutic approaches.

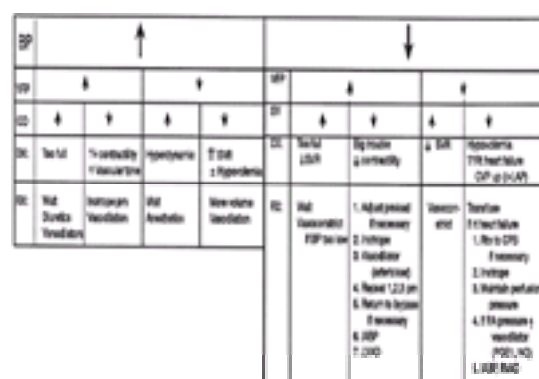

Figure 32-31. Algorithm for the diagnosis and treatment of hemodynamic abnormalities at the termination of cardiopulmonary bypass (CPB). (BP = systemic blood pressure; VFP = ventricular filling pressure; CO = cardiac output; DX = diagnosis; RX = treatment; SVR = systemic vascular resistance; CVP = central venous pressure; LAP = left atrial pressure; IABP = intra-aortic balloon pump; LVAD = left ventricular assist device; RVAD = right ventricular assist device; PA = pulmonary artery; PGE₁ = prostaglandin E₁; NO = nitric oxide; RV = right ventricle.) (Modified with permission from Amado WJ, Thomas SJ: Cardiac surgery: Intraoperative management. In Thomas SJ [ed]: Manual of Cardiac Anesthesia, 2nd ed. New York, Churchill Livingstone, 1993.)

Our approach to patients with inadequate cardiac output is summarized in Table 32-25. Heart rate is adjusted as much as possible. Ventricular filling is then optimized by transfusing blood from the pump. It is important not to overdistend the heart by transfusing to an arbitrary level of filling pressure; this may result in further myocardial dysfunction. Looking at the heart to monitor the response to small incremental volume infusions is helpful. The ratio of systemic to pulmonary artery pressure is helpful. They should change in the same direction. If, for example, pulmonary pressures increase and systemic pressure decreases, this is suggestive of ventricular failure. If cardiac output is low and systemic pressure is adequate, an arteriolar dilator may improve forward flow by decreasing afterload. If pressure is too low, precluding use of vasodilators, an inotrope should be selected. Each inotropic drug has a distinct profile with respect to its effects on rate, contractility, systemic and pulmonary vascular resistance, and cardiac dysrhythmic potential. By first defining the hemodynamic problem and then deciding what needs treatment and in what order, the most suitable drug for that situation may be selected rather than always selecting the standard “institutional inotrope.” If these initial therapies are insufficient to promote adequate forward flow, various combinations of drugs may be tested. If systemic perfusion is still inadequate, mechanical circulatory support is required.

| | |
|--------|--|
| 1 | Appropriate heart rate (pacing—A, V, A/V) and rhythm |
| 2 | Optimize ventricular filling |
| 3 or 4 | Reduce afterload if blood pressure is acceptable (arteriolar dilators) |
| 4 or 3 | Improve contractility (inotrope) |
| 5 | Recheck adequacy of ventricular filling |
| 6 | Combination therapy |
| 7 | IABP |
| 8 | VAD |

A = atrial; V = ventricular; IABP = intra-aortic balloon pump; VAD = ventricular assist device.

Table 32-25. STEPS FOR IMPROVING SYSTEMIC FLOW

A therapeutic approach to right ventricular failure is outlined in [Table 32-26](#). When pulmonary arterial pressure is normal or decreased, the etiology is usually severe right ventricular ischemia owing to intraoperative damage or to air. Initially, treatment is aimed at improving perfusion on bypass and awaiting recovery and improvement in contractility. If this does not occur, inotropic therapy and vasodilator therapy are indicated. Patients who have right ventricular failure secondary to high pulmonary vascular resistance are approached differently. The mainstay of therapy is reduction of pulmonary vascular resistance with vasodilators such as prostaglandin E₁ (PGE₁)¹⁸⁶ or nitric oxide and inotropic support. The phosphodiesterase III inhibitors, amrinone and milrinone, are particularly useful in that they significantly decrease pulmonary vascular resistance and increase contractility. Overdistention of the ventricle must be assiduously avoided. Combination therapy refers to the infusion of inotropes with vasoconstrictive properties into the left side of the circulation to maintain systemic perfusion but avoid increasing resistance in the pulmonary circulation. Persistent right ventricular failure precluding separation from cardiopulmonary bypass may require the insertion of a right ventricular assist device.

| PAP | Increased | Normal or Decreased |
|--------------|--|---|
| Diagnosis | ? Poor right ventricular protection | Air, ischemia |
| Prescription | Do not ↑ preload Inotropes Afterload reduction (PGE ₁ , etc.) ? Differential infusions RVAD | Volume Support on CFB High perfusion pressure ? CABG |

RVAD = right ventricular assist device; PAP = pulmonary artery pressure; CFB = cardiopulmonary bypass; CABG = coronary artery bypass graft.

Table 32-26. RIGHT VENTRICULAR FAILURE

Intra-aortic Balloon Pump

The simplest and most readily available mechanical support device is the intra-aortic balloon pump. It consists of a 25-cm sausage-shaped balloon composed of nonthrombogenic polyurethane mounted on a 90-cm stiff vascular catheter. It is usually inserted into the femoral artery, either percutaneously or, after surgical exposure, through a graft sutured directly to the artery, and advanced so that the tip is distal to the left subclavian artery (to prevent emboli to the upper arterial circulation). Occasionally, peripheral vascular disease prevents passage of the balloon via the femoral artery and it must be placed into the ascending aorta. The intra-aortic balloon pump is the only method that decreases myocardial oxygen demand while increasing supply.

The intra-aortic balloon pump does not pump blood. Rather, it utilizes the principle of synchronized counterpulsation to assist a beating, ejecting heart. Aortic blood volume is moved in a direction “counter” to normal flow. Immediately prior to systole, the intra-aortic balloon pump deflates, “removing blood,” precipitously reducing blood pressure (afterload reduction), enhancing forward flow, and reducing $M\dot{V}O_2$. Proper timing of balloon deflation is necessary to reduce end-diastolic pressure as much as possible to maximally off-load the ventricle. This blood is then “returned” during diastole as the balloon inflates, elevating aortic diastolic blood pressure (diastolic augmentation), increasing the gradient for coronary perfusion. The indications and contraindications for intra-aortic balloon pump placement are listed in [Table 32-27](#). The primary indications for intra-aortic balloon pump in the cardiac surgical patient are inability to separate from cardiopulmonary bypass, poor hemodynamic function, and ongoing ischemia following cardiopulmonary bypass despite increasing drug support. Myocardial function often improves with the use of the intra-aortic balloon pump, and systemic perfusion and vital organ function are preserved.¹⁸⁷ It is crucial to control heart rate and suppress atrial and ventricular dysrhythmias to ensure proper balloon timing. As cardiac function returns, the assist ratio is gradually weaned from every beat to every other beat and so on and, assuming no further cardiac deterioration, then removed.

| Indications |
|---|
| Complications of Myocardial Infarction |
| Hemodynamic—cardiogenic shock |
| Mechanical—mitral regurgitation, ventricular septal defect |
| Intractable dysrhythmias |
| Edema—pulmonary or systemic |
| ? Limitation of infarct size |
| Acute Cardiac Instability |
| Unstable angina—preinfarction angina |
| PEA, asystole |
| Pericardial tamponade |
| Cardiac contusion |
| ? Septic shock |
| Open Heart Surgery |
| Separation from cardiopulmonary bypass |
| Right or left ventricular failure |
| Increasing inotropic requirement |
| Progressive hemodynamic deterioration |
| Refractory ischemia |
| Contraindications |
| Irreversible brain damage |
| Severe aortic insufficiency |
| Inability to insert |
| Irreversible aortic disease (if not a candidate for transplant) |

Table 32-27. INTRA-AORTIC BALLOON PUMP INDICATIONS AND CONTRAINDICATIONS

Complications associated with the intra-aortic balloon pump are primarily related to ischemia distal to the site of balloon insertion. Direct trauma to the vessel, arterial obstruction, and thrombosis are most common, although aortic perforation and balloon rupture occur rarely. Platelet destruction and thrombocytopenia may also occur.

Ventricular Assist Device

Infrequently (1%), the heart is unable to meet systemic metabolic demands despite maximal pharmacologic therapy and insertion of the intra-aortic balloon pump. Under these circumstances, devices that actually pump blood and bypass either the left or right ventricle are required. These devices are effective because the injury producing myocardial dysfunction takes place intraoperatively and, more important, is often reversible. Markedly impaired cardiac function after bypass is not necessarily synonymous with cell death but, rather, may represent temporary “stunning” of the myocardium. Survival ranges from 20% to 30%, many with minimal or no decline in cardiac function.

A second group of patients who have shown benefit from assist devices are those with chronic heart failure. These devices allow for hemodynamic support as a temporizing measure prior to heart transplantation.¹⁸⁸ In the failing heart, it is important to make decisions promptly, progress through the therapeutic options, and, if repaired, move swiftly to an assist device. Very often, mechanical support for one ventricle unmasks previously unrecognized failure in the other ventricle, necessitating

additional pharmacologic or mechanical intervention.

Postcardiopulmonary Bypass

The procedure is not over when the patient is safely “off pump.” Continued vigilance is mandatory during decannulation, protamine administration, “drying up,” and chest closure. Anesthetics are administered when clinically indicated. Although removal of the atrial cannulas may trigger cardiac dysrhythmias, they are usually transient. Atrial or junctional dysrhythmias often disappear once the cannulas are out. Heparin is reversed with protamine following removal of the atrial cannulas; the arterial return remains in place for continued transfusion of pump contents. When this is completed and bleeding is controlled, the arterial cannula is removed and the chest is closed. During decannulation, the possibility exists for unexpected bleeding from the atrial or aortic suture lines, which sometimes requires rapid transfusion. Continued vigilance for new ischemia (manifested by ST segment changes, ectopy, atrial arrhythmia, regional wall motion abnormalities) is important because it may indicate a correctable problem with the grafts. Valve patients should have the adequacy of the repair or replacement (*i.e.*, perivalvular leak) assessed by TEE.

Reversal of Anticoagulation

Protamine, a polycationic protein derived from salmon sperm, is used to neutralize heparin. The initial and total doses administered vary widely. Some use a fixed ratio of protamine to heparin, others use 2–4 mg · kg⁻¹, and still others look to automated protamine titrations to suggest the initial dose. Regardless of the method selected, further requirements are assessed by repeated measures of the activated coagulation time or other clotting assay, as well as the appearance of the surgical field.

Protamine administration is associated with a broad spectrum of hemodynamic effects.^{189,190} Idiosyncratic responses include Type I anaphylactic reactions and both immediate and delayed anaphylactoid responses. True anaphylaxis, mercifully rare, is characterized by increased airway pressure, decreased systemic vascular resistance with systemic hypotension, and skin flushing.¹⁹¹ An increased incidence of reactions has been reported in patients sensitized to protamine from previous cardiac catheterization, hemodialysis, cardiac surgery, or exposure to neutral protamine Hagedorn (NPH) insulin. Perhaps the most devastating complication associated with protamine is sudden and profound pulmonary hypertension accompanied by an elevated central venous pressure, a flaccid distended right ventricle, and systemic hypotension. This complication, which may occur in approximately 1% of patients, is mediated by release of thromboxane and C5a anaphylatoxin.^{192,193} The reaction is extremely short-lived; and although reinstatement of bypass is required on rare occasions, it is usually not necessary. Whether protamine is administered via the right atrium, left atrium, or aorta or peripherally probably makes no difference. However, slow administration into a peripheral venous site is advisable.¹⁹³ Monitoring of the effectiveness of anticoagulation and its reversal is the subject of a recent review.¹⁹⁴

Postbypass Bleeding

Persistent oozing following heparin reversal is not uncommon. The usual causes include inadequate surgical hemostasis and reduced platelet count or function, neither of which is identified by a prolonged activated coagulation time. Insufficient doses of protamine, dilution of coagulation factors, and, very rarely, “heparin rebound” are also in the differential diagnosis.

After adequate hemostasis is obtained, the chest is closed. This is occasionally associated with transient decreases in blood pressure, which usually respond to volume infusion. If hypotension persists, the chest should be reopened to rule out cardiac tamponade, a kinked graft, or other serious problems.

As the surgeon completes skin closure, the anesthesiologist prepares for an orderly, unhurried transfer of the patient from the operating room to the recovery room or intensive care unit. Medicated infusions must be regulated with portable infusion pumps. Additional syringes with emergency cardiac medications and necessary equipment for airway management should be carried. Blood pressure and electrocardiograms are monitored, and adjustments of infusions are made as clinically indicated.

MINIMALLY INVASIVE CARDIAC SURGERY

Economics, combined with patient comfort, is the driving force behind the latest innovations in cardiac surgery. The initial changes were centered on avoidance of median sternotomy and the complications associated with it. Minimally invasive direct coronary artery bypass (MIDCAB) and port-access surgery were born from this shift in focus. As surgical skill and equipment improved, the off-pump coronary artery bypass (OPCAB) with sternotomy, a complete coronary vascularization without CPB, emerged.

Improvements in interventional cardiology had all but eliminated the need for single-vessel coronary bypass. Initially, MIDCAB was introduced as an alternative to angioplasty for single anterior descending coronary artery lesions. Patient comfort and speed of recovery, as well as the expense and complications from CABG, have favored treatment of a single coronary lesion with interventional rather than surgical options. An internal mammary artery anastomosis to the LAD, however, has been shown to have better long-term patency than angioplasty. The first attempts with MIDCAB approached the heart through a left minithoracotomy, allowing surgical access to both the internal mammary artery and the LAD.

Other less invasive approaches have been developed that allow the patient to avoid the major drawbacks of a full sternotomy—a large midline scar, a 6–8-week recovery period to regain use of the upper extremities, and possible complications including sternal wound infection, rib fractures, and brachial plexus injuries. Parasternal incision, minithoracotomy, inframammary incision, and partial sternotomy all improve the speed of recovery without compromising surgical outcome.¹⁹⁵ However, the accessibility of the heart and great vessels is significantly compromised, and hence these approaches remain of limited use.

Without support of the pump, coronary anastomoses were performed on a beating heart. Pharmacologic manipulation of heart rate and myocardial contractility were initially an important part of a successful operation. The slower the heart rate and the less vigorous the contractility, the lower the myocardial oxygen consumption during graft placement. More importantly, it was technically easier for the surgeon to operate on a slow-moving target. Adenosine, b-blocking drugs, and anticholinesterases were used to accomplish the appropriate degree of bradycardia. Heart rates of 40–50 beats · min⁻¹ were considered desirable. As surgical retractors improved and other equipment was developed for these cases, the need for pharmacologically induced bradycardia has all but disappeared.

Anesthetic management adapted to this change in surgical focus. Anesthesiologists had to ensure stable hemodynamic conditions during isolation of the coronary artery and suturing of the bypass graft without the support of CPB. To ensure that the anastomosis could be accomplished without terrible alterations in the patient's circulatory status, test occlusions of the coronary artery were performed prior to graft placement. The occlusions simulated the conditions that would be present during the anastomosis and also provided time to ‘precondition’ the myocardium. The benefit of preconditioning lies in the assumption that brief periods of ischemia allow the myocardium to better tolerate longer periods of ischemia later in the procedure.^{196,197} and ¹⁹⁸ After acceptable hemodynamic conditions were established and preconditioning was completed, the graft was sewn in place on the beating heart. Anesthetic management and patient positioning vary with the surgical approach. One-lung ventilation is necessary with thoracotomies. The ability to pace, cardiovert or defibrillate the heart externally becomes essential because of the inaccessibility of the heart through smaller incisions.

Monitoring concerns for MIDCAB are similar to those in standard coronary surgery. ECG and TEE are important in assessing ischemia prior to and after graft placement. Arterial and central access is necessary to identify and treat major hemodynamic alterations. Although certainly not required, a pulmonary artery catheter can provide information that is useful in treating patients with poor cardiac function or major coexisting disease states. Temperature regulation plays a larger role in MIDCAB management than in conventional heart surgery. Without the pump to warm patients, the downward drift in temperature during surgery can be significant. Normothermia facilitates normal coagulation and permits early extubation; conversely, mild hypothermia may offer a neuroprotective effect.

Variable doses of heparin are used for anticoagulation. The range has been from 100 to 300 U · kg⁻¹, depending on whether or not cardiopulmonary bypass is needed. The appropriate dose of heparin for patients undergoing MIDCAB off-bypass is undetermined.

The choice of anesthetic drugs, as with most minimally invasive procedures, is oriented toward early extubation. Neuraxial narcotics have been used as alternatives to larger doses of parenteral narcotics. Shorter-acting muscle relaxants might be of benefit in plans for early extubation.

As more MIDCAB surgeries were completed without complication, specialized equipment was developed specifically for this technique. The single-vessel bypass was gradually expanded to include more vessels, and eventually the off-pump CABG emerged.

Off-Pump Coronary Artery Bypass (OPCAB)

Complete coronary revascularization without CPB is a worthwhile goal. CPB induces a marked inflammatory response. In addition, it is associated with fluid and electrolyte shifts, potential renal dysfunction in patients with pre-existing renal disease, coagulation abnormalities, and neurologic injury. MIDCAB plus angioplasty is

one alternative; OPCAB is another. Avoiding cardiopulmonary bypass, especially in elderly patients, is a reachable goal. CPB is partially responsible for inflammatory, renal, coagulation, and neurologic complications that appear postoperatively. Additionally, the incidence of perioperative stroke is related to the severity of aortic atheromatous disease. Manipulation of an atheromatous aorta for cannulation and crossclamping increases the opportunity for an embolic event. OPCAB attempts to avoid both CPB and aortic manipulation. OPCAB is full myocardial revascularization accomplished through a median sternotomy without CPB.

An understanding of the underlying coronary anatomy and the lesions to be bypassed is vital to the planning and management of these patients. The sequence of graft placement must take into account the hemodynamic disturbances associated with the obligatory ischemia during graft placement and positioning of the heart. The most critical lesions are bypassed last so blood flow can be re-established to the remainder of the heart prior to the greatest ischemic insult. Grafting less vital lesions first allows for a smaller area of ischemia during the critical anastomosis and can help with collateral flow as well. As with a MIDCAB, the anastomosis must be accomplished on a beating heart. The artery to be bypassed is surgically occluded above and below the site of anastomosis. The myocardium distal to the surgical site may become ischemic and dysfunctional. The tighter the initial coronary lesion and the greater the collateral flow distal to it, the better tolerated are the surgical occlusion and ensuing ischemia. A variety of hemodynamic alterations can be anticipated during temporary occlusion and reperfusion. Anastomosis of a right coronary lesion might lead to atrial arrhythmias or bradycardia. Preparations for external cardioversion or epicardial pacing are important. Occasionally, left-sided lesions can be accompanied by severe LV dysfunction, requiring resuscitation with drugs, volume, and an intra-aortic balloon pump, or institution of full CPB.

Monitoring these patients is important, but presents heretofore unseen problems. Because of the surgical manipulation of the heart, methods for evaluating cardiac function or ischemia can be unreliable. The placement of lap pads or traction sutures and rotation of the heart into the right chest to reach the circumflex artery or its branches can make ECG and TEE difficult to interpret. The diagnosis of wall motion abnormalities may have to await return of the heart to its normal position in the chest.

Hemodynamic changes also accompany cardiac retraction. Arterial pressure monitoring is required to immediately identify and treat episodes of hypertension. Central access is also important to facilitate rapid infusion of vasoactive drugs and volume, if needed. Trendelenburg positioning assists in surgical exposure and in maintaining adequate ventricular preload. Many of these issues discussed for MIDCAB apply to OPCAB—degree of anticoagulation, temperature management, and selection of anesthetic plan with early extubation as a primary goal.

Bleeding can be considerable during the procedure and in the intensive care unit. The bleeding is not a result of a pump-induced coagulopathy, but can still be of sufficient degree to merit blood transfusion. It has been suggested that this type of surgery can actually promote a hypercoagulable state.¹⁹⁹

The outcome for OPCAB and MIDCAB in comparison to cardiac surgery with the use of cardiopulmonary bypass is still unknown. The crucial question of the long-term patency of grafts sewn onto the beating heart remains to be answered.

Port-Access Surgery

Port-access surgery requires full CPB but without the need for median sternotomy. Full CPB, including cardioplegia-induced cardiac arrest, is achieved by cannulation of the femoral artery and veins. Additionally, a balloon-type catheter (“endovascular clamp”) is positioned above the aortic valve to effect aortic crossclamping.^{200,201} Removing the cannulas and crossclamp from the surgical field has allowed surgery to be performed through different and less invasive incisions, including inframammary and parasternal approaches.

Both coronary artery and valve procedures can be performed with the port-access technique.²⁰² Data from a variety of sources have shown that the port-access technique offers similar or better results when compared with conventional bypass via median sternotomy.^{203,204} The benefits described include decreased blood loss, infection, sepsis, and length of hospital stay. Reported complications include aortic dissection, aortic catheter migration, arrhythmias, poor cardiac protection, perforation of the inferior vena cava and right ventricle, damage to the femoral artery, and stroke.^{205,206,207} and ²⁰⁸ Additionally, it is difficult to “de-air” after mitral and aortic valve replacements. Several contraindications to port access are described—a small adult patient, peripheral vascular disease, and an atheromatous aorta.

The anesthetic implications for port-access surgery are numerous. Monitoring is similar to that required for routine cardiac surgery. It is the responsibility of the anesthesiologist to place both a coronary sinus (to deliver retrograde cardioplegia) and pulmonary artery (to effect LV drainage) catheter via the right internal jugular vein. Initially, fluoroscopy was used to assist in coronary sinus catheter placement, although it has been almost completely superseded by TEE. The aortic cannula can migrate into the aortic arch during surgery, resulting in inadequate cerebral blood flow through the right carotid artery. Continuous TEE monitoring is essential.²⁰⁹ The placement of bilateral arterial lines simplifies diagnosis of this event when a loss of right radial artery pressure is detected. The choice of anesthetic agent should be oriented toward early awakening and extubation if possible.

Port-access cardiac surgery has proved to be an effective option in the move to noninvasive cardiac surgery. Still, it is used in only a few centers, and the question of its universal adoption remains open.

POSTOPERATIVE CONSIDERATIONS

Bring Backs

Postoperative re-exploration is needed in 4–10% of cases. The indications are persistent bleeding, excessive blood loss, cardiac tamponade, and, infrequently, unexplained poor cardiac performance (rule out tamponade). Surgery is usually required within the first 24 hours but may be later in cases of delayed tamponade. The possibility of cardiac tamponade must always be included in the differential diagnosis of the postoperative “dwindles” because the classic symptoms and signs ([Table 32-28](#)) are often absent.

| |
|--|
| Dyspnea, orthopnea, tachycardia |
| Beck's triad |
| Muffled heart sounds |
| ↑ Venous pressure (distended neck veins) |
| ↓ Arterial pressure |
| Paradoxical pulse |
| Equalization of diastolic pressures |
| RAP = RVEDP = PAEDP = LAP = LVEDP |
| ECG—ST segment change, electrical alternans |
| Chest x-ray—silhouette normal or slightly enlarged |
| Echocardiography—best diagnostic tool |

RAP = right atrial pressure; RVEDP = right ventricular end-diastolic pressure; PAEDP = pulmonary artery end-diastolic pressure; LAP = left atrial pressure; LVEDP = left ventricular end-diastolic pressure.

Table 32-28. CARDIAC TAMPONADE— CLINICAL FEATURES

Tamponade

Cardiac tamponade exists when intrapericardial pressure, not intravascular volume and venous pressure, determines venous return. The ventricle is small and underloaded despite elevations in right and left ventricular filling pressures. These increases occur because pressures are routinely measured using atmospheric pressure as the zero reference point. Normally, this is acceptable because the pressure surrounding the heart is within 1–3 mm Hg of atmospheric. With tamponade, this pressure is increased, transmural pressure (inside minus outside) is actually decreased, and intracardiac chamber pressures are deceptively elevated. Classically, there is equilibration of diastolic pressures across the heart. Stroke volume is limited and fixed, and cardiac output and blood pressure become dependent upon heart rate. Compensatory mechanisms include peripheral vasoconstriction to preserve venous return and systemic blood pressure and tachycardia. Also noteworthy is the potential for concurrent myocardial ischemia because of the tachycardia and reduced coronary perfusion pressure.

Clinically, patients present with dyspnea, orthopnea, tachycardia, and hypotension. The intubated, sedated, mechanically ventilated patient in the postanesthesia care unit following cardiac surgery may manifest only hypotension. Ventricular filling pressures are usually elevated but not consistently so. In postoperative cardiac patients, the pericardium is no longer intact, and loculated areas of clot may compress only one chamber, causing isolated increases in filling pressure (*i.e.*, mimicking right and/or left ventricular dysfunction). Urine output is usually diminished. Serial chest films typically show progressive mediastinal widening. The diagnosis of tamponade

may be confirmed by transthoracic or transesophageal echocardiography. Owing to its often atypical presentation in the cardiac surgical patient, the diagnosis of tamponade should be considered whenever hemodynamic deterioration or signs of low output failure occur in these patients.

The cure for cardiac tamponade is surgical; anesthetics can only further depress cardiac function. Therefore, drugs are selected that will preserve the compensatory mechanisms sustaining forward flow. Drugs with vasodilator (either venous or arteriolar) or myocardial depressant properties should be avoided in patients with serious hemodynamic compromise; dosages of induction agents should be appropriately reduced. Ketamine, because of its sympathomimetic effects, may be helpful in preserving heart rate and blood pressure response. It is not, however, a panacea and can induce hypotension in patients under maximal sympathetic stress. If, upon reopening the chest, there is minimal fluid or if the patient shows little improvement, a thorough search for other causes of inadequate cardiac performance, such as clotted or kinked grafts, myocardial ischemia, or valve malfunction, is indicated.

Postoperative Pain Management

Early awakening and extubation have brought the problem of postoperative pain management in cardiac surgery into focus. The standard practice has been iv opioids given as needed followed by conversion to oral pain medications. However, the quest is on to find an ideal postoperative pain management technique to complement the goal of early extubation and maximize patient satisfaction. Several studies have shown the benefits of intrathecal administration of opioids. The addition of nonsteroidal anti-inflammatory agents may play an increasing role. In cardiac patients with severe pain associated with sternal fractures due to the sternal retraction device during internal mammary harvest, epidural analgesia has been shown to be safe and effective and results in improved postoperative pulmonary function.

ANESTHESIA FOR CHILDREN WITH CONGENITAL HEART DISEASE

The child with congenital heart disease primarily suffers from structural defects of the heart and large blood vessels. Blood flow to, and oxygenation of, the myocardium is usually not a central issue in pediatric heart disease. This is in contrast to the adult, in whom the major defect is in the small myocardial vessels, resulting in ischemia. Anesthetic management of the child with congenital heart disease requires that one understand how a given anesthetic agent or combination of agents will affect myocardial function, pulmonary and systemic vascular resistance, and sympathetic tone.

Congenital defects cause either too much blood flow to a cardiac chamber (or vessel) or obstruction of flow to a chamber (or vessel). One can classify pediatric cardiac lesions by their primary effect on blood flow ([Table 32-29](#)). This classification covers most congenital defects. One must remember that there is often more than one defect present.

| |
|---|
| Volume Overload of the Ventricle or Atrium Resulting in Increased Pulmonary Blood Flow |
| Atrial septal defect (high flow, low pressure) |
| Ventricular septal defect (high flow, high pressure) |
| Patent ductus arteriosus (high flow, high pressure) |
| Endocardial cushion defect (high flow, high pressure) |
| Cyanosis Resulting From Obstruction to Pulmonary Blood Flow |
| Tetralogy of Fallot |
| Tricuspid atresia |
| Pulmonary atresia |
| Pressure Overload on the Ventricle |
| Aortic stenosis |
| Coarctation of the aorta |
| Pulmonary stenosis |
| Cyanosis Due to a Common Mixing Chamber |
| Total anomalous venous return |
| Truncus arteriosus |
| Exsitus outlet right ventricle |
| Single ventricle |
| Cyanosis Due to Separation of the Systemic and Pulmonary Circulations |
| Transposition of the great vessels |

Table 32-29. EFFECT OF PEDIATRIC CARDIAC LESIONS ON BLOOD FLOW

The best way to understand the impact of a congenital defect and how anesthetic agents will interact with this defect is to envision the path blood must follow to maintain flow to the pulmonary arteries and aorta. For example, in the presence of tricuspid atresia, there must be an associated atrial septal defect so that blood may exit the right atrium. In addition, for blood to reach the pulmonary artery there must be either a ventricular septal defect, so that blood may enter the right ventricle, or a patent ductus arteriosus, to allow for pulmonary blood flow if a ventricular septal defect is not present.

When blood can flow to either the pulmonary or systemic circulation from a given chamber or vessel (e.g., endocardial cushion defect, patent ductus arteriosus), relative flow to each circulation will be determined by the vascular resistance of each of the two beds. Decreasing pulmonary vascular resistance relative to the systemic vascular resistance will lead to increased pulmonary blood flow; conversely, increased pulmonary vascular resistance will lead to decreased pulmonary blood flow and increasing cyanosis. A variation on this theme is found in the infant with tetralogy of Fallot who has had a shunt placed to provide flow to the lungs from the subclavian artery (Blalock shunt). If the shunt is large (decreased resistance to flow), pulmonary blood flow will be large; and it is possible to have a child who is both cyanotic, due to intracardiac mixing of systemic and pulmonary venous blood, and in congestive failure, due to increased left ventricular output and increased pulmonary blood flow secondary to a large, low-resistance shunt.

Whereas congestive heart failure in the adult is most often due to ischemic insults or overt infarcts, in the child, congestive failure is most often due to enlarged ventricular dimensions secondary to tremendously increased ventricular output (e.g., ventricular septal defect or patent ductus arteriosus) or to increased afterload (e.g., coarctation of the aorta, aortic stenosis).

Preoperative Evaluation

It is essential that the anesthesiologist understand the functional implications of a child's defect(s). Valve stenosis may be mild or critical. Tetralogy of Fallot may be asymptomatic or accompanied by frequent cyanotic episodes. The severity of a lesion is best evaluated by the child's level of activity—in the newborn and infant, by the ability to feed. Slow feeding, tachypnea, sweating, increasing cyanosis, agitation, or easy fatigability indicate severe congestive failure and/or cyanosis. Infants with an anomalous left coronary artery, arising from the pulmonary artery, will often become agitated during feeding, and have associated ECG changes associated with ischemia. Failure to gain weight is an important marker of the infant with severe cardiac disease. In the older child, activity level must be related to what is normal for a child of a similar age. Rather than asking parents if the child's activity is "normal," one should ask more probing questions about what the child is actually capable of doing.

Children who have a flattening of a growth curve or increasing hematocrit have lesions that are increasing in severity. Syncopal episodes are indicative of critical left ventricular obstruction at the aortic valve. The child with tetralogy of Fallot, with a labile pulmonary outflow tract, may have a history of squatting or acute cyanotic episodes ("Tet spells"). Infants with aortic arch anomalies may also have an absent thymus (DiGeorge syndrome). In the absence of a thymus gland, it is possible for an infant to suffer a graft-versus-host reaction if they are exposed to foreign lymphocytes during transfusion. In the absence of a thymus gland, blood should be irradiated prior to administration to destroy donor lymphocytes.

Children who present for cardiac transplantation are usually in severe congestive failure and may be severely hypoxemic, since the indications for most transplant procedures in children are cardiomyopathies, irreversible pulmonary hypertension (combined heart and lung transplantation procedure), and unreconstructable heart disease.

A resting heart rate, respiratory rate, and blood pressure should be obtained. Normal values for these variables are shown in [Table 32-30](#), [Table 32-31](#) and [Table 32-32](#). Peripheral pulses should be palpated to help decide where to place an arterial catheter.

| Age | Beats per Minute |
|--------------|------------------|
| Premature | 150 ± 20 |
| Term newborn | 130 ± 20 |
| 1–6 months | 120 ± 20 |
| 6–12 months | 115 ± 40 |
| 1–2 years | 110 ± 40 |
| 2–4 years | 105 ± 35 |
| 4–6 years | 105 ± 35 |
| 6–8 years | 95 ± 30 |
| 8–10 years | 95 ± 30 |
| 12–16 years | 82 ± 25 |

Table 32-30. NORMAL HEART RATE IN CHILDREN

| Age | Systolic/Diastolic Blood Pressure (mm Hg) |
|--------------|---|
| Premature | 60/30 |
| Term newborn | 75/45 |
| 1–6 months | 89/60 |
| 6–12 months | 99/65 |
| 1–2 years | 100/60 |
| 2–4 years | 100/60 |
| 4–6 years | 100/60 |
| 6–8 years | 105/60 |
| 8–10 years | 110/60 |
| 12–16 years | 120/65 |

Table 32-31. NORMAL BLOOD PRESSURE

| Age | Respiratory Rate (breaths·min ⁻¹) |
|----------|---|
| Birth | 40–60 |
| 1 year | 30 |
| 2 years | 26 |
| 4 years | 22 |
| 8 years | 20 |
| 10 years | 20 |

Table 32-32. NORMAL RESPIRATORY RATE IN CHILDREN

Preoperatively, digoxin and diuretics are withheld on the day of surgery, unless the digoxin is being administered for control of arrhythmias. Similarly, propranolol, used either as an antiarrhythmic or for control of infundibular spasm in tetralogy of Fallot, is continued until the time of surgery, as are calcium channel blocking agents. If an infant is receiving intravenous PGE₁ to maintain ductal patency, it is crucial that this infusion not be interrupted until a shunt is constructed or cardiopulmonary bypass is established.

Anesthetic plans—including premedication, induction sequence, use of anesthetic agents, placement of arterial and venous catheters, and possibility for postoperative ventilation—should be discussed with the parents, and with the child when appropriate. In almost all cases, vascular catheters can be placed after the induction of anesthesia. A number of children will voice a common fear of waking up during the operative procedure. The anesthesiologist needs to discuss this with the child.

Adolescents, as a group, tend to be anxious patients. The adolescent facing cardiac surgery must deal with special issues of dependence owing to their cardiac defect and physical limitations, and must cope with the possibility of a visually apparent scar. This is happening while the adolescent is normally struggling with issues of independence, body image, and their place in their peer group. Adolescents may be quite distant during preoperative interviews. They may need more reassurance and explanations of procedures than do other children.

The parents should be given information about anesthetic risk and outcome.²¹⁰ An estimate of risk is based on the child's underlying condition. As discussed below, the greatest period of anesthetic risk is during induction.

Premedication

Children with cardiac lesions coming to the operating room are treated no differently than children for other surgical procedures. Oral administration of midazolam or ketamine or rectal administration of methohexital are just some of the choices for preoperative sedation.^{211,212} and ²¹³ In some cases, an inhalation induction in the presence of the child's parents is appropriate. The choice of premedicant drugs should be based on the child's physiology and the presence or absence of confounding factors such as gastroesophageal reflux. The use of an intramuscular injection of a combination of narcotic, a barbiturate, and atropine or scopolamine is rare now.

Small infants, particularly those scheduled later in the day, should not be kept without fluids while awaiting surgery. Clear fluids can be offered to infants until 2–3 hours before induction of anesthesia.²¹⁴

Children who have had long or repeated hospitalizations and previous surgery may be apprehensive prior to surgery. Such children may benefit from sedation on the day of surgery prior to going to the operating room, particularly if they may be waiting for the conclusion of earlier cases.

Induction

In the presence of significant congestive heart failure, an intravenous induction with ketamine, fentanyl, or etomidate or an intramuscular induction with ketamine may be appropriate. In the presence of compensated congestive heart failure, nitrous oxide and low-dose inhalation agent, either sevoflurane or halothane, can be administered until an intravenous route is established. Despite the theoretical argument that a right-to-left intracardiac shunt would delay the uptake of inhalation agents, clinically, this is not a problem.²¹⁵ In the child with a cyanotic lesion, in the absence of congestive failure, induction can be carried out with a variety of agents.^{216,217} The effect of an anesthetic agent(s) on peripheral oxygenation is the net result of: (1) pulmonary capillary oxygen content, which is in turn dependent on inspired oxygen concentration and hemoglobin concentration; (2) intrapulmonary and intracardiac shunt flow; (3) cardiac output; and (4) oxygen consumption.²¹⁸

In the cyanotic child, sevoflurane, halothane, ketamine, thiopental, or fentanyl are all possible induction choices. With each agent, oxygen saturation usually rises once anesthetic induction is accomplished. Despite much discussion about the ratio of systemic to pulmonary vascular resistance in the management of the child with cyanotic congenital heart disease, there is no evidence that anesthetic agents have a selective effect on one vascular bed versus the other.

In the child with increased or obstructed flow on the left side of the heart, choice of induction agent depends on the state of the ventricle. Thus, in a neonate with coarctation of the aorta, left ventricular failure, and significant metabolic acidosis, fentanyl would be a likely choice. Conversely, an 8-year-old with coarctation, left

ventricular hypertrophy, and no congestive failure might be best induced with sevoflurane or halothane. In the child with severe congestive failure, a narcotic or ketamine should probably be used.

The most critical part of the induction sequence is the maintenance of a patent airway. An obstructed airway can lead to hypercarbia and decreased oxygenation. This can lead, in turn, to increased pulmonary vascular resistance, further decreases in oxygenation, and ventricular compromise.

Maintenance

The choice of anesthetic agents following induction is governed by ventricle function (presence or absence of congestive failure), the use of cardiopulmonary bypass, and the anticipation of tracheal extubation at the end of the case, or mechanical ventilation in the postoperative period. The interaction of various anesthetic agents with the circulation in children with congenital heart disease is presented below.

Halothane

Cardiac output and blood pressure are depressed in a dose-dependent manner by halothane.²¹⁹ Myocardial contractility and left ventricular stroke work are depressed with minimal change in systemic vascular resistance. Halothane decreases sympathetic activity, resulting in reduced catecholamine release from adrenergic nerve endings and from the adrenal medulla. Hypotension (30% decrease in systolic blood pressure compared with awake values) associated with halothane is common in neonates and infants. At 1 MAC halothane the incidence of hypotension has been reported at 33% (neonates) and 44% (infants).²²⁰ Halothane must be used cautiously in children with severe left ventricular failure or severe cyanosis because the myocardial depression from the drug may further compromise the already poorly contractile ventricle.

There is a decreased threshold for arrhythmias with halothane in the presence of exogenous catecholamines such as epinephrine. It should be remembered, however, that the most common cause for arrhythmias in the prebypass period is manipulation of the heart. In the postbypass period, the most common cause of arrhythmias is the surgical repair.

Sevoflurane, halothane, or isoflurane are the agents of choice for procedures such as thoracotomy for coarctation of the aorta or patent ductus arteriosus in the older child. During these procedures, the lung is retracted to expose the aorta, and high concentrations of oxygen may be needed to compensate for the intrapulmonary shunt that is created.

Hepatic dysfunction following halothane is almost unheard of in the prepubescent child, and it is possible to use halothane repeatedly at short intervals, if needed.

Isoflurane

Isoflurane causes a decrease in blood pressure that appears to be similar in magnitude to that caused by halothane when administered at equipotent doses. However, with isoflurane, myocardial function appears to be better preserved than with halothane.²²¹ Whereas isoflurane is associated with a rise in heart rate in adults, in many children heart rate will decrease. Isoflurane has the propensity to provoke laryngospasm during an inhalation induction and is best used only after induction has been carried out with another agent.

Sevoflurane

Sevoflurane use may be associated with a decrease in blood pressure. The incidence of hypotension (defined as >30% decrease from baseline) at 1 MAC is highest in neonates and infants under 1 year of age. With incision, blood pressure tends to return toward baseline in all groups except neonates.²²² As with isoflurane, most of the decrease in blood pressure is due to a decrease in systemic vascular resistance.^{223,224} Sevoflurane use is associated with a lower incidence of arrhythmias than is halothane.²²⁵ The ability to use sevoflurane for an inhalation induction, together with its lack of significant myocardial depression, makes it a good choice for induction when an inhalation agent is used.

When tracheal extubation is planned at the termination of surgery or shortly thereafter, an inhalation agent (halothane, isoflurane, or sevoflurane) can be used. Isoflurane can be used during cardiopulmonary bypass as the sole anesthetic agent. A vaporizer can be connected to the oxygenator of the cardiopulmonary bypass circuit for administration of isoflurane during bypass, for example, during repair of an atrial septal defect. Because a number of children anesthetized with halothane will develop junctional rhythm, it is best to avoid this agent following cardiopulmonary bypass when it might not be clear if the nonsinus rhythm is due to the anesthetic agent or is a consequence of the surgery.

Nitrous Oxide

Nitrous oxide can be used in conjunction with one of the potent inhalation agents, morphine, or low-dose fentanyl. Pulmonary artery pressures do not increase in children when they are given nitrous oxide.²²⁶ The drug should be discontinued before initiating cardiopulmonary bypass to avoid an increase in size in any gas bubbles in the circulation.

Ketamine

Ketamine has enjoyed some popularity as an induction agent in children with cyanotic lesions. Its popularity stems from its hemodynamic effects, combined with the facts that it can be given intramuscularly and that spontaneous respiration is maintained while intravenous and arterial cannulas are placed.

Hemodynamic changes associated with ketamine have been examined in the catheterization laboratory and in patients following cardiac surgery. In children given ketamine at the time of cardiac catheterization, the mean heart rate, blood pressure, pulmonary artery and wedge pressure, pulmonary to systemic flow ratios (Q_p/Q_s), and PaO_2 were essentially unchanged before and after drug administration.²²⁷ (These children had previously been given thiamylal, which might have modified some of the pressor responses). Large changes in Q_p/Q_s were seen in a small number of individual patients and occurred in an unpredictable fashion. In children studied postoperatively, ketamine was shown to have no significant effects on pulmonary vascular resistance as long as ventilation was maintained.²²⁸ Should airway obstruction occur with ketamine, pulmonary vascular resistance will increase, but will drop when the obstruction is relieved.

Ketamine may be given intramuscularly ($7-10 \text{ mg} \cdot \text{kg}^{-1}$) or intravenously ($1-2 \text{ mg} \cdot \text{kg}^{-1}$). With intramuscular administration, the onset of anesthesia/analgesia occurs within 3-5 minutes. Ketamine, $6 \text{ mg} \cdot \text{kg}^{-1}$, can be used as an oral premedication.²¹² It requires approximately 20 minutes to achieve a sedative effect. Onset of drug action is heralded by the development of nystagmus. Anesthetic action is variable with ketamine. The interindividual variation in dose-response curves is large. When used as an agent for maintenance of anesthesia with additional use of muscle relaxants, dose intervals may be difficult to determine.

Very small infants are those most likely to develop airway obstruction following ketamine administration, although this is an uncommon event. Too rapid venous administration of ketamine in small infants may cause apnea. Emergence reactions seen in adults and adolescents are not a problem in young infants.

Atropine or scopolamine should be used in conjunction with ketamine to avoid pooling of secretions in the pharynx and resultant laryngospasm. Scrupulous attention must still be paid to the airway when ketamine is used. When oral ketamine is used as a premedicant drug, atropine or scopolamine can be omitted.

Ketamine is the agent of choice for induction of anesthesia in patients with cardiac tamponade. Ketamine usually produces a tachycardia and rise in blood pressure. Oxygenation is usually not impaired.

Etomidate

Etomidate can be used for intravenous induction. Its use through small peripheral veins is associated with pain.

Propofol

Propofol has been used both as an induction agent in the operating room and as the primary anesthetic in the cardiac catheterization laboratory. Data on the hemodynamic effects of propofol in the presence of congenital heart disease have been generated in the cardiac catheterization laboratory.²²⁹ Propofol decreased both

arterial pressure and systemic vascular resistance, while cardiac output increased. Notably, however, pulmonary vascular resistance was unchanged. Thus, in children with left-to-right shunts, the shunt was diminished, whereas in children with right-to-left shunts, the shunt was increased. It should be noted that children in this study were premedicated with midazolam or methohexital and received intravenous thiopental prior to propofol administration. In addition, all children breathed room air during the study.

Propofol may have advantages over other agents for anesthesia for radiofrequency ablation for tachyarrhythmias, although a recent report describes the suppression of ectopic atrial tachycardia by propofol.^{230,231}

Fentanyl

When used in large doses, fentanyl has little effect on the circulation.²³² As the dose of fentanyl is increased, it becomes long-acting. In doses of 30–50 $\mu\text{g} \cdot \text{kg}^{-1}$, combined with oxygen and a muscle relaxant, its use was advocated for patent ductus arteriosus ligation in the newborn.²³³ Given the variability of development in premature infants, it is not surprising that in a group of premature infants (postconceptional age 29–43 weeks, mean weight 1100 g), the elimination half-life of the drug varied from 6 to 32 hours.²³⁴ There appears to be poor correlation between fentanyl plasma concentration and respiratory depression following the drug's use for patent ductus arteriosus ligation. When combined with nitrous oxide, fentanyl can be used in lower doses. When 10 $\mu\text{g} \cdot \text{kg}^{-1}$ was administered with nitrous oxide 50% for patent ductus arteriosus ligation in a group of infants at approximately 30 weeks postconception, stress responses to surgery (as measured by plasma concentration of epinephrine, norepinephrine, insulin, glucagon, and glucocorticoids) were blocked compared with a group of infants operated on without fentanyl.²³⁵ No studies are available in children comparing fentanyl to other narcotics with respect to ability to block vascular and hormonal reactions to surgery. Depending on the age and condition of the child, doses of fentanyl up to 100 $\mu\text{g} \cdot \text{kg}^{-1}$ may be used.

Morphine

Fentanyl and its analogs have largely supplanted morphine in pediatric cardiac anesthesia. But morphine's lack of current popularity in no way diminishes its usefulness. In combination with nitrous oxide, morphine can provide excellent anesthesia in the child with congestive failure and/or cyanosis without depressing myocardial contractility. The sympathetic nervous system is not depressed by this combination of agents. When used alone, morphine increases venous capacitance and decreases peripheral vascular resistance. When morphine is combined with nitrous oxide, peripheral vascular resistance is increased. Hypotension from histamine release is not usually a problem in children. Occasionally, one will see red tracks along the course of the vein where morphine is injected. This is a transient phenomenon. Morphine does not lower the threshold for arrhythmias when catecholamines are present. The use of morphine in doses of 1 $\text{mg} \cdot \text{kg}^{-1}$ does commit the patient to a period of postoperative ventilation. The transition from the operating room to the ICU is a smooth one without a sudden decrease in the level of analgesia. Morphine used without supplementation either with nitrous oxide or other intravenous agents cannot be relied upon to produce amnesia or hypnosis. The usual dose of morphine is 1 $\text{mg} \cdot \text{kg}^{-1}$, administered over 15 minutes.

Succinylcholine

Succinylcholine has often been used to facilitate tracheal intubation. Because infants have an increased extracellular fluid space compared with adults and succinylcholine is distributed throughout this fluid space, a dose of 2 $\text{mg} \cdot \text{kg}^{-1}$ is required to provide muscle relaxation for intubation in infants. The drug's major side effects are bradycardia and, very infrequently, asystole. These events are more common with repeated doses. Because of the potential for bradycardia and the ability to use other agents, succinylcholine should have little place in pediatric cardiac anesthesia.

Nondepolarizing Relaxants

A nondepolarizing relaxant can be used both to facilitate tracheal intubation and to provide muscle relaxation during the operative procedure. The choice among nondepolarizing relaxants is based on their hemodynamic effects and duration of action. When an increased heart rate would be beneficial, as in the case of a small infant, pancuronium is the preferred agent. The popularity of the intermediate-acting agents atracurium and vecuronium has spilled over into cardiac anesthesia. For procedures in which the child will be ventilated postoperatively, there is little reason to use these agents.

Neuromuscular blocking agents should be titrated to effect. This is especially important in the case of a reoperation, in which the phrenic nerve may be encased in scar tissue. If excessive relaxants have been given and the diaphragm does not respond to electrical stimulation of the phrenic nerve, it is possible to transect the phrenic nerve with the electrocautery. In the small infant, loss of diaphragmatic activity can cause respiratory failure.

Cardiopulmonary Bypass

Prior to the initiation of cardiopulmonary bypass, agents such as aprotinin are administered to reduce bleeding. The infusion is continued until the end of surgery. Aprotinin has the ability to provoke an antibody response in the recipient, and children who are having repeat procedures are at risk for anaphylaxis, when aprotinin has been used in previous operations.^{236,237} and ²³⁸

During the course of cardiopulmonary bypass, vasodilating agents are employed to promote uniform cooling and rewarming. Sodium nitroprusside is most commonly used, although phentolamine can be employed as well. The adequacy of flow during cardiopulmonary bypass can be assessed by the difference between esophageal and rectal temperatures. If deep hypothermia is planned (temperature $<20^{\circ}\text{C}$), a tympanic temperature probe may be placed as well.

Separation from cardiopulmonary bypass will require pharmacologic support in some patients. Hypocalcemia is readily detected by measurement of ionized calcium concentration and is easily treatable. A number of children will require inotropic and/or chronotropic support. Dopamine or dobutamine is generally chosen as the first drug to augment ventricular function. In lesions where the presence of increased pulmonary vascular resistance is known or suspected, dobutamine, amrinone, or milrinone may be useful. Isoproterenol will provide both chronotropic and inotropic support. Pacing should be employed in the presence of a heart rate that is slow for age. Drugs that are useful in the postbypass period are given in [Table 32-33](#).

| Drug | Usual Initial Dose ($\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) | Usual Dose Range ($\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) |
|------------------------------|--|--|
| Amrinone* | 2–5 | 2–20 |
| Dopamine | 2–5 | 2–20 |
| Dobutamine | 2–5 | 2–20 |
| Epinephrine | 0.01 | 0.01–0.1 |
| Isoproterenol† | 0.05–1 | 0.1–1 |
| Lidocaine | 20 | 20–50 |
| Milrinone | 50 $\mu\text{g} \cdot \text{kg}^{-1}$ (over 3 min) | 0.3–0.7 |
| Nitroglycerin | 0.5 | 0.5–5 |
| Nitroprusside | 0.5 | 0.5–5 |
| Nonoxonylamine | 0.1 | 0.1–1 |
| Phentolamine | 0.1–1 | 0.5–5 |
| Phenyglycine | 1 | 1–3 |
| Prostaglandin E ₁ | 0.05–0.1 | 0.05–0.2 |
| Trimethoprim | 5 | 5–10 |
| Vanopresin | (1 $\mu\text{g} \cdot \text{kg}^{-1}$ U) | 0.004 |

* Requires initial bolus of 750 $\mu\text{g} \cdot \text{kg}^{-1}$ over 3 minutes before start of infusion.
 † For chronotropic effect following cardiac transplantation, doses of 0.05–0.10 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ are used.

Table 32-33. MEDICATIONS GIVEN BY CONTINUOUS INFUSION

Noncardiac Surgery in the Child with Heart Disease

Children with cyanotic disease usually have an uncompromised left ventricle. An inhalation agent can be used in the presence of cyanotic disease for noncardiac surgery such as for extensive dental restorations in a young child. In the presence of congestive heart failure, intravenous agents should be titrated slowly to effect, as in the case of a child with a cardiomyopathy who is awaiting transplant and having a Broviac catheter placed.

Regional Anesthesia

Regional anesthetic techniques can be used to supplement intraoperative anesthesia and for postoperative analgesia. For example, caudal (epidural) opioids can be used for coarctation of the aorta in the older child or ligation of a patent ductus arteriosus. Some physicians have used caudal or intrathecal morphine for cases

involving cardiopulmonary bypass (and concomitant heparin administration), although this is not a universal practice.^{239,240 and 241} The recommendation has been made that one allow 60 minutes to elapse between the placement of a neuraxial block and the administration of heparin, although there is no evidence to support this time interval. Procedures involving a thoracotomy can be supplemented with intercostal nerve blocks if, for some reason, epidural (caudal) or spinal drug administration is not possible or desired.²⁴² Because of the extremely variable drug absorption from the intercostal space in neonates, this route should be avoided in this population.²⁴³

Tracheal Extubation and Postoperative Ventilation

Children with simple lesions who have undergone a cardiopulmonary bypass (atrial septal defect, ventricular septal defect without failure repaired across the tricuspid valve) that does not involve ventricular incisions can often have tracheal tubes removed at the conclusion of surgery, or shortly thereafter in the intensive care unit.^{244,245 and 246} Children having more complex repairs, or those with ventricular impairment, may benefit from mechanical ventilation in the postoperative period. Mechanical ventilation tends to restore lung volumes and, in the presence of worsening failure or pulmonary edema, will prevent the child from becoming hypoxicemic, which would in turn lead to arrhythmias or ventricular impairment.²⁴⁷

Children most at risk for ventilatory failure following cardiac surgery are as follows:

1. Infants less than 6 months of age, high O_2 consumption, compliant chest wall, poor nutrition.
2. Infants with pulmonary to systemic flow ratios, \dot{Q}_p/\dot{Q}_s 3:4:1. The increased pulmonary blood flow will decrease lung compliance and cause airway compression. The left ventricle will also be failing, causing increased left atrial pressures, and pulmonary edema.
3. Pre-existing lung disease. There is often a history of preoperative lung disease (pneumonia, atelectasis) due to airway compression.²⁴⁸

A thoracotomy incision in a young infant, for ligation of a patent ductus arteriosus or placement of a Blalock shunt, has been shown to decrease functional residual capacity in this population, and postoperative respiratory support is indicated.²⁴⁹ In some cases, nasal continuous positive airway pressure (NCPAP) can be employed instead of mechanical ventilation.

Criteria for tracheal extubation following complex repairs are as follows: (1) ability to maintain oxygenation during spontaneous ventilation; (2) coordination of thoracic and abdominal components of respiration; (3) chest x-ray without significant atelectasis, effusions, or infiltrates; (4) short period of time without caloric input, or supplementation with enteral or intravenous feeding for patients requiring ventilation for a long period; and (5) stable inotropic support.

The effects of mechanical ventilation on cardiac performance can be judged by changes in arterial oxygenation and right atrial (central venous) or mixed venous oxygenation. Despite not having a ventricle to supply pulmonary blood flow, children who have had a Fontan procedure have been shown to tolerate mechanical ventilation with end-expiratory pressure.²⁵⁰

GOALS OF ANESTHESIA

The goals of anesthesia for vascular surgery are similar to those for any procedure: to minimize patient morbidity and maximize surgical benefit. In the current environment, we must also achieve these goals in the most cost-effective manner. The increasing age of the population in Western societies and our desire to restore functional status to the elderly will likely increase the number of vascular procedures performed in the United States. The morbidity from these procedures has decreased rapidly, from a 6-day mortality of >25% for major aortic reconstruction in the mid-1960s to a 5% mortality today. We believe that advances in preoperative preparation and anesthetic management are responsible for much of these improvements. The anesthesiologist may have a greater influence in reducing the morbidity and costs of vascular surgery than in any other surgical procedure.

This chapter discusses the pathophysiology of atherosclerotic vascular disease and the general medical problems common in patients with peripheral vascular disease, particularly coronary artery disease. We believe the heart should be the major focus of the anesthesiologist's attention insofar as myocardial dysfunction remains the single most important cause of morbidity following vascular surgery^{1,2,3,4,5,6,7,8} and 9 (Table 33-1). Recent studies have identified and emphasized the stressful nature of the postoperative period, while other workers have begun to refine preoperative risk-stratification and risk-reducing strategies. However, preservation of other organ systems (particularly renal and central nervous) is also crucial. Thus this chapter reviews current controversies in the selection of anesthetic techniques, monitoring modalities, and organ protection strategies. The specific surgical goals, anatomy, and complications for cerebrovascular, thoracic aortic, visceral, abdominal aortic, and lower extremity revascularization are placed in the context of optimal anesthetic management. New surgical techniques such as angioplasty, endovascular repair, and the placement of stent grafts, promise to further reduce morbidity and mortality.¹⁰ The anesthetic implications of these new techniques are discussed. The different scenarios that lead to emergency surgery for these conditions and their appropriate management are also discussed.

Table 33-1. PERIOPERATIVE MORTALITY ASSOCIATED WITH CARDIAC EVENTS IN AORTIC RECONSTRUCTION SERIES

VASCULAR DISEASE: EPIDEMIOLOGIC, MEDICAL, AND SURGICAL ASPECTS

Pathophysiology of Atherosclerosis

Atherosclerosis is a generalized inflammatory disorder of the arterial tree with associated endothelial dysfunction.¹¹ It has a number of recognized predisposing risk factors, including advanced age, altered serum lipid and lipoprotein profiles, hypertension, cigarette smoking, obesity and physical inactivity, male gender, diabetes mellitus, hyperhomocysteinemia,¹² and sedentary lifestyle. It is an inflammatory and degenerative process characterized by the formation of intimal plaques composed of oxidized lipid accumulation, inflammatory cells, smooth muscle cells, connective tissue fibers, and calcium deposits. Putative etiologies are endothelial damage caused by hemodynamic shear stress, inflammation from chronic infections such as gingivitis and chlamydia, hypercoagulability resulting in thrombosis, and the destructive effects of oxidized low-density lipoproteins. Disruption of the fibrous cap over a lipid deposit can lead to plaque rupture and ulceration. Vasoactive influences can result in spasm and acute thrombosis.

Morbidity associated with atherosclerosis arises from plaque enlargement and lumen obstruction (e.g., lower extremity arterial occlusion with limb ischemia) or plaque ulceration, embolization, and thrombus formation (e.g., transient ischemic attacks in patients with carotid disease). Alternatively, atrophy of the media due to atherosclerotic disease may weaken the artery wall, producing aneurysmal dilatation. The clinical expression of atherosclerosis tends to be focal, with clinical symptoms caused by localized interference with circulation occurring in several critical sites. Major arterial sites that are particularly prone to the development of advanced atherosclerotic lesions include the coronary arteries, carotid bifurcation, infrarenal abdominal aorta, and iliofemoral vessels.

Natural History of Patients with Peripheral Vascular Disease

Elderly patients with symptomatic or even asymptomatic peripheral vascular disease have greatly increased mortality rates, particularly from cardiovascular causes (6–15-fold increases).¹³ The prevalence of claudication is ~2% among older adults, but 10 times as many elderly patients have asymptomatic lower extremity atherosclerosis. The prevalence of >25% carotid stenosis in patients over 65 years was 43% in men and 34% in women in one of the Framingham studies.¹⁴ The incidence of atherosclerotic disease in one system increases the incidence in other areas.

Approximately 583,000 patients in the United States underwent vascular surgical procedures in 1992.¹⁵ Increasingly, randomized clinical trials are demonstrating the benefits of revascularization surgery. In the United States, for example, more carotid endarterectomies are being performed, presumably because trials have shown that the procedure reduces stroke in symptomatic and asymptomatic patients.¹⁶ Unfortunately, some studies have suggested that subgroups of patients, such as African Americans, women, Medicaid recipients, and diabetics, are more likely to have amputations rather than limb-salvage procedures (angioplasty or bypass surgery) performed for peripheral arterial disease.¹⁷ Abdominal aortic aneurysms occur predominantly in white men.

The goals of vascular surgery are to provide an enduring restoration of normal perfusion, so as to prevent stroke, improve functional status, or prevent death from aneurysm rupture. Current challenges remain: to create a long-lasting arterial substitute for small-caliber vessels¹⁸ and to perform revascularization less invasively and with less morbidity.

An explosion of less invasive procedures is changing vascular surgery. Radiologists, cardiologists, and vascular surgeons, working alone or in combination, place endovascular stents to treat patients with thoracic and abdominal aortic aneurysms. Other new treatment options include lasers, angioplasty, atherectomy (rotary and directional devices), gene therapy to help prevent restenosis and to promote angiogenesis, and thrombolysis, at times with concomitant or secondary surgery. Outcome studies for many of these procedures are now being published; they appear to be associated with less short-term risk and lower cost than traditional surgery.¹⁹ Less invasive approaches will invariably lead to procedures being performed in patients with such severe comorbidities that they would previously have been denied surgery. The practice of anesthesia for vascular surgery will surely change as the interventional strategies evolve, but the challenges of providing diligent care for these patients will remain.

Medical Therapy for Atherosclerosis

The goals of medical therapy for atherosclerotic peripheral vascular disease are to improve functional status, prevent stroke, prevent limb loss, and reduce potential atherosclerotic progression and cardiovascular morbidity.^{20,21} Prevention, including meticulous foot care in diabetic patients, is important to avoid infections and tissue loss. Lifestyle changes such as weight loss and exercise can forestall claudication. The use of statin drugs may reduce progression or even cause regression of atherosclerotic plaques, improve endothelial function, and reduce cardiovascular events in high-risk patients.²² The use of antioxidant vitamins such as C and E may also improve endothelial function, and folate supplementation may be of benefit for patients with hyperhomocysteinemia.¹² Exercise programs improve vascular endothelial function²³ and may delay the need for vascular surgery in those with claudication. Cessation of smoking is by far the most effective “medical” therapy. While acute smoking cessation before surgery may not reduce perioperative respiratory complications,²⁴ patients should be encouraged to stop smoking. Cessation rates are approximately 25% after major surgery.²⁵ Despite the low success rates, the benefits of smoking cessation are so great that such programs are probably very cost-effective. Our recommendations for management of concomitant medical therapy in the perioperative period are listed in [Table 33-2](#).²⁰

| Medication or Drug Class | Side Effect of Potential Concern in the Perioperative Period | Recommendation for Perioperative Use |
|--------------------------|--|--|
| Aspirin | Platelet inhibition may increase bleeding; increased CPE | Continue until day before surgery; monitor fluid and vitals status |
| NSAID/COX-2 inhibitor | Liver function test abnormalities | Assess liver function tests and continue through morning of surgery |
| β-Blockers | Bradycardia | Continue through perioperative period |
| ACE inhibitors | Induction hypotension, cough | Continue through perioperative period; consider 1/2 dose on day of surgery |
| Diuretics | Hypokalemia, electrolyte abnormalities | Continue through morning of surgery; monitor fluid and vitals status |
| Oral hypoglycemics | Hypoglycemia pre- and intraoperatively | Monitor glucose intraoperatively |

CPE = glomerular filtration rate; NSAID = nonsteroidal anti-inflammatory drug; ACE = angiotensin-converting enzyme

Table 33-2. CONCOMITANT MEDICAL THERAPY, SIDE-EFFECTS OF POTENTIAL CONCERN PERIOPERATIVELY, AND THE AUTHORS' CURRENT RECOMMENDATIONS²⁰

Antiplatelet therapy is a mainstay of medical therapy for peripheral vascular disease. Chronic therapy with aspirin or other anti-inflammatory drugs may retard the progression of atherosclerosis and prevent morbid cardiovascular events. Therefore, many patients presenting for vascular surgery will be taking aspirin, COX-2 inhibitors, ticlopidine, or clopidogrel. Clopidogrel irreversibly inhibits ADP-induced platelet aggregation, and reduces formation of both arterial and venous thrombi. Oral platelet glycoprotein IIb/IIIa inhibitors may also be used acutely during percutaneous coronary intervention and as adjunctive treatment of acute coronary syndromes.²⁶ Considerations of the adverse effects of aspirin, including increased bleeding tendency, gastritis, and renal vasoconstriction, as well as thrombotic thrombocytopenic purpura and neutropenia from ticlopidine^{27,28} must be weighed against potential benefits. In general, we recommend that patients continue to take aspirin until the day of surgery for carotid and lower extremity surgery, and individualize the choice for larger operations. When patients develop acute ischemia, systemic anticoagulation may be instituted. The agents used may range from dextran (to enhance microcirculatory blood flow) to heparin, coumadin, or thrombolytics. Therefore, when patients present to us for urgent surgery to reverse acute ischemia, we specifically ask them and their surgeons about recent or planned anticoagulation. If the answer is “yes,” we almost always forgo regional anesthesia. The implications of new antiplatelet agents on the use of regional anesthesia are unclear. However, the use of low-molecular-weight heparins is clearly dangerous when combined with regional anesthesia, as discussed below.

A primary concern with the use of anticoagulation and antiplatelet therapy is the risk of spinal hematoma after spinal-epidural anesthesia.²⁹ Therapeutic anticoagulation with intravenous heparin is routine during vascular surgery and may be continued into the postoperative period as well. Guidelines have been proposed to improve safety in such situations. Spinal and epidural anesthesia may be safely performed in a patient undergoing subsequent therapeutic heparinization provided heparinization occurs a minimum of 60 min after the needle placement. In addition, heparin effect is monitored and maintained within acceptable levels (activated clotting time or activated partial thromboplastin time 1.5–2 times baseline), and indwelling catheters are removed at a time when heparin activity is low or completely reversed.³⁰ Recently, concern has been growing about the use of low-molecular-weight heparins and the occurrence of spinal and epidural hematoma.³¹ From May 1993 through February 1998, the Food and Drug Administration (FDA) received reports of 43 patients in the United States who had spinal or epidural hematoma or bleeding after receiving enoxaparin. Emergency decompressive laminectomy to evacuate the hematoma was required in 28 patients (65%). Permanent paraplegia, often with delay in diagnosis or surgical treatment, occurred in 16 patients (37.2%). Factors suspected of predisposing patients to epidural hematoma include a dose of enoxaparin that exceeds the recommended dose (30 mg every 12 hours), use of epidural catheters, administration of concomitant medications known to increase bleeding, presence of vertebral column abnormalities, older age, and female gender. Because plasma half-life and bioavailability are higher for low-molecular-weight heparins as compared to conventional unfractionated heparin, the guidelines for spinal and epidural anesthesia are different. A single-dose spinal anesthetic may be the safest neuraxial technique in patients receiving preoperative low-molecular-weight heparins. Needle placement should occur at least 10–12 hr after the last dose of low-molecular-weight heparin. Subsequent dosing of the anticoagulant should be delayed for at least 2 hr after the needle placement. Presence of blood during needle placement may warrant an additional delay in initiation of postoperative therapy. If a continuous technique is selected, the epidural catheter should be left indwelling overnight and removed the following day, with the first dose of low-molecular weight heparin administered 2 hr after catheter removal.³²

In patients who have previously undergone procedures during which heparin was administered, heparin antibodies may be present.³³ When suspected, platelet aggregation tests may be performed with heparin *in vitro* before surgery. When undiagnosed patients with heparin antibodies receive heparin, platelet counts may drop following surgery. In the most severe cases, thrombosis may occur due to platelet activation. Heparin-induced thrombocytopenia (HIT) is one of the most common immune-mediated adverse drug reactions. HIT is caused by IgG antibodies that recognize complexes of heparin and platelet factor 4, leading to platelet activation via platelet Fc gamma IIa receptors. Procoagulant, platelet-derived microparticles, and possibly the activation of endothelium cause thrombin generation *in vivo*.³⁴ The central role of thrombin generation in this syndrome provides a rationale for the use of anticoagulants that reduce thrombin generation (danaparoid) or inhibit thrombin (lepirudin). These drugs may be given to provide anticoagulation during surgery instead of heparin; however, their half-lives are longer than those of heparin, their metabolism depends on renal function, and their interactions with regional anesthesia are unclear.

Chronic Medical Problems and Risk Prediction in Peripheral Vascular Disease Patients

Many disorders are associated with vascular disease; however, diabetes, smoking and its sequelae, chronic pulmonary disease, hypertension, renal insufficiency, and ischemic heart disease are the most common. Understanding the end-organ effects of these diseases can guide appropriate perioperative therapy.³⁵ It would be suboptimal to administer anesthesia to patients with uncontrolled medical conditions such as severe hypertension, a recent myocardial infarction, uncontrolled diabetes and hyperglycemia, or untreated pulmonary infections. However, an expanding aneurysm, crescendo transient ischemic attacks, or threatened limb loss can force one's hand. In such situations, attempts to rapidly control chronically deranged blood pressure (which could precipitate cerebral ischemia) or electrolytes (which could, for example, result in accidental administration of a bolus of potassium) may be more hazardous than leaving the condition untreated or trying to control the abnormality slowly. The National Veterans Affairs Surgical Risk Study found that low serum albumin values and high ASA physical classification were among the best predictors of morbidity and mortality after vascular surgery^{36,37} (Table 33-3).

| Predictor | Odds Ratio |
|-------------------------------------|------------|
| Ventilator-dependent | 2.71 |
| ASA class | 1.89 |
| Emergency operation | 2.40 |
| DNR status | 2.96 |
| BUN >40 mg·dL ⁻¹ | 1.47 |
| Albumin | 0.61 |
| Age | 1.03 |
| Creatinine >1.2 mg·dL ⁻¹ | 1.48 |
| Esophageal varices | 4.30 |
| Operative complexity score | 1.32 |

DNR = do not resuscitate; BUN = blood urea nitrogen. All variables are statistically significant ($p < 0.05$) and were selected after stepwise multivariable analysis. Modified from Khuri SF, Daley J, Henderson W *et al*: Risk adjustment of the postoperative mortality rate for the comparative assessment of the quality of surgical care: Results of the National Veterans Affairs Surgical Risk Study. *J Am Coll Surg* 185(4):315, 1997.

Table 33-3. THE 10 MOST IMPORTANT PREOPERATIVE PREDICTORS OF POSTOPERATIVE 30-DAY MORTALITY AFTER VASCULAR SURGERY IN VETERAN'S AFFAIRS MEDICAL CENTERS

Whereas chronic medical conditions increase the likelihood of postoperative morbidity and mortality, postoperative complications have even greater predictive value for adverse outcomes (Table 33-4).³⁸ Other causes of morbidity following vascular surgery include bleeding, pulmonary infections, graft infections, renal insufficiency and failure, hepatic failure, cerebrovascular accidents, and spinal cord ischemia resulting in paraplegia. The incidence of these other causes of morbidity has declined substantially in the past 20 years; in particular, death from renal failure after abdominal aortic reconstruction has declined from 25% to <1% at present. Much of the decline in renal failure has been the result of better perioperative fluid management.³⁹ While multisystem organ failure may account for an increasing proportion of deaths after vascular surgery, we believe that maintaining adequate cardiac function and perfusion of vital organs remains a vital aspect of reducing perioperative mortality. The factors that limit patient prognosis after vascular surgery remain primarily related to the heart (see Table 33-1). We will therefore examine more closely the effects of known or suspected coronary artery disease on patient management before, during, and after vascular surgery.

Table 33-4. DEMOGRAPHICS, HOSPITAL CHARACTERISTICS, PREOPERATIVE CHRONIC MEDICAL CONDITIONS, AND POSTOPERATIVE COMPLICATIONS AND THEIR CONTRIBUTIONS TO MORTALITY PREDICTION³⁸

Coronary Artery Disease in Patients with Peripheral Vascular Disease

Hertzer *et al*⁴⁰ performed coronary angiography in 1000 consecutive patients presenting for vascular surgery and identified severe correctable coronary artery disease in 25% of the entire series. The incidence of significant coronary artery disease (stenosis >70%) detected by angiography was 78% in those with clinical indications of coronary artery disease and 37% in patients without any clinical indications. However, subsequent analysis demonstrated that clinical risk factors still predicted the severity of coronary artery disease (Fig. 33-1).⁴¹ The absence of severe coronary stenoses can be predicted with a positive predictive value of 96% for patients who had none of the following risk factors: history of diabetes, prior angina, previous myocardial infarction, or congestive heart failure.

Figure 33-1. Clinical risk factors predict severe (left main or triple vessel) coronary artery disease. A preoperative clinical index (diabetes mellitus, prior myocardial infarction, angina, age >70 years, congestive heart failure) was used to stratify patients. INT = intermediate; ANG(+) = angiogram positive for coronary artery disease; ANG(-) = angiogram negative for coronary artery disease. (Based on data from Paul SD, Eagle KA, Kuntz KM *et al*: Concordance of preoperative clinical risk with angiographic severity of coronary artery disease in patients undergoing vascular surgery. *Circulation* 94(7):1561, 1966; secondary analysis of data from Hertzer NR, Beven EG, Young JR *et al*: Coronary artery disease in peripheral vascular patients: A classification of 1000 coronary angiograms and results of surgical management. *Ann Surg* 199:223, 1984.)

Short-term postoperative morbidity and mortality after vascular surgery is higher than after other types of noncardiac surgery. Outcome after vascular surgery is determined essentially by patient factors, surgical factors, and institution-specific factors. Cardiac-related death, myocardial infarction (MI), cardiogenic pulmonary edema, unstable angina, and dysrhythmias may occur after vascular surgery. The rates of cardiac-related death range from 0–8% and the infarction rate ranges from 0–15.3%.⁴² Complications after carotid endarterectomy are generally less frequent, regardless of the presence or absence of known coronary artery disease; but even after carotid surgery, cardiac causes produce 50–100% of the mortality encountered. Patients undergoing lower extremity revascularization often have more severe medical conditions as a group than patients undergoing abdominal aortic surgery, resulting in equal aggregate risks for cardiac complications in one series.⁴³

Long-term morbidity and mortality following vascular surgery are also greatly influenced by the presence of coronary artery disease. The presence of uncorrected

coronary artery disease appears to double 5-year mortality after vascular surgery. Coronary artery bypass graft (CABG) is associated with improved survival in peripheral vascular disease patients who have triple-vessel, but not single- or double-vessel coronary artery disease.⁴⁴ Previous percutaneous transluminal coronary angioplasty (PTCA) may or may not protect against perioperative cardiac events after vascular surgery.^{45,46} and ⁴⁷ The prevalence of asymptomatic coronary artery disease and the substantial short-term and long-term cardiac morbidity and mortality in patients undergoing vascular surgery have led investigators and clinicians to propose and undertake extensive preoperative workups to detect underlying coronary artery disease.

Controversy persists as to whether preoperative identification of patients most likely to have perioperative cardiovascular events related to myocardial ischemia benefits patients. Invasive interventions may benefit patients with vascular disease but are generally more risky than in other groups of patients.⁴⁸ Many believe that preparatory coronary revascularization may be “survival tests” that are accompanied by increased short-term morbidity; others believe that these procedures lead to better long-term survival. Patients who have survived coronary revascularization have fewer cardiac complications after vascular surgery.⁴⁹

Three essential purposes are served by preoperative cardiac risk stratification. The first would be to forgo surgery or perform a more conservative surgical procedure in those at high risk. The second goal would be to determine which patients should undergo myocardial revascularization. This goal requires that we identify patients with left main coronary artery disease and those with triple-vessel coronary artery disease and poor left ventricular function, as these patients are most likely to benefit from coronary revascularization in the long run.⁴⁴ Finally, because most perioperative myocardial ischemia and infarction occur early in the postoperative period, a third rationale for preoperative segregation of high-risk patients is to target those who might benefit from aggressive therapy in the first 24–72 hr after surgery. Risk-reducing interventions may include invasive monitoring, forced-air warming, stress-reducing anesthetic techniques, perioperative β blockade, or prolonged intensive care unit (ICU) stay. These attempts to reduce morbidity vary widely in cost and their effectiveness is controversial. The choice of risk-reducing strategies depends upon the surgical procedures, the discretion of the anesthesiologists and surgeons, and institutional protocols (clinical pathways).⁵⁰

The patient's history and bedside examination before vascular surgery serve not only to predict coronary anatomy, but also to provide important prognostic information. Studies have consistently identified congestive heart failure, previous myocardial infarction, advanced age, severely limited exercise tolerance, chronic renal insufficiency, and diabetes as risk factors for the development of perioperative cardiac morbidity.^{49,51,52} The need for emergency or urgent surgery identifies a group of patients at greatly increased risk for cardiac complications.⁵³

Previous work has suggested that risk of reinfarction depends primarily on the amount of time passed since infarction. In the modern era, however, risk stratification with specialized testing (as described below) may identify patients who are at relatively low risk despite a recent infarction. In addition, studies using aggressive hemodynamic monitoring and intensive postoperative care suggest that the rate of reinfarction after a recent infarction is currently much lower in some centers.⁵⁴

Exercise tolerance may also be a useful prognostic indicator, although claudication, orthopedic problems, and frailty may limit a patient's capabilities. Patients with limited exercise capacity have greatly increased perioperative risk.⁵¹ We believe that if patients can walk briskly for two blocks with neither angina nor dyspnea, and have no other indicators of coronary artery disease, they are very unlikely to have left main disease, triple-vessel disease, or severe left ventricular dysfunction. Such patients can probably undergo surgery without specialized noninvasive testing because they are unlikely to be at risk for adverse perioperative outcomes. However, one prospective study with consecutive patient selection of all types of vascular surgery found that clinical parameters and clinical scoring systems failed to reliably and consistently predict adverse cardiac outcomes.⁵⁵ Therefore, many investigators have proposed that specialized preoperative tests, such as stress echocardiography or thallium scintigraphy, are more accurate than clinical indicators for predicting perioperative cardiac complications.

Many patients undergo noninvasive testing to evaluate cardiovascular risk before vascular surgery. Routine coronary angiography is impractical to use routinely before vascular surgery because of the costs and risks involved.⁵⁶ The use of screening tests has remained controversial, with most recent studies showing great prognostic value^{57,58,59,60} and ⁶¹ (Table 33-5), but others showing that these tests do not perform better than the basic clinical evaluation.⁶² Given such abundant data and controversies, how can one summarize recommendations for preoperative risk stratification in a patient presenting for vascular surgery? In 1996, the American Heart Association and American College of Cardiology (AHA/ACC) published guidelines for perioperative cardiovascular evaluation before noncardiac surgery.⁶³ The algorithm incorporates clinical history, exercise tolerance, and surgical procedure in the decision to perform further evaluation. Table 33-6 summarizes some of those guidelines suited for vascular surgery patients. Semiquantitative interpretation (high-risk, intermediate-risk, or low-risk results) of both dipyridamole-thallium scintigraphy and dobutamine stress echocardiography may allow us to refer only high-risk patients for cardiac catheterization. Less severe cases of coronary artery disease (CAD) identified by weakly positive (low-risk) results on these tests may benefit from current state-of-the-art perioperative care and risk reduction. However, these less severe cases will still require careful follow-up after surgery to look for progression of coronary artery disease. Bartels *et al*⁶⁴ followed the AHA/ACC guidelines in 203 patients scheduled for aortic surgery and evaluated the short-term benefits. Cardiac-related mortality was 1% and cardiac morbidity was 12.4%. The authors concluded that the protocol was a safe strategy for preoperative evaluation before vascular surgery.

| Author (Year) | Test | No. of Patients | Quality of Study* | Cardiac Death or MI (%) | Myocardial Infarction or MI (%) | Relative Risk | odds Ratio | Likelihood Ratio |
|---------------------------------|---------------------------------|-----------------|-------------------|-------------------------|--|---------------|------------|------------------|
| Marshall (1987) ⁵⁷ | Adenosine thallium scintigraphy | 17 | Weak | 32 | <1 reversible defect at least in one segment | 3.5 | 3.07 | 2.0 |
| Hollmann (1987) ⁵⁸ | DSE | 30 | Fair | 17 | New ST-T changes at least in one segment | 10.0 | 14.2 | 5.0 |
| Vaccaro (1987) ⁵⁹ | SPIC-DES | 136 | Strong | 9 | <1 reversible defect at least in one segment | 0.7 | 2.3 | 0.2 |
| Landenberg (1987) ⁶⁰ | Preoperative clinical history | 40 | Fair | 17 | CI or II segment depression | 7.1 | 6.4 | 2.6 |

DSE = dobutamine stress echocardiography; SPIC-DES = regional wall motion abnormalities; SPIC-DES = single-photon emission computed tomography dipyridamole-thallium scintigraphy
 *As defined by American College of Physicians for studies related to preoperative evaluation of cardiac risk for noncardiac surgery.
 †Computed after adding 0.5 to all the odds because of zero event in those with negative test result. Without such correction, the relative risk and odds ratio will be infinite.

Table 33-5. NONINVASIVE TESTS TO PREDICT CARDIAC DEATH AND MYOCARDIAL INFARCTION AFTER VASCULAR SURGERY (PUBLISHED AFTER 1994)

| Precondition | Intervention | Strength of Recommendation |
|--|---|----------------------------|
| Any one of major clinical predictors (variable angina, prior MI, compensated CHF, significant arrhythmias) | Coronary angiography (CAG) | Class I* |
| One or two of intermediate clinical predictors (mild angina pectoris, prior MI, compensated CHF or prior CAB, diabetes mellitus) | Noninvasive test by DES or DSE | Class I |
| Strongly positive (high-risk) results on DES or DSE studies | CAG | Class I* |
| Intermediate results on DES or DSE studies | CAG | Class II* |
| High-risk systemic subgroup (critical CAD or left main disease [P < 0.05]) | Coronary artery bypass grafting (CABG) | Class I* |
| Documented CAD by clinical or noninvasive testing, CAG, and proceeding for surgery without CAG | Preoperative risk-reducing strategies (preoperative medical therapy or additional medical care or both) | Class I |

*Recommendation based on American Heart Association/American College of Cardiology guidelines for preoperative cardiovascular evaluation for noncardiac surgery.
 †Recent MI = recent myocardial infarction (>7 days but <1 month).
 Class I: Conditions for which there is evidence and/or general agreement that a procedure be performed or a treatment is of benefit; Class II: conditions for which there is a divergence of evidence and/or opinion about the treatment; Class III: conditions for which there is evidence and/or general agreement that the procedure/treatment is not necessary.
 CAB = coronary artery bypass; DSE = dobutamine stress echocardiography; DES = dipyridamole-thallium scintigraphy; CAD = coronary artery disease; EF = ejection fraction.

Table 33-6. CARDIAC RISK STRATIFICATION AND INTERVENTIONS IN PATIENTS SCHEDULED FOR ELECTIVE VASCULAR SURGERY

Dipyridamole-thallium scintigraphy is based on the principle of coronary steal. Dipyridamole is an antiplatelet drug and a coronary artery vasodilator. At rest, coronary arteries supplying the normal myocardium have a great vasodilatory reserve and are able to increase blood flow up to 10 times the normal to meet any extra demand. In the areas of critical stenosis, however, the coronary arteries are vasodilated in nonstressed state and have diminished reserve. Therefore, dipyridamole can vasodilate normal coronary arteries but cannot vasodilate those in areas with stenosis. When thallium radioisotope is injected, stenotic areas of myocardium will have lower concentration of the isotope (cold spot) after dipyridamole administration. When the effect of dipyridamole wears off, the isotope redistributes to ischemic zones. These areas with redistribution are considered ischemic but viable zones whereas those with persistent defects with no redistribution are indicative of infarction. Both redistribution (reversible) and persistent (fixed) defects may be abnormal test results. The early experience with dipyridamole-thallium scintigraphy yielded two important observations: an old myocardial infarction (“fixed” defect) is not a risk factor in itself, and an area of redistribution (*i.e.*, myocardium at risk) is associated with an adverse outcome. Dipyridamole-thallium scintigraphy was most helpful in the risk stratification of patients whose risks were intermediate based on clinical evaluation. In these studies, patients who had low clinical risk or a negative dipyridamole-thallium study had a low rate of adverse cardiac events after vascular

surgery.⁶⁵ When we analyzed the studies in the literature evaluating thallium scintigraphy before vascular surgery, we found that a positive scan increased a patient's chances of having a postoperative cardiac event by a factor of 4.6.⁶⁶

Congestive heart failure is a strong predictor of morbid postoperative events. Determination of systolic left ventricular function may therefore provide prognostic information. Radionuclide ventriculography can be used to define systolic and diastolic function. Our meta-analysis showed that patients who have an ejection fraction <35% by radionuclide ventriculography are 3.7 times more likely to have a postoperative cardiac event.⁶⁶ However, radionuclide ventriculography has generally been supplanted by echocardiography, which can define myocardial structure as well as function, and can also be combined with exercise or pharmacologic stress. Dobutamine ($5\text{--}30\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) stress echocardiography can produce changes in regional wall motion in patients with underlying coronary artery disease. In our meta-analysis, we found that a positive dobutamine stress test increased the risk of a postoperative cardiac event by 6.2-fold.⁶⁶

In the past, some clinicians would place a pulmonary artery catheter preoperatively to measure hemodynamics and perform risk stratification. This approach is rarely used today because catheter placement requires preoperative admission to an ICU, and most patients are now admitted on the day of surgery. Additionally, echocardiography can provide noninvasive preoperative evaluation of cardiac function. Pulmonary artery catheterization may still occasionally prove useful for preoperative optimization of unstable patients who require relatively urgent surgery.

Raby *et al* found that of the 18% of patients who had ischemia detected by Holter ECG monitoring before vascular surgery, approximately one-third had cardiac complications, while only 1% of patients without ischemia had complications.⁶⁷ Our meta-analysis for Holter monitoring of preoperative ischemia suggests that an ischemic Holter recording before surgery increases the risk of a postoperative cardiac event by 2.7-fold.⁶⁶ The biggest limitation of ambulatory ECG for preoperative risk stratification is the high percentage (at least one-fourth in our practice) of patients with baseline ECG abnormalities that obscure the diagnosis of new myocardial ischemia. These abnormalities include left ventricular hypertrophy with "strain," bundle branch block, pacemakers, and the effects of digoxin. Also, nonspecific ST-segment changes may occur owing to changes in body temperature, serum electrolytes, ventilation, or body position.

One limitation of specialized testing, including coronary angiography, is the fact that myocardial infarction and cardiac-related mortality need not necessarily be due to severely narrowed coronary arteries. Recent evidence suggests that the rupture of previously nonocclusive lipid-laden, macrophage-rich coronary plaques can cause spasm and initiate unstable angina, acute myocardial infarction, and sudden death.⁶⁸ Therefore, testing that attempts to induce ischemia will miss some patients who have nonobstructive plaques that can rupture and cause transmural infarction.

Clinicians who read the often-conflicting studies in the literature may be perplexed about choosing the best test or pathway for their patients. According to Bayes' theorem, as the prior probability of a disease in a population increases, the predictive value of a positive test increases and predictive value of a negative test decreases. (These concepts are reviewed in more detail in [Chapter 18](#).) The ideal clinical trial to help resolve these controversies would be prospective, collect data over a relatively short period of time, select patients consecutively, and would blind clinicians caring for the patients to the test results. Ethical concerns about not making test results available to clinicians have precluded large-scale randomized trials.

Meta-analysis combines evidence from multiple studies to evaluate the effectiveness of therapies or other interventions. Our meta-analysis of preoperative cardiac testing strategies allows the following conclusions.⁶⁶ Tests often demonstrate a bias for better predictive value in earlier studies. This may be due to pretest referral bias in early studies where patients were not recruited consecutively (sicker patients were chosen for earlier studies). Improvement in perioperative care over time may also explain the phenomenon of decreasing predictive value. All four tests (dipyridamole-thallium scanning, radionuclide ventriculography, Holter monitoring, and dobutamine stress echocardiography) are "effective" (the 95% confidence intervals for relative risk are >1.0) in predicting cardiac death or myocardial infarction following vascular surgery. We believe that dobutamine stress echocardiography appears to be the best among these four tests and Holter monitoring the least effective. This conclusion is subject to revision because the 95% confidence intervals for relative risk overlap.

Decision analysis is an explicit analytic tool designed to facilitate complex clinical decisions in which many variables must be considered simultaneously. The optimal decision, which is the course of action with the highest overall expected survival rate and lowest cost, is then calculated. Fleisher *et al*⁶⁹ used decision analysis to examine the effect of preoperative screening with dipyridamole-thallium scans before abdominal aortic surgery on 30-day cardiac-related mortality. The authors suggested that in patients with low prior probability of coronary artery disease, vascular surgery should be performed without cardiac screening. Their analysis demonstrates the importance of local institutional factors (particularly the institution's mortality rates for myocardial revascularization versus those for vascular surgery) in determining the optimal preoperative strategy. The outcomes of different testing strategies must be compared with their costs. Bry *et al*⁷⁰ calculated that dipyridamole-thallium scanning for screening before aortic and infrainguinal surgical procedures cost \$392,253 per life saved and \$181,039 per MI averted. They suggested that these figures may not be justifiable to society given the current trends of health care reform.

Preoperative Coronary Revascularization

Myocardial revascularization may have long-term benefits in patients with triple-vessel coronary disease or poor left ventricular function.⁴⁴ The range of options for preparatory coronary revascularization continues to expand rapidly. These include traditional surgical revascularization (CABG), transmyocardial laser therapy, percutaneous transluminal coronary angioplasty (PTCA), coronary stent placement, excimer laser, rotablator, and endoscopic CABG. However, mortality rates associated with CABG are 2.4-fold higher in patients with peripheral vascular disease (7.7% versus 3.2%) compared with those without.⁷¹ Higher complication rates can be anticipated for the newer revascularization techniques when performed in patients with peripheral vascular disease.⁴⁸

Initial observational studies of PTCA performed before major noncardiac surgery suggest that patients who survive successful PTCA do well.⁴⁷ Anticoagulation may be continued after these procedures and may preclude the use of regional anesthesia. Advances in the medical management of atherosclerosis include the use of statin drugs, which restore endothelial function, reduce ambulatory myocardial ischemia, may cause plaque regression, and may be equivalent or superior to PTCA in patients with stable angina.

Once the patient has recovered from successful coronary revascularization (1 week after angioplasty and 6–8 weeks after CABG, typically), peripheral vascular surgery is usually then performed. In some cases, CABG can be combined with vascular surgery, most commonly with carotid endarterectomy. However, patients with both symptomatic coronary and carotid disease are at high risk of both cardiac and neurologic complications following surgery, whether combined or staged; their management remains controversial.⁷² Elective abdominal aortic aneurysm repair should probably be performed before, simultaneously, or within 2 weeks of CABG because of increased risk of aneurysm rupture seen after this period.⁷³

Perioperative Cardiac Monitoring

The goals of perioperative cardiac monitoring are to detect myocardial ischemia and to identify abnormalities of preload, afterload, and ventricular function. Such monitoring may prevent myocardial infarction and allow better perfusion and preservation of other organs such as the liver, kidney, gut, and spinal cord.

Detection of Perioperative Myocardial Ischemia

ECG monitoring remains the mainstay of perioperative detection of myocardial ischemia. ECG evidence of ST-segment depression is a more common indicator of myocardial ischemia in vascular surgery patients than is ST-segment elevation. ST-segment depression occurs in 20–50% of patients undergoing vascular surgery. London *et al*⁷⁴ showed that in patients with risk factors for significant coronary artery disease, the greatest sensitivity for the detection of myocardial ischemia was achieved by intraoperative use of either lead V_5 (sensitivity 75%) or lead V_4 (sensitivity 61%). Simultaneous viewing of leads V_4 and V_5 had a sensitivity of 90% compared with a sensitivity of 80% for the combination of leads II and V_5 . Because clinicians often fail to detect intraoperative ischemic ECG changes when viewing oscilloscopes, automated ST-segment monitors promise to increase the detection of such ECG changes. We have documented that the sensitivity of ST-segment monitors for transesophageal echocardiography (TEE)-diagnosed myocardial ischemia is 40%, and 75% for ECG-diagnosed ischemia.⁷⁵ Although these monitors are not always accurate, we believe they are useful as alarms for busy clinicians.

Perioperative Holter monitoring has shown that the intraoperative period may be the least stressful for patients with coronary artery disease. Patients undergoing vascular surgery are most likely to manifest myocardial ischemia in the immediate postoperative period, with its associated pain, adrenergic stress, hypothermia, hypercoagulability, anemia, shivering, and sleep deprivation. Several studies have shown that postoperative myocardial ischemia begins earlier than has previously been thought, usually on the day of vascular surgery or the next day ([Table 33-7](#)).^{76,77,78,79} and [80](#) At present, our clinical practice is to obtain a 12-lead ECG once or twice in the first 24 hours following surgery in high-risk patients, and then daily for the next 2–3 days. We believe that such a strategy will detect most ischemia that is severe and protracted enough to represent a prodrome to infarction. Unfortunately, approximately one-fourth of vascular surgery patients will have baseline ECG abnormalities (left bundle branch block, paced rhythm, digoxin effect, left ventricular hypertrophy with strain) that preclude the detection of myocardial ischemia.

| Study (Year) | No. of Patients | Patient Group | Incidence of Postoperative Myocardial Ischemia | Incidence of Complications |
|---------------------------------|-----------------|---|--|--|
| Morgan ⁸¹ (1981) | 41 | Tetrazol, coronary artery bypass or suspected coronary artery disease | 19/41 = 47% | 15/19 = 79% 2 deaths 1 infarction |
| Owens ⁸² (1981) | 24 | Vascular surgery, known coronary artery disease | 15/24 = 62% | 7/15 = 47% 2 infarctions 1 unstable angina |
| McCann ⁸³ (1981) | 31 | Lower extremity vascular surgery | 15/31 = 39% (overall group ischemia) | 4/15 = 27% 2 deaths 2 infarctions |
| Davies ⁸⁴ (1981) | 28 | Vascular surgery | 17/28 = 39% | 11/17 = 65% 2 deaths 1 infarction |
| Landesberg ⁸⁵ (1981) | 15 | Vascular surgery | 10/15 = 67% (overall perioperative ischemia) | 5/10 = 50% 1 infarction 2 unstable angina |

Table 33-7. INCIDENCE AND PROGNOSIS OF POSTOPERATIVE MYOCARDIAL ISCHEMIA DETECTED BY CONTINUOUS ECG MONITORING

Other monitoring devices for detecting myocardial ischemia have been proposed. Pulmonary capillary wedge pressure (PCWP) monitoring in patients undergoing vascular surgery has low sensitivity and specificity (~40%) in detecting ischemia; most elevations in PCWP appear to be associated with tachycardia and hypertension, which suggests inadequate anesthesia.^{81,82} Our own group found that 90% of patients developed wall motion abnormalities on TEE when the aorta was cross-clamped above the celiac artery. However, the PCWP remained normal in >80% of these episodes.⁸³ We therefore do not routinely use PCWP as a monitor for myocardial ischemia but believe the pulmonary artery catheter provides useful information about a patient's intravascular volume status, myocardial performance, and organ perfusion.

TEE has also been proposed as a monitor for intraoperative myocardial ischemia. In animal studies and in models of coronary angioplasty during balloon inflation, mechanical dysfunction precedes surface ECG changes when myocardial ischemia is produced. Supporting these observations, Smith *et al*⁸⁴ found that regional wall motion abnormalities were more sensitive than ST-segment change on the ECG in detecting intraoperative ischemia in patients with coronary artery disease undergoing major vascular and coronary surgery. However, Eisenberg *et al* concluded that ischemia monitoring with TEE during noncardiac surgery appeared to have little incremental clinical value over preoperative clinical data and Holter monitoring in predicting perioperative ischemic outcomes.⁸⁵

Traditionally, creatine kinase myocardial band (CK-MB) isoenzyme determination has been used to document myocardial damage after vascular surgery. Limitations of this method include false-positive results owing to skeletal muscle damage during surgery. The cardiac troponins appear to offer increased sensitivity, primarily because of their prolonged diagnostic window, and may offer enhanced specificity in patients with surgical skeletal muscle damage. In a recent study of 96 vascular surgery patients, all eight patients who received a diagnosis of perioperative infarction (based on new echocardiographic abnormalities in segmental wall motion) had elevations of cardiac troponin I. This study showed that most postoperative myocardial infarctions (PMI) occurred and could be detected on the first postoperative day.⁸⁶ Badner *et al* confirmed these findings; 18 of 323 patients with known CAD undergoing major surgery (5.6%) had a PMI, of which 3 (17%) were fatal. Only 3 of 18 patients had chest pain, whereas 10 of 18 patients (56%) had other clinical findings. The PMIs occurred on the day of operation in nearly half of the cases.⁸⁷

Management of Perioperative Myocardial Ischemia and Infarction in Vascular Patients

In the modern era, rates of myocardial infarction in patients undergoing major vascular surgery can be reduced to <10%, but the rates are significantly lower for patients undergoing elective vascular repair. PMIs are much more likely to occur in patients undergoing urgent or emergent surgery, who presumably are sicker and do not have the luxury of undergoing extensive preoperative evaluation and preparation.⁵³

Stable coronary ischemic syndromes presumably occur with increased oxygen demand by the myocardium in a setting of fixed coronary plaques. Unstable syndromes are thought to be the result of active lesions caused by plaque rupture with local thrombus and vasoreactivity that produce intermittent critical decreases in coronary oxygen supply.⁶⁸ The period following vascular surgery is characterized by adrenergic stress (Fig. 33-2).⁸⁸ The postoperative adrenergic response can predispose to myocardial ischemia in numerous ways, including tachycardia and decreased diastolic time, coronary vasoconstriction, and platelet aggregation. Factors increasing the likelihood of postoperative myocardial ischemia that the anesthesiologist can control include tachycardia, hypertension, hypotension, anemia, hypothermia, shivering, endotracheal suctioning, and less than optimal analgesia. Other factors, such as postoperative hypercoagulability, rapid eye movement (REM) sleep rebound, and mild postoperative hypoxemia are more speculative culprits.

Figure 33-2. Aortic reconstructive surgery is associated with markedly elevated adrenergic tone. Epinephrine levels ($\text{pg} \cdot \text{mL}^{-1}$) rise with emergence from anesthesia but begin to fall by 6 hr after surgery. Norepinephrine levels ($\text{pg} \cdot \text{mL}^{-1}$) remain elevated for at least a day following surgery. (Reprinted with permission from Breslow MJ: The role of stress hormones in perioperative myocardial ischemia. *Int Anesthesiol Clin* 30:81, 1992.)

Postoperative myocardial ischemia confers increased risk to vascular surgical patients (see Table 33-7). Landesberg *et al* found that patients experienced twice as much ischemia after vascular surgery than before or during.⁸⁰ Ischemia that lasted >2 hr was associated with a 32-fold increase in the risk of postoperative morbid cardiac events. In this study, postoperative MI was usually preceded by long periods of severe ST-segment depression. Aggressive efforts at prevention or treatment of ischemia during these periods may improve patient outcome. We refer patients with documented severe postoperative myocardial ischemia (>2 hr; 2 mm ST-segment depression) to a cardiologist because 70% of all adverse cardiac outcomes in a two-year follow-up program were preceded by in-hospital postoperative ischemia.⁸⁹

Various strategies have been proposed to reduce cardiac morbidity during and after vascular surgery, including the prophylactic use of antianginal drugs, and special anesthetic techniques. It is crucial that patients continue to receive their chronic antianginal and antihypertensive medications before and after surgery. Often, the parenteral route for administration of these medications may be necessary following surgery. Recent reports suggest that chronic administration of the calcium entry blocker nifedipine may increase mortality⁹⁰; we are less likely to use nifedipine as first-line therapy. Prophylactic intravenous (iv) nitroglycerin $0.9 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ failed to reduce the incidence of perioperative myocardial ischemia (30% in control group versus 32% in nitroglycerin group) in patients with known or suspected coronary artery disease undergoing noncardiac surgery.⁹¹ In this study, the preponderance of myocardial ischemia occurred during emergence from anesthesia, which is associated with acute increases in heart rate.

β -Adrenergic blocking drugs, through their ability to suppress perioperative tachycardia, appear more efficacious than other anti-ischemic drugs in preventing myocardial ischemia and perhaps infarction after vascular surgery. New studies suggest that β -adrenergic blocking drugs suppress ischemia (esmolol)⁹² and reduce cardiac events (bisoprolol)⁹³ after vascular surgery. Mangano *et al* have suggested that perioperative β blockade (atenolol)⁹⁴ reduced mortality at 6 and 24 months after hospital discharge in surgical patients with known or suspected CAD. Side-effects of the β -adrenergic blocking agents, however, may increase vascular resistance, decrease cardiac output, and aggravate bronchospastic conditions and conduction delays.

High-dose narcotic anesthetics reduce the stress response and may improve overall outcome after major surgery. Postoperative infusion of sufentanil $1 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ reduced the severity of myocardial ischemia (ST-segment changes) following CABG, although clinical outcome was not improved.⁹⁵ High-dose narcotics may mandate overnight ventilation, which may not be a cost-effective therapy. Another approach using intensive analgesia involves the use of epidural analgesia. Epidural local anesthetics may reduce perioperative myocardial ischemia because preload and afterload are reduced, the postoperative adrenergic and coagulation responses are

reduced, and, with thoracic administration, the coronary arteries are dilated. Despite these effects on intermediate variables, improvement in cardiac outcomes has generally not been demonstrated.⁹⁶ Concerns about respiratory depression, neuroaxis hematomas, and the expense and reimbursement for surveillance have limited the use of peridural narcotics in greater numbers of patients. Although epidural anesthesia may improve outcome in other organ systems, especially the lungs, its ability to reduce myocardial infarction remains speculative.

Given the prominent role of coronary thrombosis in causing acute coronary syndromes and the hypercoagulable state after vascular surgery, future development in the treatment of postoperative myocardial ischemia may include drugs with antiplatelet or anticoagulant effects, such as aspirin and newer platelet inhibitors, warfarin, or heparin. Increased postoperative hemorrhage, however, makes the use of anticoagulant therapy problematic in surgical patients. At present, we do not know how to balance these risks and benefits, or which patients might benefit most from such therapy.

α_2 -Adrenergic agonists decrease noradrenergic central nervous system transmission and produce sedation, anxiolysis, and analgesia. Clonidine premedication reduces hypertension, tachycardia, norepinephrine levels, and the incidence of intraoperative myocardial ischemia in patients undergoing vascular reconstruction.⁹⁷ However, prophylactic use of the α_2 -adrenergic agonist dexmedetomidine in vascular surgery patients may require greater intraoperative pharmacologic intervention to support blood pressure and heart rate.⁹⁸ Another α_2 -adrenergic agonist, mivazerol, has recently been shown to reduce perioperative cardiac event and cardiac death rates in patients with known coronary heart disease undergoing vascular surgery.⁹⁹

Anemia (hematocrit <28%) may increase the incidence of postoperative myocardial ischemia and cardiac events in high-risk patients undergoing noncardiac surgery.^{100,101} Therefore, we are more likely to transfuse high-risk patients or those who demonstrate myocardial ischemia with packed red blood cells to augment the hematocrit to 30%. Hypothermia is also associated with increased adrenergic tone and postoperative myocardial ischemia and events in vascular surgery patients.¹⁰² We therefore aggressively warm patients and conserve heat during and after such surgery. Suctioning, extubation, and weaning from mechanical ventilation may also produce myocardial ischemia. Therefore, we attempt to extubate patients in the operating room with the same attention to the control of hemodynamics as during induction. If patients require postoperative ventilation, we provide adequate sedation, analgesia, and occasionally even paralysis (which can prevent shivering and its attendant increases in oxygen consumption). We treat tachycardia aggressively, often with β -adrenergic blocking agents, after we have corrected other potential causes such as fever, pain, anemia, and hypovolemia.

Occasionally, in patients with evolving myocardial infarction, we have resorted to using an intra-aortic balloon pump (IABP) to improve coronary blood flow while decreasing workload. Definitive studies of its effectiveness are lacking, and IABP placement can be difficult and risky in patients with peripheral vascular disease.¹⁰³ We have also referred some patients to interventional cardiologists immediately after surgery for emergent cardiac catheterization, selective thrombolysis, and PTCA for unstable angina or evolving postoperative myocardial infarction.¹⁰⁴

Other Medical Problems in Vascular Surgery Patients

Hypertension occurs in the majority of vascular surgery patients and may produce end-organ damage to the heart and kidneys. The hypertrophied left ventricle is at risk for subendocardial ischemia, even in the absence of obstructive coronary artery disease. Hypertrophied hearts may be more prone to diastolic dysfunction, which can result in "flash" pulmonary edema in the postoperative period. Therefore, antihypertensive medication should be continued in the vast majority of cases through the morning of surgery. β -Adrenergic blocking drugs are well tolerated in patients with claudication, despite theoretical concerns about peripheral vasoconstriction and bronchospasm. Calcium channel antagonists are also frequently used, as are ACE inhibitors. The ACE inhibitors may contribute to prerenal azotemia in patients with renal artery stenosis, while diuretics may produce hypokalemia. ACE inhibitors reduce central sympathetic tone and heart rate¹⁰⁵; they may be associated with an increased incidence of hypotension following induction of anesthesia if normal doses of induction agents are used.¹⁰⁶

One benefit of the modern system of same-day admission is that it allows us to interview many patients in a preanesthesia clinic a week or so before surgery. At that time, if hypertension is poorly controlled, we consult with the patient's internist or cardiologist and adjust or begin the antihypertensive regimen. Lowering blood pressure gradually in this way before surgery allows for restoration of normal intravascular volume and results in a more stable perioperative course.

Diabetic patients have a greatly increased risk for peripheral vascular disease. Aggressive treatment (home glucose monitoring program) to maintain euglycemia has recently been shown to promote wound healing and to forestall retinopathy and the development of proteinuria, but its effects on the progression of large vessel peripheral vascular disease and coronary artery disease are unknown. Coronary disease is ubiquitous in diabetic patients requiring vascular surgery. Diabetic patients generally have higher risks of myocardial infarction (5.2% versus 2.1%) and wound infection (2.6% versus 0.6%) compared with nondiabetics undergoing abdominal aortic aneurysm.¹⁰⁷ The dramatic increase in the risk of postoperative death (7%) in diabetic patients with autonomic neuropathy suggests that simple tests to identify such patients might be part of the preoperative workup.¹⁰⁸ Patients with diabetes and severe coronary artery disease may live longer if they undergo CABG rather than PTCA. We typically give our diabetic patients one-third to one-half of their usual insulin dose on the morning of surgery, begin an iv infusion of glucose-containing fluid, and check a "finger-stick" glucometer reading before commencing with an anesthetic. We attempt to maintain intraoperative euglycemia by frequently monitoring and guiding plasma glucose levels. We are especially fastidious about glucose management during carotid and thoracic aortic procedures, where hyperglycemia may exacerbate neurologic injury.

Patients with peripheral vascular disease may have hypercoagulable states.¹⁰⁹ Hypercoagulable states are more common in younger patients presenting for vascular surgery and in those with vascular thrombosis in unusual locations. Hypercoagulable responses to surgery may also predispose patients to vascular graft occlusion after surgery. Postoperative abnormalities include elevated fibrinogen levels, antithrombin III deficiency, impaired fibrinolysis, protein C deficiency, and protein S deficiency. Heparin-induced thrombosis (HIT) can occur paradoxically on an immunologic basis (IgG) after several days of exposure to heparin. This problem, which can be fatal, appears to be increasing in incidence, particularly in patients who have had previous vascular or cardiac surgery and heparin exposure. Patients typically present with thrombocytopenia, a normal prothrombin time, and normal fibrinogen levels. Mortality and complications resulting from HIT are reported to be about 20–30% each. Discontinuation of heparin (including in the flush solution of invasive monitors) is a simple and essential maneuver, and anticoagulation has to be continued by alternative drugs. Low-molecular-weight heparins are associated with a reduced, but still significant incidence of HIT. The heparinoid danaparoid-sodium and the thrombin inhibitor recombinant hirudin have been used successfully for anticoagulation of patients with HIT.³⁴ However, these have longer half-lives than heparin, have prolonged kinetics in renal failure, and cannot be reversed with protamine.

Patients with peripheral vascular disease have frequently abused tobacco. Preoperative spirometry may help identify patients likely to have postoperative pulmonary complications.¹¹⁰ In one study of vascular surgery patients, the incidence of postoperative pulmonary complications (pneumonia, ventilator dependence >48 hr, or the adult respiratory distress syndrome) was 12.9%. Patients with forced expiratory volume in 1 s (FEV_1) <2.0 L \cdot s⁻¹ had a much higher incidence of pulmonary complications (22.5% versus 5.8% for FEV_1 2.0 L \cdot s⁻¹). Not surprisingly, respiratory failure was much more common in patients undergoing repair of aortic aneurysm (~30%) than surgery for lower extremity occlusive disease (8%) or for carotid procedures (5%).¹¹¹

Renal insufficiency or failure exists in many patients who present for arterial reconstruction. Patients with pre-existing renal insufficiency have an increased risk of postoperative renal failure, as well as cardiac complications and death. Postoperative renal failure markedly increases the chance of death.³⁹ If patients receive chronic dialysis treatments, we prefer that they receive dialysis on the day before or the same day as surgery. Some patients will actually be hypovolemic as a result, which can contribute to hypotension upon induction of general or regional anesthesia. Many dialysis patients receive recombinant erythropoietin, which normally increases the hematocrit to ~30%. Left ventricular hypertrophy and mitral annular calcification are more common in dialysis patients and may predispose to pulmonary edema in the perioperative period; electrocardiography and echocardiography may help the clinician to make these diagnoses. In addition, we usually seek laboratory and electrocardiographic evidence of hyperkalemia and avoid succinylcholine when possible if we suspect hyperkalemia. We are careful when positioning patients to avoid putting pressure on the arm used for hemodialysis; we also do not measure blood pressure in that arm. Vascular access may be difficult in patients who have had multiple arteriovenous fistulae placed for hemodialysis. We also anticipate a more difficult abdominal dissection in some patients who have received peritoneal dialysis.

CAROTID ENDARTERECTOMY

The most common cause of carotid artery occlusive disease is atherosclerosis. Carotid disease is bilateral in about half of all cases. Atherosclerotic plaque usually develops at the lateral aspect of the carotid artery bifurcation (where shear stress is lowest) and commonly extends into the internal and external carotid arteries. The embolization of thrombotic material or debris from the plaque can result in stroke or transient neurologic symptoms. Risk factors for carotid disease include advanced age, hypertension, and tobacco abuse. Elevated serum lipid levels and a history of diabetes mellitus are less powerful predictors. Patients with left main coronary artery disease and other peripheral vascular disease are more likely to have carotid disease as well.¹¹²

Carotid disease may manifest itself only as an asymptomatic bruit, or as amaurosis fugax (transient attacks of monocular blindness) when embolization is to the ophthalmic artery. Other patients may experience episodes of paresthesias, clumsiness of the extremities, or speech problems, which resolve spontaneously after a short period of time. These are the classic transient ischemic attacks (TIAs). The differentiation between a TIA and a reversible ischemic neurologic deficit (RIND) is one of degree and somewhat arbitrary. A TIA resolves within 24 hr, whereas a RIND will last longer than 24 hr before complete resolution. Unfortunately, in some

patients the first manifestation of carotid artery disease may be a stroke. One of two pathophysiologic mechanisms is thought to be responsible for the development of neurologic symptoms: embolism or hypoperfusion. A high-grade (preocclusive) obstruction of the carotid lumen may reduce distal blood flow below a critical level, especially when systemic blood pressure is low.

Patients who present with TIAs have a ~10% risk of stroke during the subsequent year. Of the patients who do have a stroke after the onset of TIAs, ~20% will have the stroke within the first month and ~50% within 1 year of symptoms. In subsequent years the stroke risk decreases to ~5% per year. In asymptomatic patients with a stenosis of >75%, the stroke risk is ~5% per year; but if the asymptomatic stenosis is <75%, the risk is 1–2% per year.¹¹³ Patients with ulcerated soft plaques seem to have a higher risk of stroke that approaches 7–8% per year. The serious nature of cerebrovascular disease is underscored by the fact that about one-third of all acute strokes are fatal and another third result in significant residual functional deficit.

An isolated, cervical bruit in asymptomatic patients also seems to be associated with a higher risk of stroke, but the correlation between the location of the bruits and the type of subsequent stroke is poor. A bruit *per se* does not define the presence of a critical carotid lesion, nor are critical carotid lesions always associated with bruits. Therefore, we use the results of auscultation of a bruit to prompt further testing. The most common noninvasive test is the duplex scan, which combines B-mode anatomic imaging and pulse Doppler spectral analysis of blood flow velocity. The presence of high velocities and turbulent flow is used to predict the extent of carotid stenosis. The accuracy of duplex scanning reaches 95% in experienced hands when compared with angiography. Angiography provides measurements of the size and morphology of the atheromatous plaque and can also document aortic arch or intracranial disease, which may occur in conjunction with carotid disease and can cause strokes that are not prevented by carotid endarterectomy. Increasingly, given the risk and expense of angiography (1% rate of neurologic deficits in some studies), some surgeons will operate on the basis of duplex scanning or magnetic resonance angiography without a contrast angiogram.

There are pharmacologic and surgical treatments for carotid artery disease. Combined administration of aspirin and dipyridamole, when compared with placebo, reduces the incidence of TIAs. Therefore, most patients presenting for carotid endarterectomy will be taking aspirin; we confirm this when taking a history and continue aspirin throughout and beyond the perioperative period, unless there are clear contraindications to its use, in order to decrease morbid cardiovascular events.¹¹⁴ In contrast, carotid endarterectomy, in conjunction with aspirin therapy, has proven superior to medical therapy alone in a large trial of symptomatic patients with a stenosis >70% in the North American trial (NASCET).¹¹⁵ In this trial, major or fatal ipsilateral stroke was significantly reduced from 13.1% in the medical group to 2.5% in the surgical group. Estimates of the cumulative risk of any ipsilateral stroke at two years were 26% in the medical patients and 9% in the surgical patients. For asymptomatic patients with a stenosis of >60%, the Asymptomatic Carotid Atherosclerosis (ACAS) study also detected a substantial outcome benefit. However, the overall risk of stroke was lower in both medical and surgical groups than for symptomatic patients in NASCET. In ACAS, ipsilateral stroke and any perioperative stroke or death was estimated to be 11.0% for patients treated medically and 5.1% for surgical patients after 5 years.¹¹⁶ Of course, carotid endarterectomy is justifiable only if the operative morbidity and mortality are lower than the natural risk for ischemic events in the untreated patient. The number of asymptomatic patients who need to undergo CEA to prevent 1 stroke is approximately 20–40, leading some investigators to question its cost-effectiveness in this setting. For a thorough review of this area, the reader is referred to the guidelines published for carotid endarterectomy by the American Heart Association.¹¹⁷ Less invasive techniques using balloon dilatation and stenting of carotid stenoses are being used;¹¹⁸ randomized trials have begun to compare the outcomes of these procedures to traditional CEA.

Factors that consistently predict neurologic and cardiac morbidity and mortality after carotid endarterectomy include the following: age >75 years, experience of the surgeon, preoperative neurologic symptoms or previous stroke, history of angina, diastolic blood pressure >110 mm Hg, carotid endarterectomy performed in preparation for CABG, internal carotid artery thrombus, stenosis near the carotid siphon, or contralateral carotid occlusion. Patients undergoing CEA for lesions of the left carotid artery may suffer stroke more often, possibly due to technical difficulties, because most surgeons are right-handed.

Preoperative Evaluation and Preparation

Although the most common cause of TIAs is occlusive carotid disease, other neurologic disease such as intracerebral tumor or cerebrovascular malformation may produce similar symptoms. Cardiac diseases also may produce neurologic symptoms, including atrial fibrillation, valvular heart disease, dilated cardiomyopathy, or a myocardial infarction with akinetic ventricular segments leading to intracardiac thrombus formation and cerebral embolization. Coronary artery disease is common in patients presenting for carotid endarterectomy.⁴⁰ We are less likely to request special studies (dobutamine stress echocardiography or dipyridamole-thallium scintigraphy) or cardiac catheterization before carotid endarterectomy than for other major vascular procedures. Our rationale is that carotid endarterectomy can prevent stroke, is less stressful, and does not result in death as frequently as other vascular operations. Indeed, it has been proposed that preoperative risk can be based not only on the presence of coronary artery disease but also on the basis of exercise tolerance and extent of the surgical procedure.⁵⁶

In the North American trial, the 30-day results were as follows: death, 1.1%; disabling stroke, 1.8%; nondisabling stroke, 3.7%, cardiac death 0.3%.¹¹⁹ These values are clearly lower than those reported for CABG, even in patients free of significant carotid disease. Therefore, it is difficult to recommend a CABG procedure to a patient with symptomatic carotid disease and stable coronary disease because the combined mortality and stroke rate after CABG may be higher than that of an expertly performed carotid endarterectomy. Cerebrovascular disease is associated with increased mortality after CABG. On the other hand, patients who have had previous CABG may have lower mortality following CEA.¹¹⁹

We therefore usually undertake carotid endarterectomy in patients for whom the operation offers benefits even if they have stable coronary artery disease. Our classification of stable coronary artery disease is based on a thorough history, physical examination, and review of basic laboratory tests, not specialized testing. We do not delay urgent surgery that might prevent a stroke for extensive cardiac evaluation in the patient with stable cardiac disease. However, the long-term risks of adverse cardiac events after carotid endarterectomy are related to progression of coronary artery disease. Identification and coronary revascularization of patients with triple-vessel or left main coronary artery disease and those with very low ejection fractions may prolong their lives.⁴⁴

The approach to patients with both severe coronary artery disease and carotid occlusive disease is controversial.¹²⁰ The risk of stroke in patients with symptomatic carotid disease undergoing CABG surgery can range from 8.7–17%. In patients with asymptomatic carotid disease, CABG may entail a stroke risk ranging from 0.3–9.2%; equally important, the perioperative mortality may be as high as 13%.¹²¹ Options include either a concurrent (performed under one anesthetic) operation or two separate, staged procedures. Concurrent carotid and coronary revascularization procedures have been performed with an operative mortality rate as low as 2% and a neurologic complication rate as low as 3%, but other series have reported much higher rates of complications (combined perioperative mortality and stroke rates ranging from 8–40%). Operative strategies used in concurrent operations vary among surgeons. Some surgeons will begin with a simultaneous carotid endarterectomy and a saphenous vein harvest. After these procedures have been completed, coronary artery bypass is initiated. This technique avoids the potential threats posed to the brain by pump-associated hypotension, fluctuations in perfusion pressure, and nonpulsatile blood flow. This strategy presumes that hypoperfusion is the dominant mechanism of stroke after CABG. However, studies suggest that embolic events may predominate. Emboli may occur when the ascending aorta is cannulated or occluded with a cross-clamp and protruding aortic arch atheromas are dislodged; mobile atheroma are seen using TEE in 15% of patients with severe carotid artery disease.¹²² Therefore, other surgeons will perform a simultaneous correction of both the coronary and carotid arteries during the aortic cross-clamp period. They seek to protect the brain with systemic hypothermia of 20–25°C. With this strategy, several investigators have reported extremely low rates of perioperative strokes. Although these reports are encouraging, rigorous scientific proof for a preferred operative strategy in patients with severe coronary and carotid disease is not yet available.

Monitoring and Preserving Neurologic Integrity

The two main goals of intraoperative management are to protect the brain and to protect the heart, yet these two goals often conflict. For example, increasing arterial blood pressure to augment cerebral blood flow can increase afterload or myocardial contractility, thereby increasing the oxygen demand of the heart. Also, while hypothermia may provide effective cerebral protection, it also poses a significant challenge to myocardial well-being if patients wake up shivering. General approaches to myocardial protection have been summarized above. Our approaches to neurologic and myocardial protection during carotid endarterectomy involve compromises that must be made if both organs are to be protected.

Routine aspects of anesthetic care that may affect cerebral outcome if hemispheric ischemia occurs during carotid endarterectomy include blood pressure augmentation, manipulation of PaCO₂, glucose management, and choice of intraoperative fluid administration. Whether further interventions to reduce cerebral metabolism and cerebral oxygen requirements are neuroprotective is controversial. Recent research suggests that the outcome of cerebral ischemia may be improved by antagonizing or modifying processes that normally occur after reperfusion rather than during ischemia. Shunts may be used if cerebral hypoperfusion is suspected. Percutaneous approaches using carotid stenting are no panacea; neurologic events occur during and after these procedures as well.¹²³

The rationale behind maintaining a stable, high-normal blood pressure throughout the procedure is based on the assumption that blood vessels in ischemic or hypoperfused areas of brain have lost normal autoregulation. Flow in such areas is believed to be mainly pressure-dependent. Under these circumstances, prolonged, severe hypotension may jeopardize the brain. Consequently, we maintain blood pressure in the patient's high-normal range. Nonetheless, hypotension and hypoperfusion may not be the precipitating or sole cause of stroke after carotid endarterectomy; embolic events may be just as or even more important, and often occur postoperatively (Fig. 33-3).¹¹⁹ In addition, blood pressure augmentation with sympathomimetic drugs is not without risk to the heart. Indiscriminate use of phenylephrine to raise blood pressure during deep general anesthesia with a volatile anesthetic increases the incidence of intraoperative segmental wall abnormalities detected by TEE compared with light anesthesia without the use of phenylephrine.¹²⁴ However, the judicious use of phenylephrine to raise blood pressure only in specific instances of EEG-detected reversible cerebral ischemia seems to be without detriment to the heart.¹²⁵ While phenylephrine lowers ejection fraction measured with TEE and

causes cardiac dilatation in patients with CAD, norepinephrine maintains cardiac function while raising blood pressure.¹²⁶ Phenylephrine and norepinephrine both raise cerebral blood flow velocities to a similar extent, and the increase is proportional to increases in systemic blood pressure.¹²⁷ Whatever the choice of vasopressor, we believe that one benefit of EEG or other neurophysiologic monitoring is that it allows the anesthesiologist to use less vasopressor and to maintain a lower blood pressure during the period of temporary carotid occlusion than would be otherwise feasible. Thus, as long as the patient is without new neurologic deficits or the EEG or other neurophysiologic monitor is unchanged, the anesthesiologist may decrease the afterload in the patient who is at risk for myocardial ischemic events. Based on these studies, then, limited vasopressor use during hypotensive episodes associated with a change in neurophysiologic monitoring appears defensible, allowing the clinician to treat only those patients who might benefit most, and sparing other patients from its risks.

Figure 33-3. Data from the North American Symptomatic Carotid Trial (NASCET). Of the perioperative strokes, 35% (30/85) occurred intraoperatively, while 65% (55/85) occurred after the patient left the operating room (delayed events). The figure illustrates the time of onset of the 92 surgical outcome events.¹¹⁹

Hypercapnia dilates cerebral blood vessels and thus increases cerebral blood flow. However, hypercapnia during carotid endarterectomy may be detrimental if it dilates vessels in normal areas of the brain while vessels in ischemic brain areas that are already maximally dilated cannot respond. The net effect, then, is a “steal” phenomenon, *i.e.*, a diversion of blood flow from hypoperfused brain regions to normally perfused brain regions. Most authorities recommend the maintenance of normocarbica or moderate hypocarbica at best.

Moderate hyperglycemia may worsen ischemic brain injury. Increased cerebral lactic acidosis resulting from the anerobic glycolysis of increased brain glucose stores is postulated to be directly or indirectly responsible for the adverse effect. Because of the neuroendocrine response to surgery, with its resultant breakdown of glycogen, and the relatively high incidence of diabetes in this patient population, blood sugar levels will often already be mildly elevated during carotid endarterectomy. The administration of dextrose-containing iv fluid may exacerbate hyperglycemia. A similar effect may result from lactated solutions because lactate is metabolized to dextrose. Although there is no proof that the focal neurologic injury that may follow carotid endarterectomy is actually augmented by hyperglycemia, we nonetheless prefer normal saline for intraoperative fluid substitution. Isovolemic hemodilution with dextran or hetastarch may be beneficial in cases of cerebral ischemia because blood viscosity is reduced and attendant microcirculatory disturbances are thus ameliorated.

Virtually all commonly used anesthetic agents reduce cerebral metabolism and thereby decrease the brain's requirements for oxygen. It has been assumed that under anesthesia the brain's tolerance of temporary ischemia is enhanced. However, the notion that reduced cerebral metabolism is associated with cerebral protection has been challenged.¹²⁸ Nonetheless, we believe that as long as this method of pharmacologic brain protection is not clearly refuted, there is no good justification to deny its potential benefits to a patient. The following section reviews the putative benefits of inhalational and iv anesthetic agents as well as hypothermia in reducing cerebral metabolism.

Among the inhalational anesthetics, isoflurane has emerged as the volatile agent with the most potential protective effect against cerebral ischemia. Compared with enflurane and halothane, isoflurane decreased the frequency of EEG-detected cerebral ischemic changes during carotid endarterectomy.¹²⁹ Nonetheless, clinical neurologic outcome was not different among the anesthetic groups. However, isoflurane's protective effects are maximal only at ~2 minimal alveolar concentrations (MAC). At this MAC level systemic hypotension will occur in many patients; therefore, maximal protection may not be clinically achievable. Desflurane and sevoflurane also reduce cerebral oxygen requirements at MAC values comparable to those with isoflurane and result in faster emergence and recovery than isoflurane. Sevoflurane anesthesia for CEA was associated with ischemic EEG changes in 5 of 52 patients at an estimated $rCBF_{50}$ of $11.5 \pm 1.4 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$.¹³⁰ This value of critical cerebral blood flow is lower than values during halothane anesthesia, and slightly higher than values for isoflurane.¹³¹ Desflurane's propensity to cause tachycardia may detract from its use in a patient group in which coexisting coronary artery disease is exceedingly common.

Barbiturates may offer a degree of brain protection during periods of regional ischemia. Thiopental decreases cerebral metabolic oxygen requirements to about 50% of baseline. These maximally achievable reductions in oxygen requirements correspond to a silent, *i.e.*, isoelectric, EEG. Beyond this point additional doses of barbiturates are neither necessary nor helpful. In cases of massive global ischemia where basal cellular metabolism has already deteriorated, even high doses of barbiturates will not improve neurologic outcome. Therefore, some clinicians use thiopental not only for induction of anesthesia but also for continuous infusion and/or as a 4–6 mg · kg⁻¹ bolus just before carotid occlusion. The cardiac depressant effects of the barbiturates may require inotropic support. Unfortunately, no rigorous proof is available that the use of barbiturates in the described manner can improve neurologic outcome after carotid endarterectomy. Excellent results have been obtained for CEA using high doses of barbiturates during carotid occlusion, without neurophysiologic monitoring or shunt placement; on average, tracheal extubation was delayed until 2 hr after surgery was completed.¹³²

Both etomidate and propofol decrease brain electrical activity and thus decrease cellular oxygen requirements. Etomidate preserves cardiovascular stability and may be beneficial in a patient population whose cardiac reserves are often limited. Propofol also allows rapid awakening of the patient and neurologic assessment at the end of surgery. Propofol may also be associated with a lower incidence of myocardial ischemia than is an isoflurane-based anesthetic.¹³³ While the available evidence for the protective effects of etomidate or propofol during carotid endarterectomy is inconclusive, a small series in patients undergoing temporary ischemia for intracranial aneurysm clipping suggests that etomidate, propofol, or barbiturate use prolongs tolerable ischemia and reduces brain infarction.¹³⁴ Some animal studies have supported, and others refuted, the utility of a₂ agonists in reducing cerebral infarction in animal models.

Hypothermia can depress neuronal activity sufficiently to decrease cellular oxygen requirements below the minimum levels normally required for continued cell viability. In theory, hypothermia represents the most effective method of cerebral protection. Even a mild decrease in temperature of about 2–3°C at the time of arterial hypoxemia may reduce ischemic damage to the brain. The first reported carotid endarterectomy was performed with the patient's head covered by ice packs. Unfortunately, this method is cumbersome, unpredictable, and rarely used. We allow patients to cool passively in the operating room and avoid warming the operating suite, iv fluids, or inspired gases until the carotid repair has been completed. Afterward, forced-air warming may counteract the adrenergic response and increased incidence of myocardial ischemia associated with hypothermia in vascular surgery patients.¹⁰²

Effective pharmacologic brain protection is still theoretical. The outcome of cerebral ischemia may be improved by preventing activation of the neuron's excitatory amino acid (EAA) receptor after reperfusion. However, to date no conclusive data exist for use of this method in humans. Ischemia also leads to neuronal calcium overload, which in turn sets off a series of harmful biochemical intracellular events. Given early after the onset of stroke symptoms, nimodipine, a calcium channel blocker, may confer some benefit to patients. Nitric oxide synthesis inhibitors and free-radical scavengers may also have important therapeutic roles. Some centers still use iv steroids to protect the brain from the effects of hypoxia.

Temporary occlusion (“cross-clamping”) of the carotid artery acutely disrupts blood flow, even if flow to the ipsilateral hemisphere of the brain was already markedly diminished by severe stenosis. Continued blood supply to the brain will depend entirely on adequate collateral blood flow through the circle of Willis if no shunt is used. If carotid stenosis has worsened gradually before carotid endarterectomy is performed, collaterals from the circle of Willis may have had time to develop, and the cerebral circulation may not be compromised by carotid occlusion during surgery. However, if collateral flow is compromised because of occlusive disease of the contralateral carotid artery and/or the vertebral arteries, the chances are greater that marked hypoperfusion of the brain will occur during carotid clamping. Indeed, patients with bilateral carotid disease have a higher risk of perioperative stroke after carotid endarterectomy than patients with unilateral disease only. The need for shunts in carotid surgery remains a controversial issue. Some surgeons never use shunts, others use them routinely, and still others use them only selectively. Surgeons who never use shunts usually rely on expedient surgery to avoid neurologic problems and do not report worse overall outcome statistics than those who do.

The routine use of shunts is not risk-free. Placement of a shunt is associated with an embolism-related stroke rate of at least 0.7% from the dislodgement and embolization of atheroma. The technical problems of shunting include air embolism, kinking of the shunt, shunt occlusion against the side of the vessel wall, and injury or disruption of the distal internal carotid artery. Patients with shunts may still develop EEG abnormalities; in these situations, we alert surgeons that shunt

adjustments may be necessary. The shunt may impair surgical access to the artery, thereby increasing cross-clamp time. Most importantly, the use of a shunt is beneficial only if the cause of neurologic dysfunction is inadequate blood flow. However, the majority of studies suggest that as many as 65–95% of all neurologic deficits during carotid endarterectomy may be caused by thromboembolic events (Fig. 33-3), which may occur when the carotid artery is dissected, at which point insertion of a shunt will not prevent a deficit. Not surprisingly, there is no rigorous proof that the routine insertion of a shunt reduces the incidence of postoperative neurologic deficits. In the NASCET trial, shunting (used in 41% of patients) was not associated with a change in risk of stroke.¹¹⁹

Surgeons who use shunts selectively will need a monitoring device of cerebral perfusion to help them decide when to place the shunt. To this end, a variety of cerebral perfusion monitors are used.¹³⁵ Some surgeons simply palpate the distal end of the clamped carotid artery between their thumb and forefinger. If a pulse is detected, collateral flow is presumed to be adequate and they proceed to occlude the carotid artery. Conversely, if there is no pulse, a shunt will be placed. More commonly, however, the mean blood pressure distal to the carotid clamp (also referred to as “stump pressure”) is evaluated invasively. Under halothane anesthesia a mean stump pressure above 60 mm Hg is sufficient to prevent ischemia in most cases. If a nitrous oxide/opioid-based anesthetic is undertaken, the stump pressure must be higher than 60 mm Hg for blood flow to be adequate because cerebrovascular resistance is increased with this anesthetic technique.¹³⁶ The major criticism of stump pressure measurement is the large number of false-positive results; that is, a stump pressure of <60 mm Hg when regional cerebral blood flow (rCBF) is >24 mL · min⁻¹ · 100 g⁻¹ brain. Such results occur in about 30% of patients. Thus, a shunt may be placed when none is needed. In other cases, a false-negative result may be obtained, when an “adequate” stump pressure is measured, yet the patient has stenosis of the middle cerebral artery distal to the arteries that provide “back-bleeding.” In this situation, cerebral ischemia could occur despite a stump pressure >60 mm Hg. Despite these limitations, stump pressure monitoring has the advantages of being inexpensive and readily available; however, its overall value in terms of outcome improvement has not yet been proved.

The interpretation of the information gained from the scalp-recorded EEG has been simplified by the use of computerized data reduction methods. The EEG reflects the spontaneous electrical activity of cortical (surface) neurons. Increasing levels of ischemia lead to a decrease in recorded electrical activity. EEG deterioration begins usually below a cerebral blood flow rate of about 15 mL · min⁻¹ · 100 g⁻¹ brain tissue, but cellular metabolic failure does not seem to occur until blood flow falls below 10–12 mL · min⁻¹ · 100 g⁻¹ brain tissue.¹³⁷ Under conditions of focal cortical ischemia, the frequency of the recorded EEG waves over the affected area of the brain will slow significantly, *i.e.*, >50%. In addition, the amplitude of the waves may decrease (attenuate) to a comparable extent. The appearance of a disorganized background rhythm may also be a sign of ischemia. Finally, as ischemia becomes severe, the EEG will become isoelectric. Ischemic EEG changes occur in 28% of all monitored patients during carotid endarterectomy.¹³⁸ When they occur, they define a patient subgroup with a significantly increased risk of perioperative stroke. The most common manifestations of EEG ischemia during carotid endarterectomy are ipsilateral attenuation, ipsilateral slowing with attenuation, and ipsilateral slowing without attenuation.

In practice, the EEG can be obtained using a 16-channel strip-chart recording or a processed EEG monitor with 2 or 4 channels. A 16-channel strip-chart EEG generally requires a technician to set up the monitor and to monitor and interpret the large amount of (unprocessed) data generated. In contrast, a 2- or 4-channel processed EEG monitor provides less data but can be monitored more easily. Figure 33-4 shows a processed EEG reflecting acute cerebral ischemia following left carotid artery occlusion; the placement of a shunt in this case promptly reversed the ischemic changes.

Figure 33-4. Acute cerebral ischemia following left carotid artery occlusion detected with processed EEG; the placement of a shunt in this case promptly reversed the ischemic changes. (Courtesy of Dr. Bruce L. Gewertz.)

However, EEG monitoring has several limitations.¹³⁵ For one, deep brain structures are not monitored by EEG. Also, in patients with pre-existing or fluctuating neurologic deficits the EEG may be false negative; *i.e.*, these patients can develop perioperative strokes despite the absence of major intraoperative EEG changes. In these patients there may be cell populations that are electrically silent or immediately adjacent to regions of infarction and therefore not monitored by the EEG. The still viable regions may progress to irreversible deterioration in the course of the operative procedure. Furthermore, the EEG may not be an ischemia-specific monitor because decreases in temperature and blood pressure as well as increases in the depth of anesthesia produce EEG changes that mimic ischemic changes. However, EEG changes secondary to anesthetics or hypothermia are more likely to be bilateral, whereas hemispheric ischemia is more likely to affect the electrical activity of only one side of the brain. Thus, we are compulsive in informing the encephalographer about adjustments to the anesthetic regimen.

Intraoperative false-positive results, that is, changes in the EEG without accompanying demonstrable deficits, may be related to several factors. The brain can tolerate relatively brief periods of ischemia without infarction. Thus, temporary, reversible EEG changes should not be expected to produce postoperative deficits routinely. The flow threshold for electrical failure is higher than the flow threshold for metabolic failure. Although the EEG may be viewed as an early-warning system for cerebral ischemia, not all EEG changes indicate that irreversible ischemia is taking place. Finally, focal embolic events may not be detected by the EEG.

Most importantly, the value of relatively costly EEG monitoring has not been rigorously established. Even if the advanced warning of an EEG can prevent some strokes, it would presumably do so only in the minority of patients who suffer strokes from intraoperative hypoperfusion (Fig. 33-3).

Evaluation of the cost-effectiveness of EEG monitoring can be thought of as a comparison of the cost of monitoring with the cost of the deficits that monitoring may prevent. Let us assume that 100,000 carotid endarterectomies are performed each year with a deficit rate of 3% (3000 new deficits each year) and that the use of monitoring devices might prevent one-sixth of these deficits (500 deficits per year). Assume that an additional 15% of patients would undergo temporary shunting of carotid flow because of EEG monitoring and that 0.7% would experience shunt insertion-associated neurologic deficits. This assumption would result in an additional 106 deficits related to monitoring, or a net of 394 deficits preventable by monitoring. If each deficit cost \$100,000, on average, in medical care, loss of wages and productivity, and quality-adjusted years of life, the deficits preventable by monitoring would cost \$39,400,000 per year. The breakeven point for monitoring costs would be \$394 per patient: at that price, the cost of monitoring would equal the cost of the deficits that monitoring would prevent. If monitoring could be provided for less than \$394, it would be cost-effective. This analysis neglects the benefit that EEG monitoring may have in preserving myocardial function (by allowing the anesthesiologist to decrease the afterload in the patient who is at risk for myocardial ischemic events), permitting an unhurried and technically superior endarterectomy, identifying delayed ischemia, and aiding in the detection of shunt malfunction. Unfortunately, there are no data showing that EEG demonstration of neurologic dysfunction during carotid endarterectomy results in better patient outcome than does any other method.

Somatosensory evoked potential (SSEP) monitoring is based on the detection of cortical potentials after electrical stimuli are presented to a peripheral nerve. Detecting the potentials requires computer-assisted mathematical analysis and considerable expertise. In contrast to the EEG, which interrogates only cortical function, SSEP monitoring also evaluates deep brain structures. Any damage to these neural structures results in characteristic changes in the SSEP, usually in a decrease in amplitude and/or an increase in latency. If neural damage is severe, the cortical-evoked potential is completely abolished. Severe damage occurs at about one-third of normal cerebral blood flow, *i.e.*, at 15 mL · min⁻¹ · 100 g⁻¹ brain tissue.

Whereas some studies have been optimistic about the value of SSEP monitoring in the detection of cerebral ischemia, other investigators have concluded that SSEP is neither sensitive nor specific for the detection of ischemic injury during carotid endarterectomy.¹³⁹ Virtually all commonly used anesthetics lead to SSEP changes that mimic changes produced by cerebral hypoxia. Therefore, a constant light plane of anesthesia needs to be maintained if increased latencies and decreased amplitudes of evoked potentials are to be ascribed to inadequate cerebral perfusion. False-negative results may also occur. Based on the available data, we conclude that this monitoring system cannot yet be considered essential for a safe carotid endarterectomy.

Transcranial Doppler (TCD) techniques measure the mean blood flow velocity in the middle cerebral artery. A 40% decrease in flow velocity corresponds with major EEG changes during carotid endarterectomy.¹⁴⁰ Middle cerebral artery flow velocities are significantly lower in patients with stump pressures below 30 mm Hg. TCD can detect acute thrombotic occlusion during carotid endarterectomy, as well as microemboli that occur during initial carotid dissection. In the latter case, the surgeon might be warned to modify his or her technique in the hope of avoiding a significant embolic stroke. In addition, TCD may help in identifying patients who are at risk of developing postoperative hyperperfusion syndrome. TCD flow velocity measurements correlate well with the measurement of regional oxyhemoglobin saturation (rsO₂)

by infrared cerebral spectroscopy.¹³⁵ Whether cerebral spectroscopy alone or in conjunction with TCD will play a role in carotid endarterectomy in the future remains to be determined. Thus, although all these data are certainly encouraging, definitive proof that the use of TCD or tissue spectroscopy will lead to improved outcome is not available.

Cerebral blood flow can also be measured intraoperatively by the intravenous or intracarotid injection of radioactive xenon or krypton. However, the expense and expertise required to collect and interpret the data have limited the use of this method to only a few research centers. Jugular venous oxygen saturation has been proposed to monitor global cerebral blood flow and oxygen consumption. But because of interhemispheric mixing of venous blood, jugular venous oxygen saturation is not capable of reflecting focal cerebral perfusion and is probably of limited use during carotid endarterectomy.

In the North American trial, 93% of patients underwent CEA with general anesthesia; 51% of patients had intraoperative cerebral monitoring (31% EEG, 14% stump pressure, 7% evoked potentials, and 3% transcranial Doppler). However, the use of monitoring was not associated with reduced risk of stroke.¹¹⁹ In summary, none of the above procedures or neurophysiologic monitors has been shown to improve outcome. Because embolism, not hypoperfusion, is probably the most common cause of perioperative stroke, the real value of cerebral monitoring may lie in the avoidance of interventions such as the placement of shunts (which can cause stroke) and blood pressure augmentation (with its detrimental effects on the heart).

Anesthetic and Monitoring Choices for Elective Surgery

General discussions of cardiac function and myocardial ischemia monitoring can be found earlier in this chapter. Our practice with patients undergoing carotid endarterectomy, summarized below, is somewhat different. Our intraoperative monitors include the usual monitors employed during all major, general, or regional anesthetics: precordial stethoscope, temperature probe, blood pressure cuff, pulse oximeter, and an end-tidal carbon dioxide tension monitor. We routinely place an intra-arterial catheter for blood pressure monitoring, so that beat-to-beat changes in pressure are detected and treated promptly. However, in some patients, particularly elderly females, cannulation of the radial artery may be difficult. Before surgery, we also measure the blood pressures noninvasively in both arms because generalized peripheral vascular disease in this patient population can produce striking differences between the two upper extremities.¹⁴¹ However, it is not clear in such a circumstance whether the higher or lower blood pressure should be used to guide hemodynamic management during carotid occlusion.

We routinely monitor leads II and V₅ of the ECG for ST-T segment changes because of the high incidence of perioperative myocardial ischemia after carotid reperfusion.¹⁴² In high-risk patients, we may use TEE as an additional monitor. Rarely is it necessary to use a central venous or pulmonary artery catheter, even if TEE is not available. We seek to avoid central venous or pulmonary artery catheterization because of the risk of an accidental carotid artery puncture during cannulation of the internal jugular vein. We restrict the use of central venous access to the rare patient with uncompensated congestive heart failure undergoing urgent carotid endarterectomy, and then may insert it from the contralateral brachial or subclavian vein. Finally, in our experience, iv access for volume administration can be limited to one well secured, well running medium-bore iv catheter because major blood loss or fluid shifts during carotid endarterectomy are rare.

Maintaining intraoperative hemodynamic stability begins with the preoperative visit. For most patients, the assurance provided by the preoperative interview obviates the need for sedative drugs to prevent anxiety-induced myocardial ischemia. If sedatives are deemed indispensable, a "light" short-acting premedication is chosen to facilitate early perioperative neurologic assessment. Equally importantly, we obtain blood pressure and heart rate determinations from the preoperative clinic, other hospital or clinic visits, and at the time of admission, thus determining the range of a patient's acceptable values. We seek to maintain hemodynamics within this range intraoperatively. Chronic antianginal, antihypertensive, and aspirin medications are generally continued on the day of surgery. Patients who come to the hospital the same day as surgery must be reminded to take their medications at home. When patients forget to take their medications, we give them readily available oral or parenteral substitutes.

In the past, we would routinely administer iv normal saline the night before surgery at a rate of 100 mL · hr⁻¹ for a 70-kg patient. This amount of saline attenuates preoperative hypovolemia and reduces the incidence of severe hypotension after we induce general anesthesia in hypertensive patients. Today, however, because almost all of our patients present to the hospital on the same day as surgery, we encourage patients to drink clear fluids until midnight, and attempt to perform their surgery as the first case of the day; otherwise clear fluids are encouraged up until 4 hr before surgery. In the operating room, we generally avoid administering more than 10 mL · kg⁻¹ of crystalloid in a typical 2-hour operation because fluid overload may contribute to postoperative hypertension.

For procedures performed under general anesthesia, we typically use propofol¹³³ for induction, although thiopental or etomidate may be used. If thiopental is used, esmolol is particularly valuable to blunt hypertensive and tachycardic responses to intubation. However, when a patient has a diastolic blood pressure >100 mm Hg in the operating room or is not well hydrated (often, both conditions exist simultaneously), induction of general anesthesia may result in hypotension. The clinician can anticipate this possibility and induce general anesthesia slowly, being prepared to use pharmacologic blood pressure augmentation if blood pressure decreases excessively. Because the respiratory depression and sedation caused by opioids may persist into the postoperative period and may confound the results of early neurologic assessment, we generally restrict the use of opioids whenever possible (e.g., fentanyl 3–5 mg · kg⁻¹) or use remifentanyl.

In essence, our approach represents a "combined technique." We provide patients with a "light" general anesthetic that permits EEG monitoring and results in blood pressures in the high range of normal. We spray the trachea with 100 mg lidocaine to minimize stimulation by the endotracheal tube during surgery, and often perform a superficial cervical block before incision to decrease anesthetic requirements, postoperative pain, and the need for analgesics. Others have described the use of the laryngeal mask airway (LMA) during carotid endarterectomy. Compared to patients managed with endotracheal intubation, a reduced incidence of hypertensive and tachycardic episodes requiring interventional drug therapy was found in the group whose airway was managed by LMA.¹⁴³ Anesthesia is maintained with 50% nitrous oxide in oxygen and light levels of isoflurane because of its salutary effects on the incidence of cerebral ischemia.¹²⁹ The newer volatile agents, desflurane and sevoflurane, may be used to facilitate rapid awakening and assessment of neurologic status. We do not routinely use continuous infusions of vasopressors (such as phenylephrine) to augment blood pressure, but rely on a patient's endogenous pressure-sustaining responses. Vasopressors are used to treat hypotension or EEG changes. Because sudden onset of bradycardia and hypotension may be caused by activation of baroreceptor reflexes with surgical irritation of the carotid sinus, we ask our surgeons to infiltrate the carotid bifurcation with 1% lidocaine to attenuate this response. However, this practice may result in more postoperative hypertension. We typically use vecuronium or another medium-duration relaxant to provide muscle relaxation, although the choice of muscle relaxant depends on the heart rate we wish to obtain. One of us administers no muscle relaxant except as necessary for intubation. The other usually gives an additional dose of muscle relaxant immediately before carotid occlusion when the concentration of isoflurane is decreased to allow the blood pressure to rise. One limitation of this technique is that it lessens the potential neuroprotective effects of isoflurane because the cerebral metabolic depression it produces is dose-dependent. Passive hypothermia may provide some cerebral protection; therefore, we do not actively warm patients until after carotid reperfusion, at which time forced-air warming may be used for patients who are hypothermic. Our patients are almost always extubated at the end of the surgical procedure after we confirm neurologic integrity. Our overall institutional results are good (mortality of 1%; stroke and myocardial infarction, both 0.76%).¹⁴⁴ Others have achieved similar results using a nitrous oxide/opioid technique or a continuous infusion of thiopental. There is no proof that any one general anesthetic technique provides a superior outcome.

Regional anesthesia is used by many centers for carotid endarterectomy.¹⁴⁵ The necessary sensory blockade of the C2 to C4 dermatomes can be achieved by superficial or deep cervical block or by subcutaneous infiltration of the surgical field. Superficial and deep plexus blocks appear to be equivalent in providing good surgical conditions and patient satisfaction; deep plexus blocks are more effective when a paresthesia is obtained.¹⁴⁶ Proponents of regional anesthetic techniques claim the following advantages: greater stability of blood pressure during surgery, inexpensive and easy cerebral monitoring, avoidance of tracheal intubation in patients with chronic obstructive lung disease, and avoidance of negative inotropic anesthetic agents in patients with limited cardiac reserves. In addition, overall hospital costs associated with the use of regional anesthesia may be lower.

Disadvantages of regional anesthesia are that potential pharmacologic brain protection with anesthetics cannot be provided and that, in the case of panic, sudden loss of consciousness, or onset of seizures, control of the airway may be difficult. While emergent intubation is uncommon, it may be difficult under these circumstances and complicate surgical management. Regional anesthesia requires that the patient remain highly cooperative throughout the operation, and sedation can be provided only to a limited extent during carotid occlusion. In a study of nearly 400 patients who had regional anesthesia for carotid endarterectomy, one-fourth of the patients had neurologic changes with carotid occlusion. These patients were six times more likely (6.6% versus 1.1%) to have permanent neurologic impairment, often due to carotid thrombosis.¹⁴⁷ To date, evidence for the above cited advantages of regional anesthesia remains limited. Others have found no difference in neurologic or cardiac complications or hospital stay between patients receiving regional or general anesthesia for carotid endarterectomy. The NASCET study found no difference in event rate between regional and general anesthesia, although only 7% of the 1415 patients received a regional anesthetic. Based on the currently available evidence, the choice of anesthetic technique should take into account the preference of the surgeon and the experience and expertise of the anesthesiologist.

Initially, the internal carotid artery is isolated where the plaque or ulcerative lesion has been identified radiographically (usually starting near the bifurcation). Heparin is typically given in a dose of 50–100 U · kg⁻¹. The surgeon isolates the diseased carotid segment with clamps or ties placed on the proximal and distal internal carotid artery and on the external carotid artery. After a period of test occlusion during which the adequacy of cerebral blood flow may be assessed with the modalities previously described, an incision is made into the artery. A shunt may be inserted at this time.

The surgeon then endarterectomizes the ulcerated or plaque-containing area. Occasionally, a long or tortuous region is shortened by resection and reanastomosis; or if the remaining portion of the intima is too thin, a vein (often from the leg) or a Dacron patch is used. The use of a patch may also improve long-term patency rates.

Because suturing of the patch requires more time than suturing of the native vessel, an internal shunt is used more often during these procedures. Time is of the essence to help prevent neurologic deficits. If the shunt has been placed, it is then removed and, in all cases, the arteriotomy is closed, usually with a running suture. Shunt placement and removal rarely take less than 1 minute or more than 4 minutes, and the total occlusion time rarely exceeds 40 minutes.

Postoperative Management

Common problems arising after carotid endarterectomy include the onset of new neurologic dysfunction, hemodynamic instability during emergence from general anesthesia, and respiratory insufficiency.¹⁴⁵ Patients who have undergone general anesthesia may be awakened while still on the operating table to permit early neurologic evaluation. A new neurologic deficit may demand immediate re-exploration, or at least arteriography. A few surgeons routinely perform arteriography after restoring blood flow, but most believe that the complications of routine arteriography (emboli, allergic reactions, vasospasm, bleeding from the puncture hole, and stroke) are greater than its benefits (the detection of inadequate repairs, suture lines, or flow). With another method, duplex ultrasonography, the resutured vessel may be imaged at the end of surgery. The risks of arteriography are avoided, but the benefits have not yet been established by randomized controlled trials. Before or soon after we extubate the trachea, we ask the patient to move his extremities to exclude acute thrombosis of the endarterectomy site. The examination should also seek to identify cranial nerve (hypoglossal and facial) injuries arising from surgical manipulation.

Hyperperfusion syndrome is thought to result from blood flow to the brain that is greatly in excess of its metabolic needs following carotid endarterectomy. It often does not occur until several days after surgery, when patients present with severe ipsilateral headache and can progress to develop signs of increased cerebral excitability or frank seizures. Some clinicians have recommended that patients with a high-grade stenosis or previous stroke who develop severe ipsilateral headache following carotid endarterectomy should be started on phenytoin for seizure prophylaxis.

The incidence of both hypertensive and hypotensive episodes after carotid endarterectomy may be >60%. Hypertension is more common than hypotension; left untreated, about 30% of patients will develop severe hypertension with systolic blood pressure >200 mm Hg. Severe hypertension seems to occur more often in patients with poorly controlled preoperative hypertension. Both acute tachycardia and hypertension may precipitate acute myocardial ischemia and failure, and hypertension may lead to cerebral edema and/or hemorrhage. PostCEA hypertension is significantly associated with adverse events (stroke or death, with a statistical trend towards reduced cardiac complications), while postoperative hypotension and bradycardia do not correlate with primary or secondary outcomes.¹⁴⁸ We therefore routinely treat hypertension, if only to reduce the work of the heart. Thus, having excluded and/or treated other causes of hypertension such as bladder distention, pain, hypoxemia, and hypercarbia, we lower systolic pressures of >160 mm Hg and diastolic pressures of >95 mm Hg to within the range of a patient's perioperative values. Hyperdynamic responses accompanying emergence and extubation may be attenuated by prophylactic administration of iv lidocaine, esmolol, labetalol, or nitroglycerin. We prefer to use drugs with short half-lives that can be titrated to avoid undue hypotension. We believe that by supplementation with a regional anesthetic and tracheal lidocaine spray these responses are suppressed. The incidence of myocardial ischemia is high in the first few hours after carotid endarterectomy, even in patients who have been "awake" during carotid endarterectomy with a deep cervical block and prophylactic nitroglycerin infusions.¹⁴² Patients who undergo carotid artery stenting also manifest intra- and post-procedural hemodynamic abnormalities similar to surgical patients.¹⁴⁹ The causes of postoperative hypertension are unclear. Overzealous administration of iv fluid or surgical or chemical denervation of the baroreceptors of the carotid sinus nerve may be responsible. Postoperative hypertension may be associated with an increased incidence of neurologic deficits. Usually, the hypertensive episode has its peak 2–3 hr after surgery, but in individual cases it may persist for 24 hr.

Postoperative hypotension and bradycardia after carotid endarterectomy are less frequent than hypertension. Surgical removal of the atheroma re-exposes the baroreceptors of the carotid sinus nerve to higher levels of transmural pressure and causes brain stem-mediated vagal bradycardia and hypotension. Chemical denervation of the carotid baroreceptors with a local anesthetic by the surgeon results in fewer hypotensive patients but increases the incidence of postoperative hypertension. Over time, the baroreceptors seem to adjust and the hypotensive phase resolves within 12–24 hr. For patients who are hypotensive, some argue against any treatment as long as the ECG is unchanged and the patient's neurologic status is stable. Other clinicians, however, typically administer iv fluids and/or vasopressors such as ephedrine, dopamine, or phenylephrine to restore blood pressure to the low range of normal. Because significant hypertension and hypotension can be due to or caused by myocardial ischemia or infarction, we routinely obtain a 12-lead ECG in the recovery room.

Postoperative respiratory insufficiency may be caused by bilateral recurrent laryngeal nerve injury, a massive hematoma, or deficient carotid body function. Injury to the recurrent laryngeal nerve must be suspected in patients with a history of contralateral carotid endarterectomy or thyroid resection. In such patients, preoperative evaluation of vocal cord function may be considered. Whereas unilateral recurrent laryngeal nerve injury may only manifest as transient hoarseness, bilateral injury of the nerves may lead to paralysis of both vocal cords and hence acute airway obstruction.

Wound hematomas develop in up to 2% of patients after carotid endarterectomy. Whereas small hematomas caused by venous oozing usually can be treated by reversing residual heparin with protamine or by applying gentle digital compression for a few minutes, an expanding hematoma must be carefully and immediately evaluated because tracheal compression and loss of the airway may ensue rapidly. In some cases, evacuation of the hematoma may not relieve the airway obstruction if lymphatic obstruction has produced massive pharyngolaryngeal edema.¹⁵⁰ Indeed, four patients (0.3%) in the NACSET trial died directly due to neck hematomas.¹¹⁹ Risk factors for neck hematoma may also include failure to reverse heparin and the presence of an endotracheal tube beyond the end of surgery.¹⁵¹ Hematomas are more common and delayed if a patch angioplasty has been performed. Therefore, some clinicians routinely reverse heparin with protamine in patients who have had a patch angioplasty. Some studies, however, have suggested that protamine may contribute to postoperative stroke.¹⁵² However, in the NASCET trial, heparin reversal using protamine (used in 40% of patients) was not associated with a change in risk of stroke.¹¹⁹

Surgical manipulation may also damage the nerve supply to the carotid body. While unilateral loss of carotid body function is unlikely to be significant, a bilateral loss may prevent the patient from increasing ventilation in response to a decrease in PaO₂. Therefore, supplemental oxygen should be routinely used in the recovery area. Similarly, drugs that depress respiratory drive should be avoided as much as possible in postoperative pain management. It is our experience that administration of acetaminophen constitutes effective pain relief in most patients when skin infiltration or plexus block with local anesthetic was performed in the operating room.

In experienced centers, carotid endarterectomy causes only minor postoperative physiologic derangements in most patients. As a consequence, routine postoperative intensive care is unusual in our practice and has been questioned. In one study, postoperative intensive care surveillance was necessary only for patients with four or more of the following risk factors: stroke, congestive heart failure, chronic kidney failure, hypertension, arrhythmia, and MI. Equally important, all patients requiring interventions or with adverse outcomes could be identified by the eighth postoperative hour.¹⁵³ We believe that routine admission of all patients to the ICU is probably not necessary and that intensive care surveillance can be limited to high-risk patients. Certain complications of carotid endarterectomy, such as hyperperfusion syndrome or bleeding after a patch angioplasty, may not occur until several days after carotid endarterectomy.

Management of Emergent Carotid Surgery

The patient who awakens with a major new neurologic deficit or who develops a suspected stroke in the immediate postoperative period represents a surgical emergency and requires immediate consultation with a surgeon. Although postoperative neurologic deficits may be due to inadequate collateral flow, carotid thrombosis may cause postoperative stroke and prompt surgical re-exploration can produce significant neurologic improvement. If a new neurologic deficit occurs in the postanesthesia recovery unit, most surgeons believe that immediate re-exploration is indicated, and logic would dictate utilization of pharmacologic methods of "cerebral protection"; but this "logic" is controversial. Alternatively, if the deficit is deemed only focal and minor, it is most commonly due to microembolization. Consequently, noninvasive assessment of internal carotid flow and anticoagulation after exclusion of a hemorrhagic brain lesion usually constitute indicated treatment.

A patient undergoing emergency carotid endarterectomy may have a full stomach and thus may require protection against aspiration of gastric contents. The main goal is to minimize the hemodynamic stress of a rapid-sequence induction while maintaining adequate perfusion pressure across the stenotic lesion. General anesthesia is maintained with any of a variety of techniques aimed at attenuating hemodynamic fluctuations, achieving normocarbia (or a carbon dioxide level slightly below normal, as in elective operations), and maintaining adequate carotid artery perfusion pressure. An anesthetic technique similar to one for elective situations is used.

For patients undergoing neck exploration for a wound hematoma following carotid endarterectomy, oxygen is given at high concentration by face mask with a reservoir bag or Ayre's T-piece. In the event of acute airway obstruction, a high concentration of oxygen in the functional residual volume of the lung may provide additional protection against hypoxemia until the airway is secured by intubation or until the hematoma is evacuated surgically. A tracheostomy or cricothyroidotomy tray should be immediately available, as well as other devices for management of the difficult airway. It may be difficult to visualize the trachea because of edema or because of deviation away from the hematoma, caused by pressure of the hematoma.

If the hematoma does not obstruct the airway and the patient is not having difficulty breathing spontaneously, induction may be accomplished as in an elective procedure. If the airway appears compromised, topical anesthesia of the lips, tongue, posterior pharynx, and epiglottis is provided. The larynx may then be visualized traditionally or with fiberoptic laryngoscopy. Esmolol is particularly useful to control hyperdynamic cardiovascular responses during awake intubation. If no difficulty with tracheal intubation is anticipated, induction is performed as described previously. However, if difficulty is expected, the wound is opened and drained externally, and tracheal intubation is performed before general anesthesia is induced.

AORTIC RECONSTRUCTION

In vascular surgery, understanding the pathophysiology of the disease and anticipating the surgical approach and techniques allow the anesthesiologist to serve the patient most effectively. The surgical goal in these operations is to create an enduring restoration of the normal circulation while minimizing the duration of ischemia to viscera, especially to the renal circulation. This goal is difficult to achieve: each of the possible surgical approaches compromises some aspects while optimizing others. Surgery may be undertaken to correct aneurysmal or occlusive disease; sometimes the two coexist.

Aneurysmal Disease

Aneurysms pose an ever-present threat to life because of their unpredictable tendency to rupture or embolize.^{154,155} Mortality from rupture may be as high as 85% and even patients who receive emergent surgery have mortality rates one-half that. Therefore, early recognition and aggressive surgical management are warranted, even in the absence of symptoms. Thoracoabdominal aneurysms occur in patients with hypertension or other risk factors for atherosclerotic disease. Abdominal aortic aneurysms are not uncommonly detected in elderly patients undergoing coincidental ultrasound scan of the urinary tract.¹⁵⁶

The size of the aneurysm is the most important predictor of subsequent rupture and mortality. A prospective study followed 300 consecutive patients (mean age 70 years; 70% men) who presented with abdominal aortic aneurysm (average size, 4.1 cm) and were initially managed nonoperatively. The diameter of the aneurysm increased by a median of 0.3 cm per year. The 6-year cumulative incidence of rupture was 1% among patients with aneurysms <4.0 cm and 2% for aneurysms 4.0–4.9 cm in diameter. By comparison, the 6-year cumulative incidence of rupture was 20% among patients with aneurysms >5.0 cm in diameter.¹⁵⁷ Larger aneurysms expand even more rapidly. Patients with aneurysms of the abdominal aorta that do not undergo operation have an 80% 5-year mortality, predominantly owing to rupture.

Should these patients therefore undergo surgery for asymptomatic aneurysms? This question was answered by Szilagyi *et al*¹ in 1966 when they showed that, for aneurysms >6 cm in diameter, surgery approximately doubled a patient's life expectancy. Since then, perioperative mortality has declined from 18–25% in the mid-1960s, to 8–12% in the early 1970s, to 2–4% today. The outcome after aortic reconstructive surgery has improved dramatically over the past four decades. Perioperative mortality from supraceliac aneurysms still exceeds 4%. Most morbidity is myocardial, and most myocardial morbidity occurs postoperatively. Also, mortality in patients having repair of small abdominal aortic aneurysm is less than mortality for those having larger aneurysms resected. Consequently, even patients with abdominal aortic aneurysms larger than 6 cm in diameter are considered candidates for aortic reconstructive surgery. This change has resulted from three factors: (1) the lower morbidity associated with elective repair today, (2) the persistently higher mortality (45–90%) associated with emergency aortic reconstruction, and (3) the unpredictability of aneurysm enlargement and rupture.

Although patients undergoing open surgery for aneurysmal disease have higher perioperative morbidity and mortality (by a factor of 2) and a lower median survival time (5.8 versus 10.7 years) than do patients undergoing aortic reconstruction for occlusive disease, successful surgical repair of an abdominal aortic aneurysm is associated with prolonged life expectancy. Still, life expectancy after successful abdominal aortic aneurysm repair is diminished (62% versus 85% expected at 5 years). This suggests that in addition to resection of small aneurysms, attention to coronary artery disease, the cause of most of the late deaths, is probably required to prolong life in these patients. The diagnosis, treatment, and prognosis of coronary artery disease in patients with peripheral vascular disease have already been discussed.

Occlusive Disease

The pathologic conditions that give rise to chronic visceral ischemia include atherosclerotic occlusive disease, fibromuscular dysplasia, inflammatory arteriopathies, external compression, and aneurysmal atherosclerotic disease. They occur more commonly in the elderly, who often are hypertensive, and in persons who have abused tobacco. In most cases, symptomatic disease of the mesenteric artery is due to atherosclerotic narrowing of the origins of the three major visceral vessels: the celiac, superior mesenteric, and inferior mesenteric arteries. The extensive collateral network of the gut is usually sufficient to maintain an adequate intestinal blood supply if only one of these vessels is occluded. However, single-vessel lesions may be important when previous intra-abdominal surgery has interrupted collateral pathways. When there is occlusive disease in the celiac and superior mesenteric arteries, the major mesenteric supply often comes from the inferior mesenteric artery via the marginal artery. If the inferior mesenteric artery is not revascularized during infrarenal aortic grafting, the risk of bowel ischemia is present, with a reported incidence of colonic infarction after aortic operations of 1–2% and that of small bowel infarction of 0.15%, and with a mortality of up to 90% after the occurrence of such infarction.

Acute mesenteric occlusion can be of either embolic or thrombotic origin. If embolic, it commonly has a cardiac source and may follow a recent myocardial infarction. If thrombotic, it may occasionally be due to aortic dissection or trauma but is usually the result of progressing atherosclerosis. Sudden occlusion of the superior mesenteric artery without the previous development of collateral vessels can lead to bowel infarction within a few hours. The diagnosis must be strongly suspected in patients with cardiac disease who suddenly develop severe central abdominal pain, with minimal physical signs. If surgical intervention occurs in the first 4–6 hr before gangrene of the bowel develops, revascularization will reduce the otherwise high mortality and morbidity.

Occlusive disease of the abdominal aorta tends to be progressive, with compromise of the distal circulation leading to disabling claudication or limb-threatening ischemia. In the case of aortoiliac occlusive disease, surgical intervention is indicated only for the relief of disabling symptoms. Compared with abdominal aortic aneurysm surgery, the mean age of patients undergoing aortoiliac reconstruction is ~10 years younger, the surgical mortality is lower, and life expectancy after surgery is higher.

In setting out to correct occlusive disease of the aortoiliac segment, the surgeon endeavors to return to near normal the inflow to the limbs at the groin while maintaining flow to the internal iliac and visceral branches. Patients who have critical limb ischemia and stenotic aortoiliac disease also commonly have occlusive lesions of the femoral, popliteal, or tibial vessels. While the prevalence of distal femoral-popliteal occlusive disease in patients undergoing repair of an abdominal aortic aneurysm is only ~11%, the prevalence is almost 50% in patients presenting for occlusive aortoiliac procedures. The long-term patency of the aortobifemoral bypass depends on adequate “run-off,” that is, the status of distal occlusive disease in the femoral segment. The need for subsequent femoral-popliteal bypass can be reduced greatly if the profunda femoris artery is opened by profundoplasty performed concomitantly with the aortobifemoral bypass. This may prolong surgery but is beneficial to the patient. Despite profundoplasty, some patients will still require subsequent distal revascularization.

Pathophysiology of Aortic Occlusion and Reperfusion

Occlusion of the aorta, particularly at the supraceliac level, has consequences for many organ systems, including the cardiovascular system and visceral organs to which blood flow may be impaired. Supraceliac aortic occlusion carries higher risk for patients, particularly when concomitant renal or visceral revascularization is required. Visceral organ ischemia is usually responsible for mortality rates that can approach 25%, although institutions where these procedures are performed routinely have reported substantially lower mortality rates. Prolonged cross-clamp times are associated with increased risks of visceral ischemia. Complications include renal failure, mesenteric/colonic ischemia, hepatic ischemia with coagulopathy, and spinal cord ischemia.

Arterial hypertension routinely occurs after aortic occlusion. The mechanisms of this response have remained controversial. Beyond increased afterload, etiologies proposed include changes in preload, blood volume distribution, myocardial performance, and activation of the sympathetic nervous system. The pathophysiology of aortic clamping and unclamping has been extensively summarized by Gelman.¹⁵⁸

The level at which the aorta is occluded affects the degree of hemodynamic response. Blood volume shifts from the lower to upper half of body during high aortic cross-clamp owing to lower splanchnic venous capacitance (Fig. 33-5). Edema of the head and neck often follows supraceliac clamping, and may preclude early extubation. Shifted blood volume results in increased left ventricular preload. Our work using TEE has demonstrated a 28% increase in left ventricular end-diastolic area with supraceliac aortic occlusion (Table 33-8).¹⁵⁹ Most studies concur that cardiac output decreases with supraceliac occlusion, especially in patients with underlying coronary disease, despite compensatory mechanisms that seek to augment contractility in the setting of elevated preload and afterload (Fig. 33-6). Although elevated systemic arterial pressure may also be helpful by increasing coronary perfusion, increased preload and afterload associated with high thoracic aortic occlusion also increase myocardial oxygen demand and can produce myocardial ischemia. Renin activity increases with suprarenal or infrarenal aortic occlusion and may contribute to hypertension. Epinephrine and norepinephrine levels consistently increase after aortic occlusion. These changes may help the myocardium increase contractility to adapt to elevated afterload and preload, but our work suggests that these responses are associated with postoperative cardiac and renal dysfunction.

Figure 33-5. Blood volume redistribution during aortic cross-clamping. This schedule depicts the reason for the decrease in venous capacity, which results in blood volume redistribution from the vasculature distal to aortic occlusion to the vasculature proximal to aortic occlusion. If the aorta is occluded above the splanchnic system, the blood volume travels to the heart, increasing preload and blood volume in all organs and tissues proximal to the clamp. However, if the aorta is occluded below the splanchnic system, blood volume may shift into the splanchnic system or into the vasculature of other tissues proximal to the clamp. The distribution of this blood volume between the splanchnic and nonsplanchnic vasculature determines changes in preload. AoX = aortic cross-clamping; - and + = increase and decrease, respectively. Table 33-8. EFFECT OF LEVEL OF AORTIC OCCLUSION ON CHANGES IN CARDIOVASCULAR VARIABLES

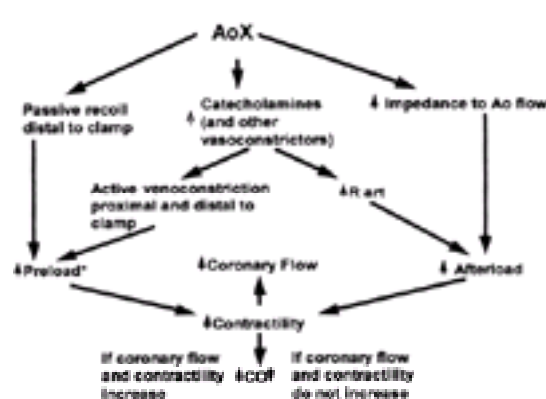

Figure 33-6. Systemic hemodynamic response to aortic cross-clamping. Preload does not necessarily increase. If during infrarenal aortic cross-clamping blood volume shifts into the splanchnic vasculature, preload does not increase (Fig. 33-5). AoX = aortic cross-clamping; Ao = aortic; Rart = arterial resistance; - and + = increase and decrease, respectively; * = different patterns are possible (see Fig. 33-5). (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology* 82:1026, 1995.)

Our work with TEE has shown that myocardial dysfunction is routine in patients undergoing supraceliac aortic occlusion. In these patients, mean arterial pressure rises 54%, PCWP rises 38%, and ejection fraction decreases by 38% (Table 33-8). Additionally, 92% of the patients studied had myocardial ischemia, as evidenced by abnormal wall motion and thickening.¹⁵⁹ Abnormal wall motion generally persists despite aggressive nitrate therapy, but usually resolves promptly after aortic unclamping. Therefore, nitrates can also be used to treat increases in preload, but they will not prevent all wall motion abnormalities. Care must be taken when using vasodilators so that decreased blood flow distal to supraceliac aortic occlusion does not promote visceral ischemia (Fig. 33-7). This sets up two competing goals, similar to the conflicts in hemodynamic management for carotid endarterectomy, because a higher blood pressure may be good for vital organ perfusion, but bad for the heart. In general, we tolerate arterial pressures up to 200 mm Hg during supraceliac occlusion, unless other means (discussed below) are used to perfuse the lower part of the body or prolong the tolerable period of visceral ischemia.

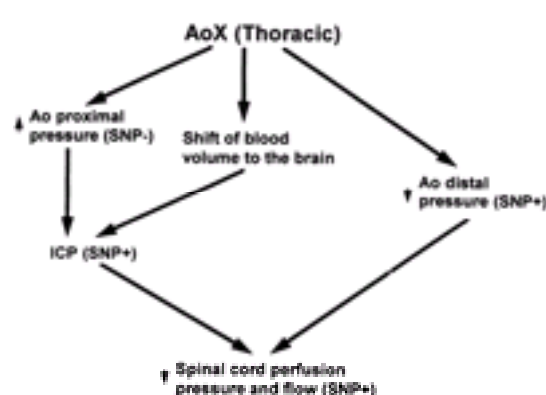

Figure 33-7. Spinal cord blood flow and perfusion pressure during thoracic aortic occlusion, with or without sodium nitroprusside (SNP) infusion. The changes (arrows) represent the response to aortic cross-clamping *per se*. SNP+ = SNP aggravates the effect of cross-clamping; SNP- = SNP counteracts the effect of cross-clamping; AoX = aortic cross-clamping; Ao = aortic; ICP = intracranial pressure; - and + = increase and decrease, respectively. (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology* 82:1026, 1995.)

Hemodynamic and echocardiographic changes are much more modest in patients undergoing infrarenal or infrarenal aortic occlusion (Table 33-8). The neuroendocrine changes are also less severe in patients undergoing infrarenal aortic occlusion compared with supraceliac occlusion. With infrarenal aortic occlusion, blood volume from the infrarenal vasculature may shift to the compliant splanchnic vasculature, producing relatively small changes in cardiac preload (Fig. 33-5). The hemodynamic responses to cross-clamping and unclamping are further attenuated in patients undergoing aortic occlusion for reconstruction of occlusive disease compared with those having aneurysm repair. Patients with occlusive disease likely have developed collateral circulation, which can continue to perfuse the lower body during aortic cross-clamping.

Unclamping of the thoracic aorta can result in severe hypotension (Fig. 33-8). Reactive hyperemia after reperfusion may be attenuated by aggressive fluid loading just before reperfusion and gradual release of the aortic clamp. Hypotension may also be due to humoral factors. Tissues distal to aortic occlusion become acidotic;

however, treatment with bicarbonate does not reliably prevent hypotension upon reperfusion. Treatment with bicarbonate does result in hypercarbia, and ventilation must be increased proportionally.

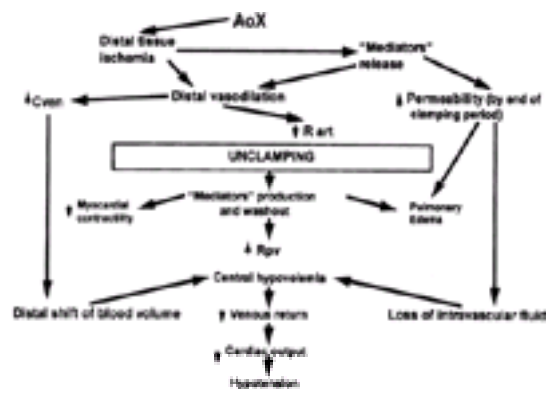

Figure 33-8. Systemic hemodynamic response to aortic unclamping. Preload does not necessarily increase. AoX = aortic cross-clamping; Cven = venous capacitance; Rart = arterial resistance; Rpv = pulmonary vascular resistance; - and $\bar{\bar{}}$ = increase and decrease, respectively. (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology* 82:1026, 1995.)

Humoral factors that may contribute to organ dysfunction after aortic occlusion include acidosis, the renin-angiotensin system, the sympathetic nervous system, oxygen free radicals, prostaglandins, platelet, and neutrophil sequestration, complement activation, and cytokine release. Tissue hypoxia leads to metabolism of ATP, producing adenosine, hypoxanthine, xanthine oxidase, and oxygen free radicals. Some workers have recommended the use of mannitol before aortic clamping and unclamping because it functions as a hydroxyl free radical scavenger and may prevent tissue injury. Mannitol decreases the production of thromboxane after aortic unclamping, possibly decreasing leukocyte deposition in the lung after aortic surgery.¹⁶⁰ Prostaglandins are increased with aortic occlusion, but studies are hampered by confounding factors, such as prostacyclin release, which can result from mesenteric traction. The response to mesenteric traction can cause profound vasodilation and facial flushing, which can be treated with a agonists or nonsteroidal anti-inflammatory drugs (NSAIDs).¹⁶¹ We ask our surgeons to release mesenteric traction while we restore intravascular volume and provide pharmacologic support of afterload; we generally prefer not to use NSAIDs because of their effects on platelet function. C3a and C5a increase during abdominal aortic aneurysm surgery and can produce smooth muscle contraction and pulmonary hypertension. Sludging in tissues distal to aortic occlusion may produce microaggregates, which can exacerbate pulmonary and other tissue injury. Hypoxic insult to the intestines during aortic occlusion and increased gut permeability can produce endotoxemia during aortic reconstruction. After thoracoabdominal aortic reconstruction, activation of polymorphonuclear leukocytes (PMNs) is highly correlated with plasma endotoxin levels; PMN activation may better predict renal and respiratory failure than aortic cross-clamp times or transfusion requirements.¹⁶²

Aortic aneurysm repair is associated with endotoxin, proinflammatory, and an almost coincidental anti-inflammatory cytokine release.¹⁶³ High tumor necrosis factor (TNF) levels may be associated with adverse outcome; however, some studies have suggested that impaired TNF responses are associated with higher APACHE scores and poor outcomes.¹⁶⁴ After open aortic aneurysm repair, peak plasma concentrations of TNF and interleukin-6 (IL-6) are significantly higher in hypotensive patients and in those who die.¹⁶⁵ During endovascular repair, the release of IL-6 from the aneurysmal thrombus can cause leukocyte stimulation and production of TNF- α .¹⁶⁶ With endovascular repair, intestinal ischemia seems less profound, with different cytokine activation patterns (increased IL-6 in conventional surgery and increased TNF- α in endovascular repair), and less dramatic compared to open techniques.¹⁶⁷ Anesthetic techniques appear to minimally influence inflammatory cytokine stress responses; rather, cytokine responses are greatest with prolonged operative times.¹⁶⁸ Therefore, further research is needed to determine if pharmacologic therapy of the inflammatory response to surgery can reduce morbidity and mortality after aortic reconstruction. High-dose methylprednisolone may be effective in reducing the inflammatory response and its mediators, improving pulmonary function, reducing pain and fatigue, and shortening hospital stay after aneurysm resection. Methylprednisolone also decreases C-reactive protein concentration and suppresses T-cell activation.¹⁶⁹

Spinal cord ischemia occurs in 1–11% of operations involving repair of the distal descending thoracic aorta.¹⁷⁰ An understanding of the spinal cord blood supply explains this dreaded complication (Fig. 33-9).¹⁷¹ The two posterior arteries, which together supply only 25% of the blood to the cord, are formed from the anastomoses of the posterior branch of the vertebral artery and the ascending branch of the bifurcation of the second posterior radicular artery. The anterior spinal artery, which supplies blood to the anterolateral 75% of the cord, is formed throughout by a series of radicular arteries. The mid-thoracic region, supplied by the anterior spinal artery, usually receives only one afferent vessel, which arises from a left or right intercostal vessel. The afferent arteries to the posterior spinal cord from T2 to T8 are also poor in collateralization. The blood supply to the thoracolumbar cord (from T8 to the conus terminalis) is derived from the radicular artery known as the artery of Adamkiewicz. It arises from the left side in 60% of cases. In 75% of cases it joins the anterior spinal artery between T8 and T12, and in 10% of cases it joins between L1 and L2. Although other radicular arteries supply this third section, much of the blood flow in the anterior spinal artery is dependent on the artery of Adamkiewicz.¹⁷² Because the flow in the spinal arteries is dependent on collateralization and is often bidirectional, the blood supply to the spinal cord can be “stolen” and “given” to the rest of the body when pressures there are lower. Such a situation may arise when a single high aorta-occluding clamp is applied. Spinal cord ischemia is a devastating complication and much energy is spent trying to prevent it. To date, the only definitive preventive methods are fast surgery and maintenance of normal cardiac function.

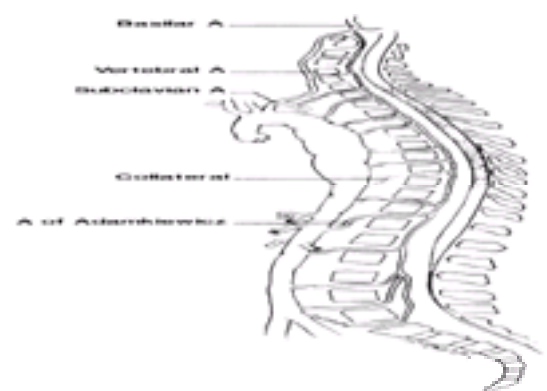

Figure 33-9. The artery of Adamkiewicz usually arises at the T11–12 level and provides the blood supply to the lower spinal cord. Its variable location and the uncertainty of additional collateral blood supply explain, in part, the unpredictability of paraplegia following descending aortic surgery. (Reprinted with permission from Piccone W, DeLaria GA, Najafi H: Descending thoracic aneurysms. In Bergan JJ, Yao JST (eds): *Aortic Surgery*, p 249. Philadelphia, WB Saunders, 1989.)

Infrarenal aortic reconstruction may be associated with a 3% incidence of renal failure, while the rates for supraceliac occlusion may be five times as great. With suprarenal occlusion, renal blood flow decreases by >80%. These significant reductions in renal perfusion are not improved by dopamine or mannitol infusion.¹⁷³ Even when the aorta is occluded below the renal arteries, renal hypoperfusion may result. In one study, infrarenal aortic cross-clamping decreased renal blood flow by 38%, increased renal vascular resistance by 75%, and redistributed blood flow from the renal cortex. These changes persisted for at least 1 hr after release of the aortic clamp, but early signs of renal tubular damage, such as the appearance of lysozyme in the urine, were never observed.¹⁷⁴ In one series of patients undergoing thoracoabdominal aneurysm resection, 13% required dialysis; this complication occurred more frequently in patients with preoperative renal dysfunction or a greater extent of the aortic replacement, and in those who developed coagulopathy, paraplegia, or paraparesis. We believe that the incidence of renal failure is related both to the amount of aorta involved and to preoperative renal dysfunction.³⁹

Patients undergoing thoracoabdominal aneurysm resection have a particularly high incidence of pulmonary complications. Aortic reperfusion may result in pulmonary sequestration of microaggregates and neutrophils, which may contribute to postoperative respiratory dysfunction. Pulmonary vascular resistance routinely rises after reperfusion; increased permeability and pulmonary edema are not uncommon. As noted above, mannitol may attenuate these responses.¹⁶⁰

Surgical Procedures for Aortic Reconstruction

In vascular surgery, anesthesiologists serve the patient most effectively by understanding the pathophysiology of the disease and anticipating the surgical approach

and techniques. The surgical goal in these operations is to create an enduring restoration of the normal circulation to the viscera while minimizing the duration of ischemia to viscera, especially to the renal circulation.

Generous exposure of the thoracic and abdominal aorta and its major branches can be obtained with a left thoracoabdominal incision and retroperitoneal dissection. The thoracoabdominal approach is favored for complex thoracoabdominal aortic replacement in the presence of stenotic or aneurysmal disease. The visceral branches are often excised from the parent aorta with a button of aortic wall. If the patient also has mesenteric occlusive disease (approximately one-fourth of patients undergoing thoracoabdominal aortic aneurysm surgery), endarterectomy of these branch vessels is performed before they are attached to small openings cut in the graft at appropriate positions. If only mesenteric revascularization is to be performed and aortic replacement is not used, endarterectomy of any or all the major branches of the aorta may be performed with this exposure.

Elective surgery for asymptomatic mesenteric occlusive disease is generally not justified because the risks of surgery often outweigh the possible gains. Perioperative mortality ranges from 7.5–18%. Cardiac disorders, postoperative hemorrhage, and early graft occlusion with bowel infarction are the major causes of perioperative death. Surgery is indicated for symptomatic patients and for a small group of asymptomatic patients with proven major occlusive disease of mesenteric vessels who are to undergo a concomitant intra-abdominal procedure that is likely to interrupt collateral pathways. Such procedures include aortic reconstruction for occlusive or aneurysmal disease and colonic, small bowel, or gastric resections. Surgery may be performed for acute or chronic visceral ischemia. Better long-term results of surgery for chronic visceral ischemia may be obtained in elective procedures by performing as complete a revascularization as possible. If single-vessel endarterectomy is performed, it may be carried out for either the celiac axis or the superior mesenteric artery. To overcome the problem of kinking from the infrarenal location, surgeons have used externally supported Gore-Tex grafts. A transabdominal approach is satisfactory for most procedures, including supraceliac grafting. A left thoracoretroperitoneal approach, as used for thoracoabdominal aneurysms, may be advantageous for transaortic endarterectomy of the celiac axis and the superior mesenteric artery.

Reconstruction of the infrarenal aorta is performed either to replace a segment in the presence of aneurysmal degenerative disease or to increase inflow to and outflow from a vessel with stenosing occlusive disease. Although the natural history of the two diseases is different, the segmental nature of the disease processes, with relatively normal vessels above and below the lesion, provides the basis for reconstruction in each. Recommended preoperative evaluations of the patient's anatomy include palpation alone, ultrasonography, computed tomography, digital subtraction angiography, aortography, and magnetic resonance imaging. Aortography exposes the patient to risks and increases costs but allows determination of the presence of iliac occlusive or aneurysmal disease, juxtarenal or suprarenal extension of the aneurysm, renal artery aneurysmal or occlusive disease, and visceral artery lesions.

The most popular surgical exposure for either occlusive or aneurysmal abdominal aortic disease is through a vertical anterior midline abdominal incision, with a transperitoneal approach to the retroperitoneal structures. Another approach gaining favor is a retroperitoneal one anterior to the kidney. In a randomized, prospective trial that compared the transabdominal with the retroperitoneal approach to the aorta for routine infrarenal aortic reconstruction, there was no difference in pulmonary complications. The retroperitoneal approach was associated with less ileus and small bowel obstruction, shorter stays in the hospital and ICU, and lower hospital costs. It was accompanied, however, by an increase in long-term incisional pain.¹⁷³

After the relevant portions of the aorta and the iliac arteries are exposed, the aneurysmal segment of the aorta is replaced with a graft. Before aortic occlusion, heparin is commonly administered systemically to reduce the risk of thromboembolic complications. It is now recognized that distal ischemia complicating aortic surgery is not generally due to thrombosis, but rather to dislodgement of atheroemboli from the diseased aorta. The recognition of the embolic nature of distal ischemic problems suggests that in the absence of major distal occlusive disease, systemic heparinization may be unnecessary in the repair of abdominal aortic aneurysms.

A tube graft (*i.e.*, end-to-end anastomoses on both sides) in which the graft is covered with old aorta is often used for aneurysmal resection. When the iliac vessels are not aneurysmal or stenotic, a tube graft may be used as replacement for the diseased aorta, thus making the procedure faster with less blood loss. The standard graft material, in use since the late 1950s, has been Dacron, in either knitted or woven form. Dacron grafts appear to be associated with rare episodes of anaphylactic reactions, which may be related to the stabilizers used in their manufacture.¹⁷⁵ More recently, polytetrafluoroethylene grafts, which are less porous, have become available.

Arterial reconstruction surgery has been developed on the basis of the principle of anatomic correctness. Although this is usually the easiest and best option, situations do occur that require less advantageous revascularization procedures. Such situations include repeat surgery, surgery for graft infection, the presence of contraindications to transabdominal surgery (*e.g.*, sepsis, adhesions, radiation therapy, malignancy), as well as less traumatic alternatives in frail, elderly, high-risk patients. In general, the price paid when alternative techniques such as axillofemoral bypass are used is reduced long-term patency (~50% at 3 years). Temporary axillofemoral bypass may also be performed to decompress the upper half of the body during surgery requiring thoracic aortic occlusion. Another option for reconstruction in the presence of unilateral iliac occlusive disease is femorofemoral bypass, either alone or in combination with axillo-unifemoral or aorto-unifemoral bypass. These procedures also have lower long-term patency rates than anatomically correct revascularization.

Several situations may cause the surgeon to change from an infrarenal procedure, which is less risky to the heart and other organs, to a suprarenal procedure. Aneurysms of the abdominal aorta involve the pararenal aorta in up to 20% of cases. Also, significant stenosis of the renal artery may coexist and require repair. Significant stenosis of the celiac trunk or superior mesenteric artery may be repaired at the time of abdominal aortic reconstruction. The patient who has previously undergone aortic surgery, para-aortic lymph node dissection, or radiotherapy will frequently require anastomosis to a higher graft origin. Ruptured aneurysms often must be controlled initially by supraceliac clamping. In these cases, great care must be taken so that material is not dislodged into the renal arteries during operative manipulation and clamping.

Endovascular Surgery of Aortic Aneurysms

Endovascular repair has exploded recently.¹⁰ It is associated with less hemodynamic changes,¹⁷⁶ reduced stress responses, lower mortality, and shorter hospital length of stay compared to open surgery.¹⁹ With experience, many centers report an evolution from general anesthetics to regional anesthetics to local with sedation. However, complications can occur, particularly during the early experience ("learning curve") in an institution. A large European registry found that 2.5% of patients underwent a conversion to an open AAA repair; 10% had device-related or procedure-related complications; and 3% had arterial complications.¹⁷⁷ Thirty-day mortality was 2.6% overall, and higher with higher ASA physical classification. Older patients (>75 years), patients with impaired cardiac status, and those considered too "sick" for open surgery had more complications. Myocardial ischemia, angina, and dysrhythmias may result from the fever and tachycardia that routinely occur after endovascular repair. Endoleak (failure to completely exclude the aneurysm sac from the systemic circulation) occurred in 16% immediately after the procedure and in 9% at 30 days, and may require subsequent open operation. We conclude that endovascular procedures show great promise, but their long-term viability remains unknown. These procedures will continue to challenge anesthesiologists, especially when performed in patients who would not have been considered surgical candidates in the past.

Protecting the Spinal Cord and Visceral Organs

Thoracic aortic occlusion reduces distal blood flow tremendously (see Fig. 33-7). In 1–11% of operations involving repair of the distal descending thoracic aorta, spinal cord ischemia does occur. Various strategies have been used to protect the spinal cord from ischemia, including maintenance of proximal hypertension during cross-clamping, local or systemic hypothermia, magnesium, cerebrospinal fluid drainage, papaverine, and a variety of other drugs to protect the brain and spinal cord during resection of abdominal or thoracoabdominal aneurysms or coarctation repairs.¹⁷⁰ Spinal cord sensory-evoked or motor-evoked potentials may prove useful in predicting patients at risk for spinal cord ischemia and in gauging spinal cord protection, but there has not been much experience in the use of the techniques. Spinal cord metabolism can be reduced by moderate hypothermia and high-dose barbiturates. Local hypothermia achieved by infusion of cold saline into the epidural space, when combined with CSF drainage, has been reported to significantly reduce paraplegia rate.¹⁷⁸ Alternatively, femoral-femoral bypass and deep hypothermic cardiac arrest may be used in patients at high risk of paraplegia.¹⁷⁹ Reperfusion injury may be addressed by the use of mannitol, steroids, calcium channel blockers, and avoidance of hyperglycemia. The multitude of proposed pharmacologic and surgical maneuvers to reduce spinal cord ischemia and neurologic deficits after thoracic aortic occlusion highlights the serious nature of this complication and the lack of consensus on its prevention. Table 33-9 summarizes some of these approaches.¹⁷⁰ We still believe that short cross-clamp times are the common element of successful regimens.

| |
|--|
| Limitation of cross-clamp duration |
| Distal circulatory support |
| Reattachment of critical intercostal arteries |
| CSF drainage |
| Hypothermia |
| Moderate systemic (32–34°C) |
| Epidural cooling |
| Circulatory arrest |
| Maintenance of proximal blood pressure |
| Pharmacotherapy: |
| Systemic: |
| Corticosteroids, barbiturates, sodium, calcium channel antagonists, O ₂ free radical scavengers, NMDA antagonists, mannitol, magnesium, vasodilators (aldosterone papaverine, prostacyclin), perfluorocarbons, colchicine |
| Intraaortic: |
| Papaverine, magnesium, tetracaine, perfluorocarbons |
| Avoidance of postoperative hypotension |
| Sequential aortic clamping |
| Enhanced monitoring for spinal cord ischemia |
| Somatosensory evoked potentials (SSEP) |
| Motor evoked potentials (MEP) |
| Hydrogen saturated saline |
| Avoidance of hyperglycemia |

Table 33-9. METHODS OF SPINAL CORD PROTECTION DURING DESCENDING THORACIC AORTIC SURGERY¹⁷⁰

Some surgeons place a Gott shunt, a heparinized tube that can decompress the heart and also provide distal perfusion. The Gott shunt can be placed proximally into the ascending aorta (the most common site), the aortic arch, the descending aorta, or the left ventricle, and inserted distally into the descending aorta (most commonly), the femoral artery, or the abdominal aorta. Even with a Gott shunt or partial bypass, there is an obligatory time of visceral ischemia when the visceral blood supply arises from a point between the proximal and distal clamps. Placement of a shunt may result in atheroembolism, which can produce rather than prevent ischemic injury and death. Other surgeons may place a temporary *ex vivo* right axillofemoral bypass graft before positioning for thoracotomy. After the thoracic aortic surgery is completed, the axillofemoral graft is removed. The placement of a shunt or distal perfusion attenuates the hemodynamic response to aortic unclamping, reduces acidosis, and could conceivably ameliorate the hormonal and metabolic changes that accompany aortic occlusion.

Other groups have chosen to use partial bypass, either from the left atrium or ascending aorta, to the iliac or femoral artery to provide distal perfusion and decompress the heart. A heat exchanger may be used to induce hypothermia, which may be neuroprotective. Segmental sequential surgical repair may minimize the duration of ischemia to any given vascular bed.¹⁸⁰ Intercostal artery reattachment in hopes of preserving blood flow to the anterior spinal cord may also be beneficial. After reperfusion, the heat exchanger can be used to warm the patient. Other potential advantages of left atrial–left femoral artery shunt with centrifugal pump support are better operative field exposure, afterload reduction, avoidance of clamp injury, and maintenance of stable distal aortic perfusion without heparin.

Using rapid autotransfusion, some surgeons repair aneurysms of the descending thoracic and thoracoabdominal aorta by using an “open” technique, in which a single cross-clamp is placed proximal to the aneurysm to exsanguinate the lower body.¹⁸¹ A low incidence of spinal cord injury (8.5%) and renal insufficiency (5.6% dialysis) using this technique may result from the free draining of the intercostal and lumbar arteries during aortic occlusion, which decreases cerebrospinal fluid and central venous pressures and increases spinal cord perfusion gradients. A markedly reduced incidence of neurologic deficits has been reported when distal aortic perfusion is combined with drainage of cerebrospinal fluid.¹⁸² Cerebrospinal fluid drainage is used in the hope of improving the pressure gradient, allowing spinal cord blood flow as aortic occlusion lowers distal arterial pressures and increases the central venous pressure. As in almost all other successful series, patients with short cross-clamp times (<30 min) had fewer neurologic deficits.¹⁷⁰ The new endovascular techniques represent an alternative therapy when anatomy permits; lower paraplegia rates have been reported compared to open surgery.¹⁸³

The development of acute renal failure after aortic reconstruction is associated with a high morbidity and a mortality exceeding 30%.³⁹ This complication is most frequent in patients with ruptured aneurysms who have significant hypotensive episodes and in those for whom suprarenal aortic clamping is required. Approximately one-fourth of patients undergoing thoracoabdominal aortic aneurysm repair have occlusive visceral disease, which may also be corrected to reduce the risk of renal failure without increasing the risk of gastrointestinal complications. As in the preservation of other organ function, we believe that maintenance of cardiac function represents the best prophylaxis against renal failure.

Previous work from our group has shown that intraoperative urinary output is not predictive of postoperative renal function. In 137 patients undergoing aortic reconstruction (38 at the suprarenal level), we found no significant correlation between intraoperative mean urinary output, or lowest hourly urinary output, and changes from preoperative to postoperative levels of creatinine or blood urea nitrogen (Fig. 33-10).¹⁸⁴ Thus, urinary output, which is believed to be an index of perfusion and is therefore monitored routinely during surgery, was not predictive of postoperative renal function in normovolemic patients. When patients who underwent aortic occlusion at the suprarenal level were compared with those who underwent occlusion at the infrarenal level, there was no difference in postoperative renal function. Rather, preoperative renal dysfunction was the most powerful predictor of postoperative renal dysfunction.

Figure 33-10. Lowest hourly intraoperative urinary output and maximal adverse change in renal function as assayed by change in creatinine from preoperatively to 7 days postoperatively; there was no correlation between lowest intraoperative urinary output and change in renal function postoperatively. (Modified with permission from Alpert RA, Roizen MF, Hamilton WK *et al*: Intraoperative urinary output does not predict postoperative renal function in patients undergoing abdominal aortic revascularization. *Surgery* 95:707, 1984.)

The use of mannitol, furosemide, dopamine, or fenoldopam, however, has not been clearly shown to prevent renal failure.³⁹ We believe that preoperative renal function and the maintenance of an appropriate intravascular volume and normal myocardial function are the most important determinants of postoperative renal function. Recent work in patients with diabetes and chronic renal insufficiency undergoing coronary angiography has shown that maintaining intravascular volume is superior to the use of furosemide or mannitol in preventing dye-associated tubular necrosis.¹⁸⁵ These results may be particularly applicable to vascular surgery patients who frequently undergo angiography shortly before surgery.

If prolonged renal ischemia is anticipated, selective profound hypothermia and the direct intra-arterial infusion of mannitol into the kidneys may decrease the incidence of postoperative renal impairment. Our management, however, is biased by the results of our own studies. Thus, when intraoperative urinary output is $<0.125 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$, we exclude mechanical problems in urine collection and ensure the adequacy of left-sided cardiac filling volumes or pressures. We then continue to monitor but do not usually treat. Urinary output usually returns to acceptable levels within 2 hr. If it does not, or if we are uneasy about low urinary output, 2–5 mg of furosemide or mannitol $0.25 \text{ g} \cdot \text{kg}^{-1}$ is administered intravenously to stimulate urine production. Dopamine at $3\text{--}5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ may be used, but its prophylactic value has not been proven in patients undergoing aortic surgery.¹⁸⁶ It may even result in visceral hypoperfusion.¹⁸⁷ Thus, virtually all investigators have concluded that maintenance of adequate intravascular volume and myocardial function largely prevents renal insufficiency.

Monitoring and Anesthetic Choices for Aortic Reconstruction

We routinely place arterial catheters in patients undergoing aortic reconstruction. In patients undergoing thoracic aortic clamping with distal perfusion, we may measure distal pressure as well. We also routinely place a pulmonary artery catheter (PAC) in patients undergoing suprarenal aortic cross-clamp, but not in patients when the clamp will be infrarenal. Placement of the PAC can usually wait until induction of anesthesia is completed. In some relatively healthy patients, the risk of pulmonary artery catheterization probably exceeds the benefit.^{188,189} However, we do place PACs routinely in patients with a history of congestive heart failure, diabetes with end-organ damage, cor pulmonale, renal insufficiency, or poor left ventricular function on preoperative or intraoperative echocardiography.

For patients undergoing thoracic or thoracoabdominal aortic resection, we may place a dialysis catheter in a femoral or subclavian vein. This large catheter provides two very large-bore sites for transfusion and facilitates postoperative hemodialysis in the unfortunate cases in which renal failure occurs. For a patient undergoing an infrarenal procedure, we are generally satisfied with a 9 French introducer in the right internal jugular vein (with a triple-lumen central venous catheter or a PAC) and a large-bore peripheral iv catheter.

If we elect to drain cerebrospinal fluid, we use two regular epidural trays and place catheters into the intrathecal space at L3–4 and L4–5. We use two catheters because one may kink. We allow cerebrospinal fluid to drain passively, typically removing 50 mL before aortic cross-clamp and another 50 mL during aortic occlusion. Catheters with a one-way pressure valve allow drainage only when the cerebrospinal fluid pressure exceeds 5–10 mm Hg. Some clinicians have used larger needles made specifically for lumbar cerebrospinal fluid drainage¹⁸⁰; these are placed the night before surgery in case a “bloody tap” results, so that clotting may be assured. We generally wait until coagulopathy, which is common after thoracoabdominal repair, has resolved to remove cerebrospinal fluid drains, usually on the first or second postoperative day.

Virtually all anesthetic techniques and drugs have been used for aortic reconstructive surgery. We believe that our ability to maintain hemodynamic equilibrium and attend to detail is more crucial to outcome than is the choice of drugs.

Halogenated agents produce vasodilation that has advantages and disadvantages. It provides an additional means of controlling afterload and preload but can lead to an increased need for intravascular volume. An increase in intravascular volume can be detrimental at the end of the procedure by causing relative hypervolemia and even pulmonary edema. To prevent this problem, we simulate the increase in central blood volume that occurs with awakening for the 30–45 min of closure by tilting the patient (head lower than feet). Tilting allows one to predict the patient's postanesthetic volume status and make appropriate adjustments. Volatile drugs also permit careful, deliberate induction, manipulation of hemodynamic variables, and adjustment of dose. They can also be used to treat stress-induced increases in left ventricular filling pressures.¹⁹⁰ They provide a moderate degree of muscle relaxation, decreasing the need for muscle relaxants, and increasing the ease of reversing paralysis. Volatile anesthetics also facilitate tracheal extubation at the end of surgery. Thus, the stressful stimuli and hypertension associated with continued intubation of the trachea after surgery are avoided. Also, this approach permits early assessment of neurologic function and the presence of angina (although the vast majority of episodes of postoperative myocardial ischemia are “silent”).

Since isoflurane was introduced, we have avoided using halothane; occlusion of the aorta at the supraceliac level tends to make the liver hypoxic for a time during which halothane can, in theory, create a hepatitis-like condition. Isoflurane may be a coronary vasodilator, but it does not appear to place patients at increased risk for myocardial ischemia, infarction, or cardiac death compared with halothane anesthetics.¹⁹¹ Current FDA labeling suggests that “sevoflurane should be used with caution in patients with renal insufficiency (creatinine >1.5 mg · dL⁻¹). . . . While a level of compound A exposure at which clinical nephrotoxicity might be expected to occur has not been established, it is prudent to consider all of the factors leading to compound A exposure in humans, especially duration of exposure, fresh gas flow rate, and concentration of sevoflurane. . . . Sevoflurane may be associated with glycosuria and proteinuria when used in long procedures at low flow rates.”¹⁹²

All commonly used opioids produce similar cardiovascular effects unless they are administered rapidly in large doses. Induction of anesthesia with opioids, which can be accomplished quickly, decreases the cardiac index by a small amount. In sufficient doses, opioids produce analgesia and hypnosis, with only slight decreases in cardiac contractility and blood pressure. Higher doses predictably decrease peripheral vascular resistance, especially when administered after benzodiazepines. With continual infusion of opioids or other drugs, anesthesia can be maintained throughout the surgical procedure. Surgical stimulation after opioid induction significantly increases the heart rate, arterial blood pressure, and systemic vascular resistance. Nitroglycerin, nitroprusside, or a volatile anesthetic can be added to the opioid for manipulation of the circulation during cross-clamping and unclamping.

Nitrous oxide can be used with opioids or with the inhalational drugs. However, it increases afterload and myocardial work while depressing myocardial inotropic performance and output. In one study of patients undergoing abdominal aortic surgery, nitrous oxide increased the need for nitroglycerin to treat elevated PCWP and myocardial ischemia, although clinical outcome was not affected.¹⁹³ Nitrous oxide may decrease renal and splanchnic blood flows¹⁹⁴ and may have long-lasting toxic effects by causing nutritional, neurologic, and immunologic deficits. It can also contribute to bowel distention.

Our work¹⁹⁵ suggests that large doses of the synthetic narcotic sufentanil improve patient outcome after aortic reconstruction. In a prospective, controlled study, patients were randomly assigned to receive either an isoflurane- or sufentanil-based anesthetic for aortic reconstruction. Intraoperatively and postoperatively, systemic and pulmonary capillary blood pressures and heart rates were kept within 20% of mean preoperative (baseline) values. Sufentanil anesthesia alone was associated with less major (cardiac and renal) morbidity than isoflurane anesthesia (Table 33-10).¹⁹⁵ Sufentanil may have a protective effect because of its superior blockade of the adrenergic stress response. Further study is needed to determine whether all opioids are protective. A disadvantage of the opioids is that most linger into the postoperative period. However, in >50% of the patients who received a high-dose, opioid–nitrous oxide anesthetic technique (sufentanil 15–20 µg · kg⁻¹) for suprarenal aortic reconstruction, tracheal extubation was accomplished in the operating room. High-dose opioid anesthetics also produce excellent postoperative analgesia.

| Morbidity | Isoflurane-Based Anesthetic (n = 58) | Sufentanil-Based Anesthetic (n = 46) |
|---|--------------------------------------|--------------------------------------|
| Renal insufficiency | 16 | 0* |
| Congestive heart failure | 13 | 0* |
| Ventilation > 24 hr | 9 | 4 |
| Pneumonia | 2 | 1 |
| Renal failure | 3 | 1 |
| Stroke | 2 | 0 |
| Myocardial ischemia | 0 | 1 |
| Death | 2 | 1 |
| Important or severe complications | 20 | 10* |
| Important or severe complications and failure | 17 | 7* |

Table 33-10. MORBIDITY AFTER AORTIC RECONSTRUCTION WITH EITHER OF TWO DIFFERENT ANESTHETIC AGENTS

Combined general-epidural and general-spinal anesthetics have been used successfully for aortic reconstruction.^{32,196} A detailed description of the advantages and disadvantages of regional anesthetics can be found below in Lower Extremity Revascularization. For patients requiring thoracotomy, the analgesia provided by thoracic epidural infusion of narcotics and/or local anesthetics may be particularly helpful in improving spirometric function. Thoracic epidural local anesthetics can also dilate coronary arteries¹⁹⁷ and help to prevent stress-induced elevations in PCWP. Some clinicians are reluctant to use epidural anesthesia for supraceliac aortic reconstruction because of concerns about concurrent heparinization and the associated incidence of paraplegia. In such patients, the use of peridural narcotics without local anesthetics can preserve sensory and motor function and can allow early assessment of neurologic integrity. Because urinary catheters are typically left in place for at least 36 hr after aortic reconstruction surgery, urinary retention is not a major issue. We often use intrathecal or epidural narcotics after supraceliac aortic occlusion. Animal studies have shown that intrathecal naloxone improves neurologic function after thoracic aortic occlusion, but results in humans have been inconclusive. Another disadvantage of epidural local anesthetics is that although patients must receive increased amounts of iv fluids, they are still likely to become hypotensive after reperfusion.¹⁹⁸ Therefore, we are prepared for the possibility of fluid overload toward the end of the procedure. Alternatively, infusions of dopamine or dobutamine may be used to maintain systemic vascular resistance and contractility in the presence of the sympathectomy induced by the use of local anesthetics for regional block.¹⁹⁹

We believe that prophylaxis of stress and pain by any mechanism (epidural anesthetics, opiate infusion, or a₂ agonists) may result in lower morbidity in those least able to tolerate the myocardial and cardiovascular demands of stress.

The choices of muscle relaxants for use today are many. We choose an agent based primarily on the hemodynamic goals, the patient's renal function, and on whether or not the patient's trachea will be extubated in the operating room. We typically use an intermediate-duration relaxant with lower doses of narcotics (or remifentanyl) supplemented with volatile anesthetics, propofol, b-adrenergic blocking drugs, or a₂ agonists in patients to be extubated in the operating room. For patients whose lungs will be ventilated postoperatively and who have received high doses of narcotics, we may take advantage of pancuronium's vagolytic effects to prevent severe bradycardia.

Management of Elective Aortic Surgery

We believe that prehydration reduces variations in blood pressure on induction of anesthesia. After the patient's preoperative condition has been optimized, the range of hemodynamic variables for that patient is determined. The anesthetic management is then planned to keep the patient within 20% of this range, as long as the PCWP does not exceed 15 mm Hg, the heart rate does not exceed 80–90 beats · min⁻¹, and signs of organ ischemia are absent. We typically provide premedication with the patient's usual medications and fentanyl 1–2 µg · kg⁻¹ iv and 1–2 mg midazolam iv in the holding area (these dosages are reduced for old age, debility, or pulmonary disease). Anticholinergic drugs are usually avoided because they produce dry mouth and tachycardia, which increases myocardial oxygen consumption. The patient should be given antihypertensive medication, including diuretics, before being brought to the operating room. Many diabetic patients who require insulin are given an insulin infusion throughout surgery. Preoperative considerations and drug therapy for diabetic patients have already been described earlier in this chapter.

In the preoperative holding area or in the operating room, the monitors and catheters that are needed for induction of anesthesia are placed, usually a radial artery catheter in the nondominant hand, a manual blood pressure cuff, pulse oximeter, ECG (leads II and V₅), ST-segment trend monitor, precordial stethoscope, a 16-gauge iv line, and, occasionally, a central venous or pulmonary artery catheter.

Our anesthetic technique using sufentanil is as follows. After 3 mg of *d*-tubocurarine is given, an infusion of 750 µg of sufentanil in 100 mL of saline is begun at a rate of about 15–50 µg · min⁻¹ · 70 kg⁻¹, and the patient is coached to breathe 100% oxygen from a face mask. After about 3 min, 75 mg of thiopental iv is administered, and 0.1 mg · kg⁻¹ pancuronium or vecuronium is given over 3–5 min. When the depth of anesthesia is judged adequate by the lack of response to Foley catheter insertion or by pinpoint pupils, and when muscle relaxation is adequate, the trachea is intubated and mechanical ventilation begun with 0–60% nitrous oxide in oxygen. The remainder of the pre-cross-clamping phase is devoted to meticulous attention to the details of maintaining temperature homeostasis (unless hypothermia is desired for its potential spinal cord protection): maintaining volume homeostasis as judged by heart rate, blood pressure, pulmonary capillary pressure, or central venous pressure; maintaining left ventricular end-diastolic volume as assessed by echocardiography; ensuring absence of organ ischemia; monitoring (but usually not treating) urine output; and keeping systemic and pulmonary blood pressures and heart rate in the patient's usual range. Every increase in blood pressure or heart rate is either anticipated or treated as soon as it occurs with 25–50 µg of sufentanil. Further increases are treated with repeated doses, or with the addition of nitroglycerin or nitroprusside, volatile anesthetic, esmolol, or propranolol, depending on the event and the suspected cause.

For the half hour immediately before cross-clamping and aortic occlusion, the patient is kept slightly hypovolemic by examining the ventricular volume by means of echocardiography or by keeping PCWP at 5–15 mm Hg. At the time of occlusion we are prepared to give a vasodilating drug through an iv catheter placed specifically for that purpose to avoid hypotension from an accidental bolus of vasodilator. This catheter site is often the third lumen of a triple-lumen central venous catheter or pulmonary artery catheter. The difference in our management of aortic occlusion at different levels (*e.g.*, supraceliac versus infrarenal) is that we rigorously and meticulously plan the management and execute the procedure for all occlusions at renal vessels or above.

Without evidence to the contrary, it is assumed that a little hypertension is just as harmful as a little hypotension. For example, in extreme cases, we might permit the systolic blood pressure of a patient whose preoperative range is 110–170 mm Hg to decrease to as low as 90 mm Hg, or to increase to as high as 190 mm Hg. If values approach or exceed these limits, we execute our contingency treatment plan. Hypertension may be treated by increasing the amount of anesthetic, infusing nitroprusside, or tilting the patient head-up. Hypotension may be treated by placing the patient in a head-down position, infusing more fluid, or beginning a dilute infusion of phenylephrine at a rate that restores systolic blood pressure to ~100 mm Hg.

Our accepted range for the patient's heart rate is similarly based on preoperative determinations. If a normal range of 60–90 beats · min⁻¹ is established preoperatively, we initiate treatment once these limits are exceeded intraoperatively. Bradycardia is better tolerated than tachycardia during these operations, because minimizing myocardial oxygen demand is one of our primary concerns. If the intravascular fluid volume is acceptable, we treat tachycardia aggressively, by increasing the level of anesthesia with more opioid or volatile agent, or with an iv infusion of a β -adrenergic receptor blocking drug. Imaging with TEE allows some latitude in the range of acceptable values before intervention must be undertaken. However, PCWPs are not allowed to remain abnormal—*i.e.*, <5 mm Hg or >15 mm Hg—during this procedure, assuming that these values correlate with the echocardiographic values. Increases in pulmonary artery pressures are treated aggressively with more anesthetic, nitroglycerin, or nitroprusside. For low filling pressures, more fluid is infused, except in the 1- or 2-min interval immediately before application of the aortic cross-clamp.

Our approach is different when we are concerned about spinal cord perfusion in patients whose aorta will be occluded at the thoracic level without distal perfusion. In these instances, we will accept some proximal hypertension while the aorta is occluded in the hope of obtaining higher distal perfusion pressures and preventing distal ischemia. This choice may come at the expense of myocardial well-being.

The application of a cross-clamp to the supraceliac aorta probably produces the greatest hemodynamic stress ever experienced by a patient. In fact, 92% of the patients we studied had ischemia, as evidenced by abnormal motion and thickening of the left ventricle (see [Table 33-8](#)).¹⁵⁹ More distal levels of temporary occlusion are less stressful hemodynamically. Stabilizing pulmonary and systemic arterial pressures by administering vasodilating drugs before and during suprarenal cross-clamping may not be sufficient to normalize myocardial performance. We have used phosphodiesterase inhibitors, which increase contractility and reduce afterload, before application of the aortic cross-clamp, but we still see myocardial dysfunction with supraceliac occlusion.

Another technique for maintaining normal volumes during cross-clamping is controlled volume depletion, that is, the removal of a specific amount of blood from the patient just before or during application of the cross-clamp for a short period of time. During the minutes remaining just before the cross-clamp is removed, this amount of blood is replaced. Although we have used this technique, we do not advocate its routine use. A third technique for maintaining normal hemodynamic values is the use of volatile anesthetics, rather than nitroglycerin or nitroprusside, as the vasodilating agent. This technique is usually effective, but close observation is necessary to ensure that myocardial dilation and dysfunction do not occur. The kinetics of desflurane may make it suitable for use in this manner with infrarenal aortic occlusion.

Administration of exogenous vasoconstrictors is avoided if possible. In patients undergoing carotid endarterectomy, phenylephrine doubles the incidence of wall motion abnormalities observed by echocardiography in patients whose blood pressure is maintained simply by light anesthesia and endogenous vasoconstrictors.⁸⁴ Phenylephrine causes the heart to dilate in patients with coronary artery disease, whereas norepinephrine raises blood pressure without causing myocardial depression.¹²⁶

To ensure adequate volume at the time of cross-clamp removal, blood lost during occlusion is replaced with crystalloid or colloid, warmed cell-saver blood or banked blood to keep the hematocrit slightly above 30%, because it will decrease to 30% in the postocclusion period. We believe that this is the minimal acceptable value for patients in this risk group.¹⁰⁰ Guided by filling pressures or echocardiographic estimates of volume, we are careful not to dilate the left ventricle to an abnormal size.

We routinely use autotransfusion devices and prefer to have a second person (usually a technician) to operate them. We continue to do this even though a recent trial suggests that autotransfusion devices do not reduce transfusion of allogenic blood.²⁰⁰ After the sixth unit of blood has been given and if more blood loss is anticipated, or after 8 units of blood has been administered, 10 units of platelets is requested for the patient (and occasionally 2 units of fresh frozen plasma). After giving 8–10 units of packed cells, we routinely administer 1 unit of fresh frozen plasma for each unit of packed cells. When no more blood is at hand, and if it is absolutely necessary (*i.e.*, when colloid or crystalloid cannot be used), the best available type-specific, washed packed cells are administered.

Because a large part of the vascular tree is excluded from circulation during temporary aortic occlusion, blood loss can be considerable during supraceliac cross-clamping without the onset of hypotension or tachycardia. Therefore, if we find ourselves decreasing the concentration of volatile anesthetic or the infusion rate of vasodilators, or worse, find ourselves giving vasopressors while the aorta is still occluded, we order more blood and seek to correct what is now severe hypovolemia. Observation of the surgical field and close communication between anesthesiologist and surgeon are of key importance. Evisceration of bowel, often necessary for optimal exposure of the thoracoabdominal aorta, further depletes intravascular volume. Blood loss into the pleural or retroperitoneal cavity may not be readily detected. Watching the volumes in the suction bottles supplements the data, as does observation of left ventricular cavity size on echocardiography.

Thus, immediately before and during removal of the cross-clamp, we stop infusing vasodilators. We allow blood pressure, PCWP, and filling volumes to go as high as possible without the occurrence of myocardial ischemia. The surgeon then opens the aorta gradually to ensure that severe hypotension does not develop and that there is not too much bleeding from the suture line. Pathophysiologic events on removal of the aortic cross-clamp are associated with inadequate preload. We therefore infuse crystalloid, colloid, or blood; usually, 2 units of banked or cell-saver blood is pressured into venous access sites just before reperfusion. Guided by filling pressures or echocardiographic estimates of volume, or both, we are careful not to dilate the left ventricle.

Moderate hypotension (*i.e.*, a decrease in systolic pressure of 40–60 mm Hg) typically accompanies removal of the aortic cross-clamp, regardless of whether the clamp is replaced infrarenally or so that blood flow to only one leg is obstructed. Our observations of the echocardiogram lead us to believe that hypotension is caused mainly by relative volume depletion. If hypotension persists for more than 4 min after removal of the clamp and does not return toward normal after blood deficits have been replaced, we search for other causes, including hidden blood loss or myocardial dysfunction. Myocardial dysfunction may be caused by inadequate metabolism of the citrate present in replacement blood; such blood has not yet gone to the liver, where citrate is metabolized. This problem can be treated by administration of calcium, which is chelated by citrate. If necessary, the surgeon can reclamp or occlude the aorta, preferably below the renal arteries. Thus, volume replacement and maintenance are mainstays of therapy before, during, and immediately after removal of the aortic cross-clamp. At this point in the procedure, pulmonary artery

pressures may not be low on the oscilloscope because reperfusion of ischemic tissues is associated with the release of lactic acid and other unknown mediators that can cause pulmonary vasoconstriction. Mannitol prophylaxis may prevent part of this response, and we frequently give mannitol 0.5-1.0 g · kg⁻¹ immediately before release of the clamp.¹⁶⁰ Removal of the clamp from the second leg usually causes fewer hemodynamic effects, presumably because of collateral blood vessels across the pelvis.

During closure, we again ensure adequate organ perfusion as well as hemodynamic and temperature homeostasis, and we reverse the effects of muscle relaxants. Reversal is easier when patients are warm. Hypothermia after aortic reconstruction is associated with other complications, including coagulopathy, low cardiac output states, and significantly higher incidences of organ dysfunction and death. Whether hypothermia causes these problems or is a marker for sicker patients who undergo more extensive operations is unclear. We routinely use forced-air warming on the upper portion of the body in these patients, although their lateral position and extensive exposure during thoracic procedures make maintaining normothermia difficult.

During emergence from anesthesia, we use infusions of nitroglycerin and esmolol or another β -adrenergic blocking agent to prevent hemodynamic variations outside the patient's normal range. If ventilation is adequate (as is common 6 hr after an initial dose of sufentanil), the trachea is extubated; otherwise, controlled ventilation is maintained until spontaneous ventilation is judged adequate. If we elect to use a predominantly inhalational anesthetic technique, we often place an epidural catheter and administer epidural local anesthetics and opioids for postoperative analgesia. When the sufentanil-based technique described above is used, rarely is much additional pain therapy needed for 24 hr. Continuing care into the postoperative period is important for patient outcome.

Anesthesia for Emergency Aortic Surgery

The most common cause of emergency aortic reconstruction is a leaking or ruptured aortic aneurysm. Ruptured aneurysms can be atherosclerotic, mycotic, syphilitic, or inflammatory, or may occur in patients with the marfanoid syndrome. Ruptured aneurysms carry associated mortality roughly ten times greater than elective repair.²⁰¹ Therefore, efforts should be made to increase the number of elective operations performed for aortic aneurysms before they rupture, as urgent/emergent surgery is associated with increased mortality even in the absence of frank rupture.

Symptoms of ruptured abdominal aortic aneurysms include pain, faintness or frank collapse, and vomiting. Pain in the back, abdomen, or both is almost always present. Therefore, many surgeons believe that pain in combination with a known abdominal aortic aneurysm or pulsatile abdominal mass indicates dissection or rupture and the immediate need for surgical exploration until proved otherwise. Ruptures most commonly occur into the retroperitoneum. This site permits tamponade of the hemorrhage; however, retroperitoneal hemorrhage and subsequent hematoma can displace the left renal vein, inferior vena cava, and intestine, possibly leading to damage to these structures during the surgical approach. Venous hemorrhage is often much more difficult to control than arterial hemorrhage.

Approximately 25% of aneurysms rupture into the peritoneal cavity, a site associated with a great degree of exsanguination. Other sites of rupture include adjacent structures after formation of fistulae with the inferior vena cava, iliac veins, or renal veins. Aortoenteric fistulae most commonly rupture into the fixed third position of the duodenum. These fistulae usually occur between the overlying bowel and a portion of the aorta that has previously undergone resection and grafting for an existing aneurysm. The mortality from these fistulae is high, often exceeding 50%. In rare cases, an abdominal aortic aneurysm may dissect proximally, resulting in hemopericardium. The overall mortality rates vary in published series from 15–90%, and the time from the onset of symptoms to control of bleeding appears to be the key to determining outcome. The importance of controlling bleeding gives credence to the inescapable sense of urgency that accompanies such events. Other factors that adversely affect outcome are a history of chronic hypertension, age >80 years, heart disease, renal insufficiency, a hematocrit <32.5% at diagnosis, hypotension at diagnosis, surgery lasting >400 min, hypotension lasting >110 min, a systolic blood pressure <100 mm Hg at the end of the operation, and blood loss >11,000 mL.²⁰²

Management of hemodynamically unstable patients is challenging. Shock frequently accompanies rupture. However, the absence of hypotension does not rule out the possibility of rupture, and shock may occur suddenly. Patients with dissection may have severe hypertension, which must be controlled immediately if rupture is to be prevented. Rapid diagnosis with immediate laparotomy and control of the proximal aorta are of the highest priority. If systolic blood pressure is <90 mm Hg, some clinicians advocate the administration of oxygen by face mask, with tracheal intubation performed only after proximal control of the aorta has been achieved. Because experienced anesthesia personnel can usually intubate the trachea rapidly, and because of the substantial threat of aspiration pneumonia, we prefer an awake intubation or a rapid-sequence tracheal intubation after small doses of etomidate (0.1 mg · kg⁻¹) and a steroid. We believe that this method causes little morbidity, creates only a slight delay, and prevents a potentially serious complication. However, if the patient has lost consciousness or has marked hypotension unresponsive to rapid volume infusion, the probability of rupture into the free peritoneal cavity is high. In this case, the trachea is immediately intubated in a rapid-sequence fashion, usually with the aid of muscle relaxants and perhaps a small dose of etomidate; ventilation with 100% oxygen is also started. Almost simultaneously, laparotomy is begun so that the surgeon can clamp the aorta.

We attempt to replace volume to normalize systemic blood pressure (at this time, often the only guide to volume replacement in the patient with an uncontained rupture). However, when rupture is suspected, rapid control of the proximal portion of the aorta is probably more important than is optimizing the patient's preoperative condition. A difference from elective surgery is that heparin is not administered before aortic cross-clamping.

The patient is resuscitated quickly (before induction of anesthesia, if possible) with type-specific non-cross-matched blood and crystalloid administered via large-bore venous catheters by roller pumps or pressured bags. If type-specific blood is not available, O-negative washed red blood cells may be given. We emphasize the importance of large-bore catheters placed in the most easily accessible vein. A 14-gauge catheter placed in each antecubital fossa is more useful for rapid volume expansion than are attempts at placement of a pulmonary artery catheter. We recommend the use, when possible, of fluid warmers that deliver rapid volumes of normothermic fluids.

Once the aorta is controlled with a cross-clamp and blood pressure and perfusion are restored, additional venous access and a radial, brachial, or axillary arterial line are secured. It is often necessary to have a second anesthesiologist secure vascular access while the first is securing the airway, monitoring blood pressure, and administering volume. Attention may be turned to placing a pulmonary artery catheter once blood pressure is adequate. Even more quickly, an echocardiographic probe can be inserted for rapid assessment of left ventricular volume and contractility. At this point, volume administration is guided by means of PCWP or by the echocardiogram (left ventricular end-diastolic area). High-normal filling pressures are desirable for attenuation of hypotension after removal of the aortic clamp. Some patients with hemorrhagic shock will require infusions of dopamine, epinephrine, or norepinephrine to sustain an adequate blood pressure even after restoration of normal blood volume. Recent work suggests that vasopressin may be particularly effective in restoring blood pressure when hemorrhagic shock is resistant to catecholamines.²⁰³ These patients are often profoundly acidotic; if we administer sodium bicarbonate, we increase ventilation to help eliminate the extra carbon dioxide produced. Augmentation of cardiac output with dopexamine increases oxygen delivery perioperatively, with only limited increase in total body or myocardial oxygen demand, and may improve survival.²⁰⁴ However, similar studies with dobutamine have yielded opposite conclusions.²⁰⁵ At the present time, given the high incidence of cardiac-related morbidity, we restrict our use of inotropic support to patients with hypotension or low cardiac output (cardiac index <2 L · min⁻¹ · m⁻²) despite adequate filling pressures. We do not hesitate to paralyze and administer propofol, midazolam, and/or opioids to these patients if they are hemodynamically stable, because they usually require postoperative mechanical ventilation of the lungs and sedation to minimize cardiovascular stress. The acute respiratory distress syndrome (ARDS) develops frequently in patients who survive surgery for a ruptured aneurysm. Recent advances in ventilation strategies for patients with the ARDS may include permissive hypercapnea, "open lung" (high PEEP to optimize lung compliance) ventilation, noninvasive ventilation, and aggressive CPAP trials. These approaches may reduce the length of postoperative ventilation, reduce cytokine release,²⁰⁶ and even reduce mortality.²⁰⁷

Hemodynamically stable patients constitute a second group of patients in whom shock is reversible with volume administration. In such patients, it may be assumed that hemorrhage has been at least partially contained. However, because rapid exsanguination can occur at any time, patients are transported immediately to the operating room for emergency laparotomy, and the same urgency is maintained. Venous access is then ensured. If the blood pressure and heart rate are stable when the patient arrives, sterile preparation of the abdomen is begun. The intravascular volume status may be assessed by observation of the patient for a decrease in systemic blood pressure or an increase in the heart rate when the head is raised 10–15 degrees. Administration of a 25-mg bolus of thiopental iv may also aid in the assessment of volume. Normally, induction of anesthesia is delayed until the patient's abdomen is prepared and draped and the surgeon is ready. Thus, in this situation, minimal extra time is spent on inserting and attaching monitors.

Preoxygenation is followed by rapid-sequence induction of anesthesia with small doses of a narcotic and an induction agent, often etomidate, a rapidly acting muscle relaxant, application of cricoid pressure, and tracheal intubation. To blunt the hemodynamic effects of laryngeal visualization and tracheal intubation, one may administer an iv bolus of lidocaine or esmolol, or an additional narcotic or an induction agent. However, hypotension may easily occur following induction, in which case we administer 100% oxygen, elevate the patient's legs, and rapidly administer blood and fluids. If these measures fail to restore adequate blood pressure and perfusion, we infuse phenylephrine or dopamine until the aorta can be occluded.

Because of hypothermia from massive fluid resuscitation and the aortic occlusion above the hepatic artery, replacement blood may not pass through the liver in amounts adequate to allow for metabolism of citrate. Therefore, if either hypotension due to poor myocardial contractility (which may be easily assessed with echocardiography) or coagulopathy develops, administration of calcium may be therapeutic. It has been suggested that the aggressive fluid resuscitation of trauma patients in the emergency room before transport to the operating room may result in increased mortality, perhaps by causing hypothermia or dilutional coagulopathy, or by raising blood pressure and increasing bleeding.²⁰⁸ At present, however, we cannot recommend allowing patients to remain hypotensive but believe that attention

should be paid to maintaining temperature, adequate hematocrit, and coagulation in addition to simply normalizing intravascular volume.

We routinely use autotransfusion in patients with actual or suspected rupture of an aortic aneurysm, even though a recent study questions its effectiveness in reducing transfusion requirements.²⁰⁰ This device can be operated by a separate team, allowing the primary anesthesiologist to direct all of his or her attention to the patient's volume status, gas exchange, and depth of anesthesia. Our mnemonic for treatment of such patients is "wovcath," for wonder what (if any) anesthetic to give, oxygen, vecuronium, coagulation, acid-base change, temperature change, and hemodynamic change. This mnemonic lists, in reverse order, the important aspects of patient care that we try to remember when everything about these patients invites disorganization.

After successful surgery for ruptured abdominal aortic aneurysm, the survival rate is about 50% at one month and 33% at 3 years, much lower than survival rates after elective operation. Survival is highest if intraoperative urine output is >200 mL and respiratory failure or myocardial infarction does not occur. The decision to repair a ruptured abdominal aortic aneurysm can be made on clinical grounds. However, after surgery (when information on intraoperative and postoperative variables is also available), these prognostic variables assist clinical judgment and guide discussions of prognosis with the family.²⁰²

The complications that occur during aortic occlusion can usually be linked to the heart, central nervous system, or kidneys. Organ dysfunction can be minimized by maintaining intraoperative values for hemodynamic variables within the normal preoperative range, ensuring that cardiac dilation does not occur at any point, and minimizing episodes of tachycardia. Attention to the details of preoperative drug therapy, preoperative hydration, and temperature homeostasis may also promote an improved outcome. Further, vigilance must continue into the postoperative period if morbidity and mortality are to be minimized. As opposed to elective aortic reconstruction, in which preserving myocardial function is the primary goal, in emergency resection the crucial factor for patient survival is first rapid control of blood loss and reversal of hypotension, and then preservation of myocardial function.

LOWER EXTREMITY REVASCULARIZATION

The number of patients undergoing lower extremity revascularization has increased as surgeons attempt to improve functional status in elderly patients. In our institution, many vascular patients undergo revision or repeat operations. They often have complex medical histories and diseases of multiple organ systems. Their coexisting diseases present additional challenges beyond those of routine anesthetic management. Despite this fact, patients are now frequently admitted to the hospital on the day of surgery. For others, surgery is emergent or urgent. In all of these situations, the primary goal of anesthetic management is to prevent the development of perioperative complications. These patients are at particularly high risk for perioperative cardiac complications including myocardial ischemia and infarction, low cardiac output (forward failure), and pulmonary edema (backward failure). Krupski *et al*⁴³ have shown that the incidence of cardiac morbidity after infrainguinal procedures may exceed that associated with abdominal aortic procedures because patients scheduled for distal procedures often have more preoperative cardiac risk factors than patients scheduled for aortic procedures. Patients undergoing lower extremity revascularization may also receive less attentive care than patients undergoing "major" procedures.

In addition to maintaining adequate cardiac function, another goal of our anesthetic and perioperative care is to assure adequate perfusion and prevent hypercoagulable responses to surgery so as to maintain graft patency in the immediate postoperative period. Pulmonary, renal, neurologic, and hepatic dysfunction may occur following vascular surgery; proper intraoperative and postoperative management may help to prevent these adverse outcomes as well. Vascular surgery represents a tremendous stress to patients whose reserve is already marginal, as suggested by the increased mortality of patients who receive surgery rather than thrombolytic therapy for acute limb ischemia.²⁰⁹ Anesthetic techniques that reduce the stress response may improve outcome. We believe that ideal anesthetic management of these patients may decrease morbidity and mortality and hasten recovery and hospital discharge. These combined effects should increase the cost-effectiveness of lower extremity revascularization.

The number of patients undergoing arterial reconstruction with angioplasty as well as surgically is increasing in the United States, while the rate of amputation has remained stable.²¹⁰ Because some patients may undergo multiple procedures, an anesthesiologist may become cynical about the effectiveness of lower extremity revascularization; but long-term patency and limb-salvage rates are good, demanding that anesthesiologists do all they can to optimize outcome in these procedures (Fig. 33-11).²¹¹ The typical cost of a limb-salvage procedure approaches \$20,000, which may be less than the costs of amputation when rehabilitation and the loss of independence are considered.

Figure 33-11. Cumulative life-table of limb salvage rates of all patients undergoing reconstructive arterial operations for limb-threatening infrainguinal arteriosclerosis. The number with each point indicates the number of cases observed with intact limbs for that length of time. (Reprinted with permission from Veith FJ, Panetta TF, Wengertter KR *et al*: Femoro-popliteal-tibial occlusive disease. In Veith FJ, Hobson RW, Williams RA, Wilson SE (eds): *Vascular Surgery*, 2nd ed, p 421. New York, McGraw-Hill, 1994.)

There are three clinical indications for elective surgery for chronic peripheral occlusive disease: (1) claudication, (2) ischemic rest pain or ulceration, and (3) gangrene. Patients with claudication have symptoms on walking that are relieved by rest. Such patients are not at significant risk for imminent limb loss. Patients with rest pain, ulceration, or gangrene are at variable risk for imminent limb loss and may have severe progressive ischemia. Thus, reconstruction for such patients is semiurgent or urgent. When a patient presents with a gangrenous (black) or pre-gangrenous (blue) toe, several causes other than progression of chronic arteriosclerotic occlusive disease must be considered. Local infection is particularly common in diabetic patients. Emboli may originate from the heart, a proximal aneurysm, or any proximal atherosclerotic lesion. Intra-arterially administered lytic agents, particularly urokinase, may have been administered, precluding regional anesthesia.³²

Vascular reconstruction procedures are generally categorized as either inflow or outflow procedures. Inflow reconstruction involves bypass of the obstruction in the aortoiliac segment, whereas outflow procedures are those performed distal to the inguinal ligament for bypass of femoral-popliteal or distal obstructions. The most common inflow reconstruction procedure for obstructions in the aortoiliac segment is aortofemoral bypass. The usual vascular reconstruction below the inguinal ligament is a bypass graft that originates in the common femoral artery and extends to the popliteal or tibial artery. Such a bypass may be performed with a reversed saphenous vein, the saphenous vein *in situ*, or a prosthetic graft.

The complexity of femoral-popliteal and femorotibial bypass varies widely. The site for distal anastomosis and the quality of the outflow vessels are assessed by preoperative angiography. Prosthetic bypasses can be performed more quickly and require less dissection than the saphenous vein bypass, because it is not necessary to make multiple incisions for vein harvest. Prosthetic bypasses, however, have significantly lower patency rates than saphenous vein bypasses, particularly when they extend below the knee. The best short- and long-term results are achieved with the saphenous vein, but this technique requires longer operative time and greater technical expertise than are needed for prosthetic grafts. The duration and complexity of the operation are usually determined by the quality of the saphenous vein and the quality and size of the distal outflow vessels.

In a reversed saphenous vein bypass, the vein is dissected, all branches are ligated and divided, and the vein is excised. The direction of the saphenous vein is reversed to permit blood flow in the direction of the valves, and the vein is tunneled from the femoral artery to the distal vessel. The use of the vein *in situ* offers significant advantages over the reversed-vein bypass; because the vein is not removed from its bed, it is subjected to little trauma; twisting or kinking is unlikely. These advantages have improved patency rates. The use of intraluminal angioplasty is reported to result in better vein preparation, smaller incisions, improved patency, and shorter hospital stay.²¹² The quality of the repair is determined from the pulse quality, Doppler ultrasound studies, or completion angiography.

The surgeons' concerns for patients with peripheral vascular insufficiency include not only those problems involving the cardiovascular system but also specific problems related to the operative repair. Tunneling of the graft between the incisions may be more stimulating than other parts of the procedure and may cause hypertension under general anesthesia. The patient is usually given heparin during the procedure. In most cases, the heparin effect is not antagonized because

bleeding problems are rare and graft reocclusion is a concern. Graft patency is evaluated carefully in the recovery room. Most surgeons believe that the patient's feet should be kept warm and that the patient should be well hydrated so that peripheral vasoconstriction, which may limit outflow from the new graft, is prevented. If graft thrombosis develops early in the postoperative period, the patient is promptly returned to the operating room for graft thrombectomy and for evaluation and correction of the cause of the thrombosis. It can be anticipated that, during graft thrombectomy, significant blood loss will occur with flushing of the graft.

Anesthetic Management of Elective Lower Extremity Revascularization

There is perhaps no other disease entity about which the anesthesiologist can be misled so easily than vascular disease of the lower extremity. One is apt to hear, "Oh, it's just a local procedure," or "Just put a spinal in and let's get on with it; you don't have to read the chart." However, the morbidity and mortality following distal operations approach those following infra-aortic reconstruction and are mainly of cardiac origin.⁴³ Thus, although we often use epidural or spinal anesthetics and opioids for pain relief, we pay as close attention to body temperature, oxygen delivery, and hemodynamic homeostasis during peripheral vascular procedures as during aortic procedures that involve much greater hemodynamic fluctuations. The devices and the concerns previously described apply, with special attention to the postoperative period. It is during the postoperative period that most cardiac problems arise and pain relief and correction of hemodynamic and fluid disequilibria are most likely to be needed. Care must be taken not to allow overhydration to occur intraoperatively in support of blood pressure, and then to cause congestive heart failure as the epidural sympathectomy wears off. Dye loads given for "completion angiography" also contribute to fluid shifts; thus, monitoring of cardiac preload is important for a successful outcome.

We routinely monitor hemodynamic variables invasively in patients undergoing lower extremity revascularization. Our preference is to place a radial arterial line in almost all patients, because the associated morbidity is low. An arterial line provides real-time information on blood pressure that can guide pharmacologic therapy for the rapid hemodynamic fluctuations that accompany induction of, and emergence from, anesthesia. Arterial cannulation also facilitates blood drawing in the crucial first 24 hr after surgery. Arterial catheterization is difficult in ~10% of patients, most of whom are women. Guide wire techniques may improve the rate of success. If radial artery catheterization is impossible, we usually forgo placement in other arteries or surgical placement ("cut-down"), relying instead on noninvasive blood pressure measurement.

We also commonly place central venous pressure catheters for a variety of reasons. Blood loss may be insidious and unrecognized during prolonged, revision, infrapopliteal, or *in situ* procedures. Rapid blood loss or hemodynamic changes are not usually encountered with distal reconstruction, but the procedure tends to be lengthy, making intraoperative urinary drainage advisable. Our experience is that blood loss is generally underestimated, and we routinely measure the central venous pressure and obtain a hematocrit every 2 hr in patients undergoing below-knee procedures. Because the major morbidity and mortality with this procedure are related to the cardiovascular system, with rates above 8% and 2%, respectively, the noninvasive nature and the absence of hemodynamic alterations should not lull the anesthesiologist into a casual attitude.

Cardiac preload is reduced by epidural and spinal anesthesia due to the venodilation caused by their sympatholytic properties. Later, as the spinal or epidural anesthetic recedes, the patient's blood volume is distributed back to the central circulation. This "autotransfusion" can lead to elevated filling pressures, which may precipitate congestive heart failure if not recognized and treated appropriately. In our experience, central venous pressure monitoring is helpful in diagnosing and treating postoperative hypovolemia. The early diagnosis and treatment of even subtle hypovolemia are thought to be important in preventing postoperative renal dysfunction and early graft thrombosis. In some patients (for example, the female octogenarian with poor venous access), the placement of a triple-lumen catheter allows for concurrent volume loading, multiple drug infusions, and central venous pressure monitoring. Triple-lumen central venous catheters are also useful in the patient who will have vein harvested from the upper extremities. The risks associated with central catheter placement can be minimized by attention to strict aseptic technique during placement by an experienced or closely supervised practitioner. The risks associated with an indwelling catheter can be minimized by inserting a single- or double-lumen catheter where feasible and removing the catheter as soon as it is no longer needed.

We do not believe that the information obtained from a PAC justifies the additional risks (including heart block, dysrhythmia, pulmonary artery rupture, and pulmonary infarction)¹⁸⁹ associated with routine use of this monitor in this patient population. Berlauk *et al*²¹³ found that patients who were monitored during lower extremity revascularization with PACs had a lower incidence of early graft occlusion than did patients with central venous pressure monitoring. This study has been criticized because patients in the PAC group received nitroglycerin and volume loading (which have been previously shown to reduce morbidity from vascular surgery),²¹⁴ whereas those in the central venous pressure group did not. Also, the investigators and practitioners were not blinded to the randomization groups, so the potential for introduction of bias during diagnosis and treatment was very high. We believe that the prophylactic use of nitrates and volume loading in this study may have contributed more to the observed improved outcome than did the use of PACs. Therefore, we do not routinely use PACs, but rather restrict their use to the ~10–20% of patients with the most severe co-morbidity. These conditions include severe left ventricular dysfunction, renal failure, diabetes mellitus with autonomic neuropathy, and severe cor pulmonale and pulmonary hypertension. Further discussions about invasive monitoring can be found earlier in the chapter.

The choice of anesthetic for lower extremity revascularization is individualized for each patient. Table 33-11 summarizes advantages and disadvantages of regional versus general anesthesia for this procedure. The patient may have a preference for one technique over another based on previous experiences. Technical factors may contribute to the decision: obesity, previous laminectomy, or severe kyphoscoliosis may make it difficult to establish regional blockade. Septicemia, local infection, anticoagulation, and certain neurologic diseases provide varying degrees of relative and absolute contraindications to regional anesthetic techniques. Regional anesthesia may be poorly tolerated by patients who are orthopedic, uncomfortable lying still for many hours, or demented and uncooperative. Indeed, failed regional anesthesia (11% of spinals and 16% of epidurals) is associated with a 9% mortality, compared to 2% for successful regional or general anesthesia for femoral bypass.²¹⁵ Sedation allows patients to better tolerate a regional anesthetic for a long procedure, but we administer sedation judiciously as these patients are often frail or at risk for pulmonary aspiration. The combination of a high level of regional blockade and sedation may rarely produce cardiovascular collapse.²¹⁶ The patient with rest pain who has received narcotic premedication may become very sedated or even apneic when the pain is suddenly relieved by a regional anesthetic. The argument that regional anesthesia allows the patient to be a monitor for myocardial ischemia, by being able to complain of angina, may be specious, as the vast majority of episodes of perioperative myocardial ischemia are painless. Regional anesthesia may offer several advantages, however, including avoidance of hyperdynamic responses to tracheal intubation and extubation, reduced incidences of postoperative respiratory and infectious complications, and reduced postoperative hypercoagulability and graft thrombosis (Table 33-11).³² Other studies refute any effects of regional anesthesia on thrombotic outcomes,^{217,218} and suggest only higher costs for postoperative surveillance.²¹⁹ In some cases, the combination of regional and general anesthesia may provide patients with the benefits of each technique. To reduce the incidence of pruritus and respiratory depression from epidural narcotic analgesia, some anesthesiologists routinely infuse naloxone or place partial opiate agonists into the epidural space.

| Anesthetic Technique | Advantages | Disadvantages |

From Toney DP: Neurologic assessment and regional anesthesia for vascular surgery. *Post Med* 11:37, 1996

Table 33-11. REGIONAL ANESTHESIA VS. GENERAL ANESTHESIA

The operative procedure may also dictate the choice of anesthetic. Prolonged *in situ* and/or repeat procedures are usually not amenable to a single-shot spinal technique; catheter spinal or continuous epidural techniques may be useful in these situations. The use of microcatheters for continuous spinal anesthesia was abandoned after reports of cauda equina syndrome, but the use of continuous spinal anesthesia through a larger catheter (such as those intended for use in the epidural space) does not appear to be a problem as they permit better dispersal and dilution of local anesthetic in the cerebrospinal fluid. The incidence of postdural puncture headache is low in elderly patients. At times, we have combined spinal and epidural anesthesia for lengthy procedures. A standard epidural needle is placed into the lumbar epidural space, and through it, a longer spinal needle is advanced into the subarachnoid space. Long-acting local anesthetics (often supplemented with 0.1–0.2 mg of preservative-free morphine) are injected into the subarachnoid space, the spinal needle is removed, and an epidural catheter is passed. The spinal anesthetic provides the rapid onset of a reliable, dense, and long-lasting anesthetic. If the procedure takes longer than the 4–6 hr, the spinal anesthetic is effective; then the epidural catheter can be used to supplement surgical anesthesia and to provide postoperative analgesia.

The formation of an epidural hematoma is a dreaded complication of any neuroaxial anesthetic technique. We try to ensure that every health care provider who

participates in the care of patients who have had epidural or spinal anesthesia is vigilant for the signs of an epidural hematoma and is aware of the need for its emergent operative evacuation. Severe back pain or pressure is the earliest symptom of epidural hematoma formation. The pain often develops a radicular component and the patient may develop focal neurologic findings that correlate with injury to the spinal cord or nerve root. Both CT and MRI are acceptable imaging modalities for the diagnosis of a lumbar epidural hematoma. Time is of the essence, for if the spinal cord compression persists for longer than 6–12 hr, catastrophic paralysis may result. One must realize that if the patient is recovering from a general or a regional anesthetic, the spinal cord may have been compressed long before the patient started to complain. If a hematoma is diagnosed by CT, MRI, or myelography, the patient must have an emergent laminectomy and decompression if the risk of paralysis is to be minimized.³²

Coagulopathy therefore represents a relative contraindication to regional anesthesia. The degree of coagulopathy at which it becomes unsafe to perform regional anesthesia is unknown, is highly controversial, and must be part of the risk–benefit calculation in each patient. Use of NSAIDs such as aspirin and the use of subcutaneous heparin before surgery do not seem to be problematic,²²⁰ while anecdotal reports suggest that thrombolytic therapy is a contraindication for the use of regional anesthesia.^{32,221} The placement of epidural catheters with subsequent systemic heparinization before arterial occlusion appears to be safe. However, the authors of the most often quoted study (with ~3100 patients) in support of such practice postponed surgery for a day for patients who had a “bloody tap” during attempted epidural catheterization.²²² The surgery was then subsequently performed under general anesthesia. Beginning oral coumadin after surgery also appears safe in patients who have a pre-established epidural catheter.³² Many practitioners do not feel comfortable removing an epidural catheter from a patient who is coagulopathic or is receiving a heparin infusion. Some clinicians advocate the cessation of the heparin infusion and the correction of coagulopathy before catheter removal. [Table 33-12](#) summarizes some suggestions for management of regional anesthetics and anticoagulation therapy.³²

| Anticoagulant | Neuraxial Blockade Recommendations |
|---|--|
| Low-dose aspirin (81 mg) | Appropriate for regional anesthesia. |
| Low-dose aspirin (81 mg) + clopidogrel (75 mg) | Appropriate for regional anesthesia. |
| Warfarin (2–5 mg) | Appropriate for regional anesthesia. If INR is > 3.0, consider postponing surgery. |
| Unfractionated heparin (5000 units) | Appropriate for regional anesthesia. If aPTT is > 1.5 times normal, consider postponing surgery. |
| Low-molecular-weight heparin (4000 units) | Appropriate for regional anesthesia. If aPTT is > 1.5 times normal, consider postponing surgery. |
| Direct thrombin inhibitors (bivalirudin, dabigatran, edoxaban, rivaroxaban) | Appropriate for regional anesthesia. If aPTT is > 1.5 times normal, consider postponing surgery. |
| Factor Xa inhibitors (apixiban, betrixaban, edoxaban, rivaroxaban) | Appropriate for regional anesthesia. If aPTT is > 1.5 times normal, consider postponing surgery. |

Table 33-12. ANTICOAGULATION THERAPIES AND NEURAXIAL BLOCKADE RECOMMENDATIONS

General anesthesia for lower extremity revascularization has the advantage of obviating patient discomfort and lack of cooperation ([Table 33-11](#)). It allows for adequate oxygenation and ventilation and facilitates hemodynamic manipulation. Its use is virtually mandated in patients who are to have vein harvested from an arm (unless spinal and brachial plexus blocks are performed coincidentally). General anesthesia has been associated with a higher incidence of postoperative respiratory complications in some studies.²²³ However, while reduction in cardiac complications is often a stated reason for avoiding general anesthesia, recent series ([Table 33-13](#)) have been unable to show such an effect in patients undergoing lower extremity revascularization.²¹⁵ Regional anesthetics may or may not reduce postoperative thrombotic complications ([Table 33-13](#)). We do not feel that the evidence favoring regional anesthesia is so overwhelming that we would withhold a general anesthetic from most patients to whom we have offered a regional anesthetic.

| Authors Reference | Anesthetic Technique | | |
|---|----------------------|--------------------|---------|
| | General | Epidural | Spinal |
| Christopherson <i>et al</i> ¹⁹⁵ (n = 100) | 45% ischemia | 35% ischemia | — |
| Bode <i>et al</i> ²¹⁷ (n = 326) | 3.9% MI 3.6% MI | 4.1% MI 6.3% MI | 3.7% MI |

* The choice of anesthetic technique does not seem to influence rates of perioperative myocardial ischemia or infarction after lower extremity revascularization. In the first study, myocardial ischemia was diagnosed by continuous ambulatory electrocardiography (Holter monitoring).

Table 33-13. MYOCARDIAL ISCHEMIA AND MYOCARDIAL INFARCTION (MI) AFTER DIFFERENT ANESTHETIC TECHNIQUES FOR LOWER EXTREMITY REVASCULARIZATION

Specific types of general anesthetic may be preferred for patients undergoing vascular surgery. High-dose narcotic anesthetics may be associated with less renal insufficiency and congestive heart failure after aortic reconstruction than are volatile anesthetics.¹⁹⁵ This effect may be attributed to the superior ability of narcotics to blunt the adrenergic response to surgery. Despite these findings, we usually provide general anesthesia with doses of narcotics, which, although generous, still permit extubation in the operating room. Whether the benefits of prolonging anesthesia justify the risks and costs incurred by patients undergoing lower extremity revascularization remains to be studied.

Patients who receive general anesthesia can have a carefully controlled emergence and extubation, whether in the operating room or later in the ICU. We prefer to perform tracheal extubation at the end of surgery in the operating room, with the same intense monitoring of hemodynamics used during induction of anesthesia. We believe it important to appreciate the complex physiology of the anesthetic emergence. This period is punctuated by large increases in catecholamine levels (see [Fig. 33-2](#)) and a high incidence of myocardial ischemia.²²⁴ Emergence is a period of careful titration: opiates are infused to control pain and blunt sympathetic discharge while still allowing the patient to ventilate effectively. Therefore, while still intubated and breathing spontaneously, patients receive incremental doses of narcotics titrated to adequate respiration (respiratory rate 8–16 min⁻¹; end-tidal PC_{O2} <50 mm Hg). The anesthesiologist does not have the luxury of administering large amounts of opiates to blunt this response during the anesthetic emergence if he or she wishes to extubate the patient in the operating room. Therefore, additional iv drugs are often required to control hemodynamics during emergence. Our usual practice is to titrate iv labetalol, metoprolol, or esmolol for extubation to keep heart rate below 80 beats · min⁻¹ in the vast majority of patients who can tolerate b-adrenergic receptor blockade.

Anesthesia for Emergency Surgery for Peripheral Vascular Insufficiency

Emergency surgery for peripheral vascular insufficiency is required when acute arterial occlusion results in severe ischemia and threatens the viability of a limb. Immediate operation and restoration of blood flow are needed if limb loss is to be avoided. Depending on the etiology of the occlusion, the patient may or may not be at very high risk. Although this problem may appear to be localized to an extremity, the occluding material may originate in the heart or in major arteries. Therefore, peripheral vascular occlusion may be the result of a more serious cardiovascular problem. In fact, some patients with peripheral vascular occlusion are the sickest patients we have ever anesthetized.

With acute arterial occlusion, the involved extremity suddenly becomes cold and pulseless. Patients usually complain of coldness, pain, numbness, and paresthesias, and they may lose motion and sensation. Abnormal sensation in the toes, feet, and legs in response to light touch and pinprick, as well as abnormal proprioception and loss of motor function in the feet and toes, are hallmarks of acute ischemia and nonviability. If the ischemia is not reversed in a matter of hours, irreversible loss of viability is likely to result.

Acute arterial occlusion may develop in patients with pre-existing peripheral occlusive or aneurysmal disease caused by thrombosis of a stenotic or ulcerated atherosclerotic artery. Acute arterial occlusion can also occur in patients with normal peripheral arteries that contain emboli. Such embolism is usually of cardiac origin in patients with cardiac dysrhythmias, recent MIs, or ventricular aneurysms.

The cause is important in planning operative treatment. If the cause is an arterial embolus, Fogarty embolectomy through a groin incision, angioplasty, or laser atherectomy under local anesthesia may suffice. However, if the cause is thrombosis of severely diseased atherosclerotic arteries, bypass reconstruction will be required. Although preoperative angiography may be of help in the differential diagnosis, often the cause is not uncovered until the vessel is opened. Thus, the anesthesiologist must be prepared for either a simple procedure or a complex, extended procedure. An incision in the groin is usually made for exposure of the femoral artery. Attempts to pass Fogarty catheters proximally and distally are made in the effort to establish flow and extract the thrombus. If flow is not restored in this manner, more complex reconstructive procedures such as aortofemoral, axillofemoral, or femoral-popliteal bypass may be required. Femoral venous drainage on restoration of flow to the femoral artery can aid in management by washing the initial venous effluent from an acutely ischemic extremity. Drainage may entail significant blood loss. Significant fluid losses can also be anticipated when the artery is flushed during thrombectomy and fluid is sequestered in edematous revascularized tissue. Serum potassium levels can change quickly because cell death and release of intracellular potassium into the circulation can be anticipated. Venous drainage into the autotransfusion suction with subsequent washing before reinfusion has been used to prevent the complications of hyperkalemia. Myoglobin may also be released into the circulation, and the development of a compartment syndrome is a possibility. Skill and intensive care as meticulous as that given patients with visceral ischemia may also benefit patients with peripheral vascular insufficiency.

Anticoagulants are commonly administered to patients suspected of having peripheral vascular occlusion. If a patient has received anticoagulants, the appropriateness of using a major conduction block (subarachnoid or epidural block with or without catheter placement) is controversial. We believe that regional anesthesia should be avoided when patients have received thrombolytic therapy.³²

CONCLUSIONS

Patients undergoing vascular reconstruction are generally elderly. Vascular disease is a generalized process; thus, patients having surgery for a specific vascular disorder are likely to have atherosclerotic disease elsewhere in the vascular system. Most of the patients have coronary artery disease. The skills of the anesthesiologist can therefore greatly influence outcome in vascular surgery. The considerations for preoperative patient evaluation are the same as for patients with cardiac disease undergoing other noncardiac procedures. Many have a history of smoking, and chronic obstructive pulmonary disease, renal insufficiency, and lipid abnormalities are frequently present. The major morbidity in each of the operations relates to myocardial well-being; therefore, the heart should be the major focus of the anesthesiologist's attention. Attempts to segregate patients who have significant coronary artery disease by use of preoperative testing are controversial. The benefits of coronary revascularization are likely to persist long after vascular surgery in patients with triple-vessel coronary artery disease.

In cerebrovascular surgery, the goals in anesthesia management, *i.e.*, ensuring adequate myocardial and brain perfusion and a rapidly arousable patient, may be facilitated with the use of neurophysiologic monitoring as a guide to afterload reduction. In aortic reconstruction, ensuring intact myocardial function is probably the best way of making certain that spinal cord, visceral, and renal perfusion will be adequate.

In the case of peripheral occlusive disease, the absence of hemodynamic changes should not lull the anesthesiologist into loss of vigilance with regard to myocardial well-being. In addition, vigilance in ensuring routine prehydration and use of a warming device are probably more important to outcome than is occasional brilliance. We prefer the diligent, compulsive practitioner to the occasionally brilliant one. Nowhere is such diligence needed more than in the postoperative period, when most morbidity related to the heart occurs. Perhaps it is most important to remember that the best patient results are achieved when intraoperative vigilance is extended to the preoperative and postoperative periods as well.

Anesthesia for ophthalmic surgery presents many unique challenges ([Table 34-1](#)). In addition to possessing technical expertise, the anesthesiologist must have detailed knowledge of ocular anatomy, physiology, and pharmacology. It is essential to appreciate that ophthalmic drugs may significantly alter the reaction to anesthesia and that, concomitantly, anesthetic drugs and maneuvers may dramatically influence intraocular dynamics. Patients undergoing ophthalmic surgery may represent extremes of age and coexisting medical diseases (e.g., diabetes mellitus, coronary artery disease, essential hypertension, chronic lung disease), but they are likely to be in the elderly age group. Apprehension is predictable in blind or potentially blind patients awaiting surgery.

Safety
Akinesia
Profound analgesia
Minimal bleeding
Avoidance or obtundation of oculocardiac reflex
Control of intraocular pressure
Awareness of drug interactions
Smooth emergence

Table 34-1. REQUIREMENTS OF OPHTHALMIC SURGERY

It is mandatory to be knowledgeable about the numerous surgical procedures unique to the specialty of ophthalmology. Whereas the list of ocular surgical interventions is lengthy, these procedures may, in general, be classified as extraocular or intraocular. This distinction is critical because anesthetic considerations are different for these two major surgical categories. For example, with intraocular procedures, profound akinesia (relaxation of recti muscles) and meticulous control of intraocular pressure (IOP) are requisite. However, with extraocular surgery, the significance of IOP fades, whereas concern about elicitation of the oculocardiac reflex assumes prominence.

OCULAR ANATOMY

The anesthesiologist should be knowledgeable about ocular anatomy to enhance his or her understanding of surgical procedures and to aid the surgeon in the performance of regional blocks when needed^{1,2} ([Fig. 34-1](#)). Salient subdivisions of ocular anatomy include the orbit, the eye itself, the extraocular muscles, the eyelids, and the lacrimal system.

Figure 34-1. Diagram of ocular anatomy.

The orbit is a bony box, or pyramidal cavity, housing the eyeball and its associated structures in the skull. The walls of the orbit are composed of the following bones: frontal, zygomatic, greater wing of the sphenoid, maxilla, palatine, lacrimal, and ethmoid. A familiarity with the surface relationships of the orbital rim is mandatory for the skilled performance of regional blocks.

The optic foramen, located at the orbital apex, transmits the optic nerve and the ophthalmic artery, as well as sympathetic nerves from the carotid plexus. The superior orbital fissure transmits the superior and inferior branches of the oculomotor nerve, the lacrimal, frontal, and nasociliary branches of the trigeminal nerve, as well as the trochlear and abducens nerves and the superior and inferior ophthalmic veins. The inferior orbital or sphenomaxillary fissure contains the infraorbital and zygomatic nerves and a communication between the inferior ophthalmic vein and the pterygoid plexus. The infraorbital foramen, located about 4 mm below the orbital rim in the maxilla, transmits the infraorbital nerve, artery, and vein. The lacrimal fossa, which contains the lacrimal gland in the superior temporal orbit. The supraorbital notch, located at the junction of the medial one third and temporal two thirds of the superior orbital rim, transmits the supraorbital nerve, artery, and vein. The supraorbital notch, the infraorbital foramen, and the lacrimal fossa are clinically palpable and function as major landmarks for administration of regional anesthesia.

The eye itself is actually one large sphere with part of a smaller sphere incorporated in the anterior surface, constituting a structure with two different radii of curvature. The coat of the eye is composed of three layers: sclera, uveal tract, and retina. The fibrous outer layer, or sclera, is protective, providing sufficient rigidity to maintain the shape of the eye. The anterior portion of the sclera, the cornea, is transparent, permitting light to pass into the internal ocular structures. The double-spherical shape of the eye exists because the corneal arc of curvature is steeper than the scleral arc of curvature. The focusing of rays of light to form a retinal image commences at the cornea.

The uveal tract, or middle layer of the globe, is vascular and in direct apposition to the sclera. A potential space, known as the suprachoroidal space, separates the sclera from the uveal tract. This potential space, however, may become filled with blood during an expulsive or suprachoroidal hemorrhage, often associated with surgical disaster. The iris, ciliary body, and choroid compose the uveal tract. The iris includes the pupil, which, by contractions of three sets of muscles, controls the amount of light entering the eye. The iris dilator is sympathetically innervated; the iris sphincter and the ciliary muscle have parasympathetic innervation. Posterior to the iris lies the ciliary body, which produces aqueous humor (see [Formation and Drainage of Aqueous Humor](#)). The ciliary muscles, situated in the ciliary body, adjust the shape of the lens to accommodate focusing at various distances. Large vessels and a network of small vessels and capillaries known as the choriocapillaris constitute the choroid, which supplies nutrition to the outer part of the retina.

The retina is a neurosensory membrane composed of 10 layers that convert light impulses into neural impulses. These neural impulses are then carried through the optic nerve to the brain. Located in the center of the globe is the vitreous cavity, filled with a gelatinous substance known as vitreous humor. This material is adherent to the most anterior 3 mm of the retina as well as to large blood vessels and the optic nerve. The vitreous humor may pull on the retina, causing retinal tears and retinal detachment.

The crystalline lens, located posterior to the pupil, refracts rays of light passing through the cornea and pupil to focus images on the retina. The ciliary muscle, whose contractile state causes tautness or relaxation of the lens zonules, regulates the thickness of the lens.

In addition, six extraocular muscles move the eye within the orbit to various positions. The bilobed lacrimal gland provides most of the tear film, which serves to maintain a moist anterior surface on the globe. The lacrimal drainage system, composed of the puncta, canaliculi, lacrimal sac, and lacrimal duct, drains into the nose below the inferior turbinate. Blockage of this system occurs not infrequently, necessitating procedures ranging from lacrimal duct probing to dacryocystorhinostomy, which involves anastomosis of the lacrimal sac to the nasal mucosa.

Covering the surface of the globe and lining the eyelids is a mucous membrane called the conjunctiva. Because drugs are absorbed across the membrane, it is a popular site for administration of ophthalmic drugs.

The eyelids consist of four layers: (1) the conjunctiva, (2) the cartilaginous tarsal plate, (3) a muscle layer composed mainly of the orbicularis and the levator palpebrae, and (4) the skin. The eyelids protect the eye from foreign objects; through blinking, the tear film produced by the lacrimal gland is spread across the surface of the eye, keeping the cornea moist.

Blood supply to the eye and orbit is by means of branches of both the internal and external carotid arteries. Venous drainage of the orbit is accomplished through the multiple anastomoses of the superior and inferior ophthalmic veins. Venous drainage of the eye is achieved mainly through the central retinal vein. All these veins empty directly into the cavernous sinus.

The sensory and motor innervations of the eye and its adnexa are very complex, with multiple cranial nerves supplying branches to various ocular structures. A branch of the oculomotor nerve supplies a motor root to the ciliary ganglion, which in turn supplies the sphincter of the pupil and the ciliary muscle. The trochlear nerve supplies the superior oblique muscle. The abducens nerve supplies the lateral rectus muscle. The trigeminal nerve constitutes the most complex ocular and adnexal innervation. In addition, the zygomatic branch of the facial nerve eventually divides into an upper branch, supplying the frontalis and the upper lid orbicularis, whereas the lower branch supplies the orbicularis of the lower lid.

OCULAR PHYSIOLOGY

Despite its relatively diminutive size, the eye is a complex organ, concerned with many intricate physiologic processes. The formation and drainage of aqueous humor and their influence on IOP in both normal and glaucomatous eyes are among the most important functions, especially from the anesthesiologist's perspective. An appreciation of the effects of various anesthetic manipulations on IOP requires an understanding of the fundamental principles of ocular physiology.

Formation and Drainage of Aqueous Humor

Two thirds of the aqueous humor is formed in the posterior chamber by the ciliary body in an active secretory process involving both the carbonic anhydrase and the cytochrome oxidase systems ([Fig. 34-2](#)). The remaining third is formed by passive filtration of aqueous humor from the vessels on the anterior surface of the iris.

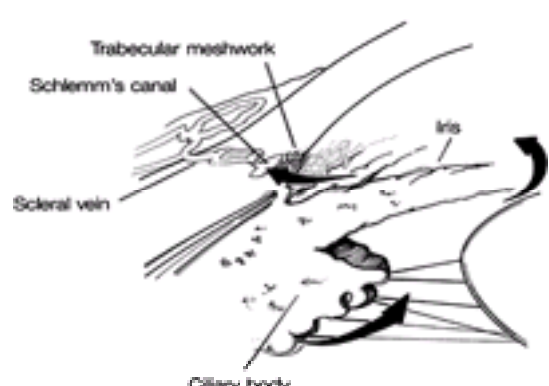

Figure 34-2. Ocular anatomy concerned with control of intraocular pressure.

At the ciliary epithelium, sodium is actively transported into the aqueous humor in the posterior chamber. Bicarbonate and chloride ions passively follow the sodium ions. This active mechanism results in the osmotic pressure of the aqueous being many times greater than that of plasma. It is this disparity in osmotic pressure that leads to an average rate of aqueous humor production of $2 \mu\text{l} \cdot \text{min}^{-1}$.

Aqueous humor flows from the posterior chamber through the pupillary aperture into the anterior chamber, where it mixes with the aqueous formed by the iris. During its journey into the anterior chamber, the aqueous humor bathes the avascular lens, providing essential metabolic materials and removing metabolic wastes. Once in the anterior chamber, the aqueous also bathes the corneal endothelium, maintaining healthy corneal metabolism. Then the aqueous flows into the peripheral segment of the anterior chamber and exits the eye through the trabecular network, Schlemm's canal, and the episcleral venous system. A network of connecting venous channels eventually leads to the superior vena cava and the right atrium. Thus, obstruction of venous return at any point from the eye to the right side of the heart impedes aqueous drainage, elevating IOP accordingly.

Maintenance of Intraocular Pressure

Intraocular pressure normally varies between 10 and 21.7 mm Hg and is considered abnormal above 22 mm Hg. This level varies 1–2 mm Hg with each cardiac contraction. Also, a diurnal variation of 2–5 mm Hg is observed, with a higher value noted on awakening. This higher awakening pressure has been ascribed to vascular congestion, pressure on the globe from closed lids, and mydriasis—all of which occur during sleep.

Intraocular pressure far exceeds not only tissue pressure (2–3 mm Hg) but intracranial pressure (7–8 mm Hg). Apparently the maintenance of such a relatively high pressure in the eye is demanded by the optical properties of refracting surfaces; the corneal surface should be kept at a constant curvature, and the stroma must be under constant high pressure to maintain a uniform refractive index.³ However, an abnormally high pressure may result in opacities by interfering with normal corneal metabolism.

During anesthesia, a rise in IOP can produce permanent visual loss. If the IOP is already elevated, a further increase can trigger acute glaucoma. If penetration of the globe occurs when the IOP is excessively high, rupture of a blood vessel with subsequent hemorrhage may transpire. IOP becomes atmospheric once the eye cavity has been entered, and any sudden rise in pressure may lead to prolapse of the iris and lens, and loss of vitreous. Thus, proper control of IOP is critical.

Three main factors influence IOP: (1) external pressure on the eye by the contraction of the orbicularis oculi muscle and the tone of the extraocular muscles, venous congestion of orbital veins (as may occur with vomiting and coughing), and conditions such as orbital tumor; (2) scleral rigidity; and (3) changes in intraocular contents that are semisolid (lens, vitreous, or intraocular tumor) or fluid (blood and aqueous humor). Although all these factors are significant in affecting IOP, the major control of intraocular tension is exerted by the fluid content, especially the aqueous humor.

Sclerosis of the sclera, not uncommonly seen in the aged, may be associated with decreased scleral compliance and increased IOP. Other degenerative changes of the eye linked with aging can also influence IOP, the most significant being a hardening and enlargement of the crystalline lens. When these degenerative changes occur, they may lead to anterior displacement of the lens–iris diaphragm. A resultant shallowness of the anterior chamber angle may then occur, reducing access of the trabecular meshwork to aqueous. This process is usually gradual, but, if rapid lens engorgement occurs, angle-closure glaucoma may transpire.

Changes in the nature of the vitreous that affect the amount of unbound water also influence IOP. Myopia, trauma, and aging produce liquefaction of vitreous gel and a subsequent increase in unbound water, which may lower IOP by facilitating fluid removal. However, under different circumstances, the opposite may occur, that is, the hydration of more normal vitreous may be associated with elevation of IOP. Hence, it is often prudent to produce a slightly dehydrated state in the surgical patient with glaucoma.

Intraocular blood volume, determined primarily by vessel dilation or contraction in the spongy layers of the choroid, contributes significantly to IOP. Although changes in both arterial or venous pressure may secondarily affect IOP, excursions in arterial pressure have much less importance than do venous fluctuations. In chronic arterial hypertension, ocular pressure returns to normal levels after a period of adaptation brought about by compression of vessels in the choroid as a result of increased IOP. Thus, a feedback mechanism reduces the total volume of blood, keeping IOP relatively constant in patients with systemic hypertension.⁴

However, if venous return from the eye is disturbed at any point from Schlemm's canal to the right atrium, IOP increases substantially. This is caused both by increased intraocular blood volume and distention of orbital vessels, as well as by interference with aqueous drainage. Straining, vomiting, or coughing greatly increase venous pressure and raise IOP as much as 40 mm Hg or greater. The deleterious implications of these activities cannot be overemphasized. Laryngoscopy and tracheal intubation may also elevate IOP, even without any visible reaction to intubation, but especially when the patient coughs. Topical anesthetization of the larynx may attenuate the hypertensive response to laryngoscopy but does not reliably prevent associated increases in IOP.⁵ Ordinarily, the pressure elevation from such increases in blood volume or venous pressure dissipates rapidly. However, if the coughing or straining occurs during ocular surgery when the eye is open, as in cataract extraction or in penetrating keratoplasty, the result may be a disastrous expulsive hemorrhage, at worst, or a disconcerting loss of vitreous, at best.

Despite the significant role of venous pressure, scleral rigidity, and vitreous composition, maintenance of IOP is determined primarily by the rate of aqueous formation and the rate of aqueous outflow. The most important influence on formation of aqueous humor is the difference in osmotic pressure between aqueous and plasma.³ This fact is illustrated by the equation:

$$\text{IOP} = K[(\text{OP}_{\text{aq}} - \text{OP}_{\text{pl}}) + \text{CP}] \quad (34-1)$$

where K = coefficient of outflow, OP_{aq} = osmotic pressure of aqueous humor, OP_{pl} = osmotic pressure of plasma, and CP = capillary pressure. The fact that a small change in solute concentration of plasma can markedly influence the formation of aqueous humor and hence IOP is the rationale for using hypertonic solutions, such as mannitol, to lower IOP.

Fluctuations in aqueous outflow may also produce a dramatic alteration in IOP. The most significant factor controlling aqueous humor outflow is the diameter of Fontana's spaces,⁶ as illustrated by the equation:

$$A = \frac{r^4 \times (\text{Piop} - \text{Pv})}{8\eta L} \quad (34-2)$$

A = volume of aqueous outflow per unit of time, r = radius of Fontana's spaces, Piop = IOP, Pv = venous pressure, η = viscosity, and L = length of Fontana's spaces. When the pupil dilates, Fontana's spaces narrow, resistance to outflow is increased, and IOP rises. Because mydriasis is undesirable in both closed- and open-angle glaucoma, miotics such as pilocarpine are applied conjunctivally in patients with glaucoma.

Glaucoma

Glaucoma is a condition characterized by elevated IOP, resulting in impairment of capillary blood flow to the optic nerve with eventual loss of optic nerve tissue and function. Two different anatomic types of glaucoma exist: open-angle or chronic simple glaucoma, and closed-angle or acute glaucoma. (Other variations of these processes occur but are not especially germane to anesthetic management.)

With open-angle glaucoma, the elevated IOP exists with an anatomically open anterior chamber angle. It is thought that sclerosis of trabecular tissue results in impaired aqueous filtration and drainage. Treatment consists of medication to produce miosis and trabecular stretching. Commonly used eyedrops are epinephrine, timolol, dipivefrin, and betaxolol. Closed-angle glaucoma is characterized by the peripheral iris moving into direct contact with the posterior corneal surface, mechanically obstructing aqueous outflow. People who have a narrow angle between the iris and posterior cornea are predisposed to this condition. In these patients, mydriasis can produce such increased thickening of the peripheral iris that corneal touch occurs and the angle is closed. Another mechanism producing acute, closed-angle glaucoma is swelling of the crystalline lens. In this case, pupillary block occurs, with the edematous lens blocking the flow of aqueous from the posterior to the anterior chamber. This situation can also develop if the lens is traumatically dislocated anteriorly, thus physically blocking the anterior chamber.

It was previously thought by some clinicians that patients with glaucoma should not be given atropine premedication. However, this claim is untenable. Atropine premedication in the dose range used clinically has no effect on IOP in either open- or closed-angle glaucoma. When 0.4 mg of atropine is given to a 70-kg person, approximately 0.0001 mg is absorbed by the eye.⁷ Garde *et al*⁸ reported, however, that scopolamine has a greater mydriatic effect than atropine and recommended not using scopolamine in patients with known or suspected closed-angle glaucoma.

[Equation 34-2](#), describing the volume of aqueous outflow per unit of time, clearly demonstrates that outflow is exquisitely sensitive to fluctuations in venous pressure. Because a rise in venous pressure produces an increased volume of ocular blood as well as decreased aqueous outflow, it is obvious that considerable elevation of IOP occurs with any maneuver that increases venous pressure. Hence, in addition to preoperative instillation of miotics, other anesthetic goals for the patient with glaucoma include perioperative avoidance of venous congestion and of overhydration. Furthermore, hypotensive episodes are to be avoided because these patients are allegedly vulnerable to retinal vascular thrombosis.

Primary congenital glaucoma is classified according to age of onset, with the infantile type presenting any time after birth until 3 years of age. The juvenile type presents between the ages of 37 months and 30 years. Moreover, childhood glaucoma may also occur in conjunction with various eye diseases or developmental anomalies such as aniridia, mesodermal dysgenesis syndrome, and retinopathy of prematurity.⁹

Successful management of infantile glaucoma is crucially dependent on early diagnosis. Presenting symptoms include epiphora, photophobia, blepharospasm, and irritability. Ocular enlargement, termed *buphthalmos*, or “ox eye,” and corneal haziness secondary to edema are common. Buphthalmos is rare, however, if glaucoma develops after 3 years of age because by then the eye is much less elastic.

Because infantile glaucoma is frequently associated with obstructed aqueous outflow, management of it often requires surgical creation, by goniotomy or trabeculotomy, of a route for aqueous humor to flow into Schlemm's canal. However, advanced disease may be unresponsive to even multiple goniotomies, and the more radical trabeculectomy or some other variety of filtering procedure may be necessary.

The juvenile form of glaucoma, in which the cornea and eye size are normal, is commonly associated with a family history of open-angle glaucoma and is treated similarly to primary open-angle glaucoma.

In cases of pediatric secondary glaucoma, goniotomy and filtering may be unsuccessful, whereas cyclocryotherapy may effect a reduction in IOP, pain, and corneal edema. The ciliary body is destroyed with a cryoprobe, cooled to -70°C, thus dramatically decreasing aqueous formation.

It is essential to appreciate that the high IOP frequently encountered in infantile glaucoma can be reduced by more than 15 mm Hg when surgical anesthesia is achieved. One study, however, demonstrated minimal effect of halothane on IOP when the concentration ranged narrowly between 0.5 and 1.0%.¹⁰ Some clinicians maintain that ketamine is a useful drug to use for examination under anesthesia when infantile glaucoma is part of the differential diagnosis because ketamine does not appear to reduce IOP, giving a spuriously low reading. Moreover, even normal infants sporadically have pressures in the mid-20s. Hence, diagnosis is not based exclusively on the numerical pressure recorded under anesthesia. Other factors such as corneal edema and increased corneal diameter, tears in Descemet's membrane, and cupping of the optic nerve are considered in making the diagnosis. If these aberrations are noted, surgical intervention may be mandatory, even in the setting of a reputedly normal IOP.

EFFECTS OF ANESTHESIA AND ADJUVANT DRUGS ON INTRAOCULAR PRESSURE

Central Nervous System Depressants

Inhalation anesthetics purportedly cause dose-related decreases in IOP.¹¹ The exact mechanisms are unknown, but postulated etiologies include depression of a central nervous system (CNS) control center in the diencephalon,⁴ reduction of aqueous humor production, enhancement of aqueous outflow, or relaxation of the extraocular muscles.⁷ Moreover, virtually all CNS depressants, including barbiturates,¹² neuroleptics,¹³ opioids, tranquilizers,⁷ and hypnotics, such as etomidate¹⁴ and propofol,¹⁵ lower IOP in both normal and glaucomatous eyes. Etomidate, despite its proclivity to produce pain on intravenous (iv) injection and skeletal muscle movement, is associated with a significant reduction in IOP.¹⁶ However, etomidate-induced myoclonus may be hazardous in the setting of a ruptured globe.

Controversy, however, surrounds the issue of ketamine's effect on IOP. Administered iv or intramuscularly (im), ketamine initially was thought to increase IOP significantly, as measured by indentation tonometry.¹⁷ Corssen and Hoy¹⁸ had also reported a slight but statistically significant increase in IOP that appeared unrelated to changes in blood pressure or depth of anesthesia. However, nystagmus made proper positioning of the tonometer difficult and may have resulted in less-than-accurate measurements.

Conflicting results arose from a study in which 2 mg · kg⁻¹ of ketamine given iv to adults failed to have a significant effect on IOP.¹⁹ Furthermore, a pediatric study reported no increase in IOP after an im ketamine dose of 8 mg · kg⁻¹. Indeed, values obtained were similar to those reported with halothane and isoflurane.^{20,21}

Some of the confusion may arise from differences in premedication practices and from the use of different instruments to measure IOP. More recent studies have used applanation tonometry rather than indentation tonometry. However, even if future studies should confirm that ketamine has minimal or no effect on IOP, ketamine's proclivity to cause nystagmus and blepharospasm makes it a less-than-optimal agent for many types of ophthalmic surgery.

Ventilation and Temperature

Hyperventilation decreases IOP, whereas asphyxia, administration of carbon dioxide, and hypoventilation have been shown to elevate IOP.^{3,22}

Hypothermia lowers IOP. On initial consideration, hypothermia might be expected to raise IOP because of the associated increase in viscosity of aqueous humor. However, hypothermia is linked with decreased formation of aqueous humor and with vasoconstriction; hence, the net result is a reduction in IOP.

Adjuvant Drugs

Ganglionic Blockers, Hypertonic Solutions, and Acetazolamide

Ganglionic blockers such as tetraethylammonium²³ and pentamethonium effect a dramatic decrease in IOP. Trimethaphan also significantly lowers IOP in normal subjects, despite mydriasis.

Intravenous administration of hypertonic solutions such as dextran, urea, mannitol, and sorbitol elevates plasma osmotic pressure, thereby decreasing aqueous humor formation and reducing IOP.²⁴ As effective as urea is in reducing IOP, iv mannitol has the advantage of fewer side effects. Mannitol's onset, peak (30–45 minutes), and duration of action (5–6 hours) are similar to those of urea. Moreover, both drugs may produce acute intravascular volume overload. Sudden expansion of plasma volume secondary to efflux of intracellular water into the vascular compartment places a heavy workload on the kidneys and heart, often resulting in hypertension and dilution of plasma sodium. Furthermore, mannitol-associated diuresis, if protracted, may trigger hypotension in volume-depleted patients.

Glycerin has the advantage of being effective orally. However, the ocular hypotensive effect is said to be less predictable than that of mannitol. Onset usually occurs within 10 minutes of ingestion, and peak action is noted at 30 minutes. The duration of action is 5–6 hours. Unfortunately, glycerin may trigger nausea or vomiting, and gastric fluid trapping increases the risk of aspiration.

Intravenous administration of acetazolamide inactivates carbonic anhydrase and interferes with the sodium pump. The resultant decrease in aqueous humor formation lowers IOP. However, the action of acetazolamide is not limited to the eye, and systemic effects include loss of sodium, potassium, and water secondary to the drug's renal tubular effects. Such electrolyte imbalances may then be linked to cardiac dysrhythmias during general anesthesia.

An advantage of acetazolamide is its relative ease of administration. Whereas large volumes of hypertonic solutions must be infused to reduce IOP, acetazolamide is easily given as a typical adult dose of 500 mg dissolved in 10 ml of sterile water. Acetazolamide may also be given orally, and topical carbonic anhydrase inhibitors are commercially available.

Neuromuscular Blocking Drugs

Neuromuscular blocking drugs have both direct and indirect actions on IOP. Hence, a paralyzing dose of *d*-tubocurarine directly lowers IOP by relaxing the extraocular muscles.²⁵ The same is true of equipotent doses of the other nondepolarizing drugs, including pancuronium²⁶ (Fig. 34-3). However, if paralysis of the respiratory muscles is accompanied by alveolar hypoventilation, the latter secondary effect may supervene to increase IOP.

Figure 34-3. Mean intraocular pressure after administration of thiopental, 3–4 mg · kg⁻¹, and pancuronium, 0.08 mg · kg⁻¹ at 0. A = loss of lid reflex; **p* < 0.05. (Reprinted with permission from Litwiller RW, DeFazio CA, Rushia EF: Pancuronium and intraocular pressure. *Anesthesiology* 42:750, 1975.)

In contrast to nondepolarizing drugs, the depolarizing drug succinylcholine elevates IOP. Lincoff *et al*²⁷ reported extrusion of vitreous after succinylcholine administration to a patient with a surgically open eye. An average peak IOP increase of about 8 mm Hg is produced within 1–4 minutes of an iv dose. Within 7 minutes, return to baseline usually transpires.²⁸ The ocular hypertensive effect of succinylcholine has been attributed to several mechanisms, including tonic contraction of extraocular muscles,⁷ choroidal vascular dilation, and relaxation of orbital smooth muscle.²⁹ One study speculates that the succinylcholine-induced increase in IOP is multifactorial but primarily the result of the cycloplegic action of succinylcholine producing a deepening of the anterior chamber and increased outflow resistance.³⁰ Because they studied eyes with the extraocular muscles detached and still observed an elevation in IOP, these investigators proposed that changes in extraocular muscle tone do not contribute significantly to the increase in IOP observed after succinylcholine administration.

A variety of methods have been advocated to prevent succinylcholine-induced elevations in IOP. In truth, although some attenuation of the increase results, none of these techniques consistently and completely blocks the ocular hypertensive response. Prior administration of such drugs as acetazolamide,³¹ propranolol, and nondepolarizing neuromuscular blocking drugs has been suggested. The efficacy of pretreatment with nondepolarizing drugs is controversial.

In 1968, Miller *et al*,³² using indentation tonometry, reported that pretreatment with small amounts of gallamine or *d*-tubocurarine prevented succinylcholine-associated increases in IOP. However, in 1978 Meyers *et al*,³³ using the more sensitive applanation tonometer, were unable consistently to circumvent the ocular hypertensive response after similar pretreatment therapy (Table 34-2). In addition, Verma³⁴ in 1979 had claimed that a “self-taming” dose of succinylcholine was protective, but Meyers *et al*³⁵ in 1980, in a controlled study using applanation tonometry, challenged this claim. Although iv pretreatment with lidocaine, 1–2 mg · kg⁻¹, may blunt the hemodynamic response to laryngoscopy,^{5,36} such therapy does not reliably prevent the ocular hypertensive response associated with succinylcholine and intubation.³⁷ However, Grover and associates³⁸ claimed that pretreatment with lidocaine, 1.5 mg · kg⁻¹ iv, 1 minute before induction with thiopental and succinylcholine offered protection from IOP increases due to succinylcholine and may therefore be of value in rapid-sequence induction for open eye injuries.

| Pretreatment* | Mean Age (yr) | Intraocular Pressure (mm Hg, mean ± SD) | | |
|------------------------|---------------|---|------------------------------|--------------------------------|
| | | Basilar | 3 Minutes After Pretreatment | 1 Minute After Succinylcholine |
| <i>d</i> -Tubocurarine | 134 | 130 ± 1.0 | 123 ± 1.2 | 24.0 ± 1.3 |
| Gallamine | 87 | 109 ± 1.1 | 106 ± 1.0 | 21.4 ± 1.3 |

**d*-Tubocurarine, 0.08 mg · kg⁻¹, or gallamine, 0.3 mg · kg⁻¹.

Table 34-2. EFFECTS OF SUCCINYLCHOLINE ON INTRAOCULAR PRESSURE: DOUBLE-BLIND *d*-TUBOCURARINE OR GALLAMINE PRETREATMENT

Certainly, no one would disagree that succinylcholine—if unaccompanied by pretreatment with a nondepolarizing neuromuscular blocking drug—is contraindicated in patients with penetrating ocular wounds and should not be given for the first time after the eye has been opened. Nonetheless, it no longer is valid to recommend that succinylcholine be used only with extreme reluctance in ocular surgery. Clearly, any succinylcholine-induced increment in IOP is usually dissipated before surgery is started. Of concern, however, is Jampolsky's³⁹ warning that succinylcholine be avoided in patients undergoing repeat strabismus surgery because the forced duction test (FDT) does not return to baseline for approximately 30 minutes after administration of the drug. More recent and quantitatively sophisticated studies by France *et al*⁴⁰ have supported this caveat, although the latter investigators suggest waiting only 20 minutes after administration of succinylcholine before performing the FDT.

OCULOCARDIAC REFLEX

Bernard Aschner and Giuseppe Dagnini first described the oculocardiac reflex in 1908. This reflex is triggered by pressure on the globe and by traction on the extraocular muscles as well as on the conjunctiva or on the orbital structures. Moreover, the reflex may also be elicited by performance of a retrobulbar block,⁴¹ by ocular trauma, and by direct pressure on tissue remaining in the orbital apex after enucleation.⁴² The afferent limb is trigeminal and the efferent limb is vagal. Although the most common manifestation of the oculocardiac reflex is sinus bradycardia, a wide spectrum of cardiac dysrhythmias may occur, including junctional rhythm, ectopic atrial rhythm, atrioventricular blockade, ventricular bigeminy, multifocal premature ventricular contractions, wandering pacemaker, idioventricular rhythm, asystole, and ventricular tachycardia.^{43,44} and ⁴⁵ This reflex may appear during either local or general anesthesia; however, hypercarbia and hypoxemia are thought to augment the incidence and severity of the problem, as may inappropriate anesthetic depth.

Reports on the alleged incidence of the oculocardiac reflex are remarkable in their striking variability. Berler's study⁴¹ reported an incidence of 50%, but other sources quote rates ranging from 16 to 82%.^{43,46} Commonly, those articles disclosing a higher incidence included children in the study population, and children tend to have more vagal tone.

A variety of maneuvers to abolish or obtund the oculocardiac reflex have been promulgated. None of these methods has been consistently effective, safe, and reliable. Inclusion of im anticholinergic drugs such as atropine or glycopyrrolate in the usual premedication regimen for oculocardiac reflex prophylaxis is ineffective.⁴⁷ Nearly complete vagolytic blockade in the adult mandates 2–3 mg of atropine or 0.03–0.05 mg · kg⁻¹.⁴⁸ Insofar as the peak action of im atropine occurs approximately 30 minutes after administration, it is not surprising that studies of the usual, routine, much smaller doses of atropine administered more than 1 hour before surgery have shown inconsistent protection against the oculocardiac reflex.

For the young child who is extremely apprehensive about “shots,” giving oral atropine, 0.04 mg · kg⁻¹, with a small amount of water 60–90 minutes before surgery is an alternative.⁴⁹ However, the oral route has not enjoyed tremendous popularity with anesthesiologists because of its slower absorption and more erratic efficacy.

Atropine given iv within 30 minutes of surgery⁴⁶ is thought to effect a reduced incidence of the reflex. However, reports differ concerning dosage and timing. Moreover, some anesthesiologists claim that prior iv administration of atropine may yield more serious and refractory cardiac dysrhythmias⁵⁰ than the reflex itself. Clearly, atropine may be considered a potential myocardial irritant. A variety of cardiac dysrhythmias^{51,52} and several conduction abnormalities,⁵³ including ventricular fibrillation, ventricular tachycardia, and left bundle-branch block, have been attributed to iv atropine.

Although administration of retrobulbar anesthesia may provide some cardiac antidysrhythmic value by blocking the afferent limb of the reflex arc, such a regional technique is not devoid of potential complications, which include, but are not limited to, optic nerve damage, retrobulbar hemorrhage, and stimulation of the oculocardiac reflex arc by the retrobulbar block itself.

It is generally believed that, in adults, the aforementioned prophylactic measures, fraught with inherent hazards, are usually not indicated. If a cardiac dysrhythmia appears, initially the surgeon should be asked to cease operative manipulation. Next, the patient's anesthetic depth and ventilatory status are evaluated. Commonly, heart rate and rhythm return to baseline within 20 seconds after institution of these measures. Moreover, Moonie *et al*⁵⁴ noted that, with repeated manipulation, bradycardia is less likely to recur, probably secondary to fatigue of the reflex arc at the level of the cardioinhibitory center. However, if the initial cardiac dysrhythmia is especially serious or if the reflex tenaciously recurs, atropine should be administered iv, but only after the surgeon stops ocular manipulation.

During pediatric strabismus surgery, however, current popular practice favors administration of iv atropine, 0.02 mg · kg⁻¹, before commencing surgery.⁵⁵ Alternatively, glycopyrrolate, 0.01 mg · kg⁻¹ administered iv, may be associated with less tachycardia than atropine in this setting.

Clearly, considerable controversy surrounds the issues of incidence and prophylaxis of the oculocardiac reflex. Nonetheless, there is consensus that continuous monitoring of the electrocardiogram (ECG) is important during all types of eye surgery to detect potentially dangerous cardiac rhythm disturbances.

ANESTHETIC RAMIFICATIONS OF OPHTHALMIC DRUGS

There is considerable potential for drug interactions during administration of anesthesia for ocular surgery. Topical ophthalmic drugs may produce undesirable systemic effects or may have deleterious anesthetic implications. Systemic absorption of topical ophthalmic drugs may occur from either the conjunctiva or the nasal mucosa after drainage through the nasolacrimal duct. In addition, some percutaneous absorption, from spillover, through the immature epidermis of the premature infant may transpire.⁵⁶ Occluding the nasolacrimal duct by pressing on the inner canthus of the eye for a few minutes after each instillation greatly decreases systemic absorption.

Some of the potentially worrisome topical ocular drugs include acetylcholine, anticholinesterases, cocaine, cyclopentolate, epinephrine, phenylephrine, and timolol. In addition, intraocular sulfur hexafluoride and other intraocular gases have important anesthetic ramifications. Furthermore, certain ophthalmic drugs given systemically may produce untoward sequelae germane to anesthetic management. Drugs in this category include glycerol, mannitol, and acetazolamide.

Acetylcholine

Acetylcholine is commonly used intraocularly after lens extraction to produce miosis. The local use of this drug may occasionally result in such systemic effects as bradycardia, increased salivation, and bronchial secretions, as well as bronchospasm. The side effects, including hypotension and bradycardia,⁵⁷ that may develop in patients given acetylcholine after cataract extraction may be rapidly reversed with iv atropine. Furthermore, vagotonic anesthetic agents such as halothane can accentuate the effects of acetylcholine.

Anticholinesterase Agents

Echothiophate is a long-acting anticholinesterase miotic that lowers IOP by decreasing resistance to the outflow of aqueous humor. Useful in the treatment of glaucoma, echothiophate is absorbed into the systemic circulation after instillation in the conjunctival sac. Any of the long-acting anticholinesterases may prolong the action of succinylcholine⁵⁸ because, after a month or more of therapy, plasma pseudocholinesterase activity may be less than 5% of normal.⁵⁹ It is said, moreover, that normal enzyme activity does not return until 4–6 weeks after discontinuation of the drug.⁶⁰ Hence, the anesthesiologist should anticipate prolonged apnea if these patients are given a usual dose of succinylcholine. In addition, a delay in metabolism of ester local anesthetics should be expected.

Cocaine

Cocaine, introduced to ophthalmology in 1884 by Koller, has limited topical ocular use because it can cause corneal pits and erosion. However, as the only local anesthetic that inherently produces vasoconstriction and shrinkage of mucous membranes, cocaine is commonly used in a nasal pack during dacryocystorhinostomy. The drug is so well absorbed from mucosal surfaces that plasma concentrations comparable to those after direct iv injection are achieved.⁶¹ Because cocaine interferes with catecholamine uptake, it has a sympathetic nervous system potentiating effect.⁶¹

Historically, epinephrine had often been mixed with cocaine in hopes of augmenting the degree of vasoconstriction produced. This practice is both superfluous and deleterious because cocaine is a potent vasoconstrictor in its own right, and the combination of epinephrine with cocaine may trigger dangerous cardiac dysrhythmias. It has been shown that cocaine used alone, without topical epinephrine, to shrink the nasal mucosa in conjunction with halothane or enflurane does not sensitize the heart to endogenous epinephrine during halothane or enflurane anesthesia.⁶² However, animal studies have shown that after pretreatment with exogenous epinephrine, cocaine facilitates the development of epinephrine-induced cardiac dysrhythmias during halothane anesthesia.⁶³

The usual maximal dose of cocaine used in clinical practice is 200 mg for a 70-kg adult, or 3 mg · kg⁻¹. However, 1.5 mg · kg⁻¹ is preferable, because this lower dose has been shown not to exert any clinically significant sympathomimetic effect in combination with halothane.⁶⁴ Although 1 g is considered to be the usual lethal dose for an adult, considerable variation occurs. Furthermore, systemic reactions may appear with as little as 20 mg.

Meyers⁶⁵ described two cases of cocaine toxicity during dacryocystorhinostomy, underscoring that cocaine is contraindicated in hypertensive patients or in patients receiving drugs such as tricyclic antidepressants or monoamine oxidase inhibitors. In addition, sympathomimetics such as epinephrine or phenylephrine should not be given with cocaine.

Obviously, before administering cocaine or another potent vasoconstrictor for dacryocystorhinostomy, the physician should carefully search out possible contraindications. To avoid toxic levels, doses of dilute solutions should be meticulously calculated and carefully administered. If serious cardiovascular effects occur, labetalol should be used to counteract them.⁶⁶ In the past, propranolol was widely used to control cocaine-induced hypertension,⁶⁷ but a lethal hypertensive exacerbation has been ascribed to unopposed α -adrenergic stimulation.⁶⁸ Labetalol offers the advantage of combined α and β blockade.

Cyclopentolate

Despite the popularity of cyclopentolate as a mydriatic, it is not without side effects, which include CNS toxicity. Manifestations include dysarthria, disorientation, and frank psychotic reactions. Purportedly, CNS dysfunction is more likely to follow use of the 2% solution as opposed to the 1% solution.⁶⁹ Furthermore, cases of convulsions in children after ocular instillation of cyclopentolate have been reported.⁷⁰ Hence, for pediatric use, 0.5–1.0% solutions are recommended. At higher concentrations, cyclopentolate also causes cycloplegia.

Epinephrine

Although topical epinephrine has proved useful in some patients with open-angle glaucoma, the 2% solution has been associated with such systemic effects as nervousness, hypertension, angina pectoris, tachycardia, and other dysrhythmias.⁷¹

Some anesthesiologists have maintained that it is unwise to use epinephrine in patients being anesthetized with a halogenated hydrocarbon. However, Smith and colleagues⁷² reported on the administration of epinephrine into the anterior chamber of patients undergoing cataract surgery by phacoemulsification and aspiration. They concluded it is safe to administer epinephrine into the anterior chamber in doses up to 68 $\mu\text{g} \cdot \text{kg}^{-1}$ under these circumstances. It was postulated that the iris, with its rich supply of adrenergic receptors, may be able to capture with extreme rapidity the epinephrine given into the eye. Apparently, there is not much systemic absorption from the globe.

Phenylephrine

Pupillary dilation and capillary decongestion are reliably produced by topical phenylephrine. Although systemic effects secondary to topical application of prudent doses are rare,⁷³ severe hypertension, headache, tachycardia, and tremulousness have been reported.⁷¹

In patients with coronary artery disease, severe myocardial ischemia, cardiac dysrhythmias, and even myocardial infarction may develop after topical 10% eyedrops. Those with cerebral aneurysms may be susceptible to cerebral hemorrhage after phenylephrine in this concentration. In general, a safe systemic level follows absorption from either the conjunctiva or the nasal mucosa after drainage by the tear ducts. However, phenylephrine should not be given in the eye after surgery has begun and venous channels are patent.

Children are especially vulnerable to overdose and may respond in a dramatic and adverse fashion to phenylephrine drops. Hence, the use of only 2.5%, rather than 10%, phenylephrine is recommended in infants and the elderly, and the frequency of application should be strictly limited in these patient populations.

Timolol and Betaxolol

Timolol, a nonselective b-adrenergic blocking drug, is a popular antiglaucoma drug. Because significant conjunctival absorption may occur, timolol should be administered with caution to patients with known obstructive airway disease, congestive heart failure, or greater than first-degree heart block. Life-threatening asthmatic crises have been reported after the administration of timolol drops to some patients with chronic, stable asthma.⁷⁴ Not unexpectedly, the development of severe sinus bradycardia in a patient with cardiac conduction defects (left anterior hemiblock, first-degree atrioventricular block, and incomplete right bundle-branch block) has been reported after timolol.⁷⁵ Moreover, timolol has been implicated in the exacerbation of myasthenia gravis⁷⁶ and in the production of postoperative apnea in neonates and young infants.^{77,78}

In contrast to timolol, a newer antiglaucoma drug, betaxolol, a b₁ blocker, is said to be more ocularspecific and have minimal systemic effects. However, patients receiving an oral b blocker and betaxolol should be observed for potential additive effect on known systemic effects of b blockade. Caution should be exercised in patients receiving catecholamine-depleting drugs. Although betaxolol has produced only minimal effects in patients with obstructive airways disease, caution should be exercised in the treatment of patients with excessive restriction of pulmonary function. Moreover, betaxolol is contraindicated in patients with sinus bradycardia, congestive heart failure, greater than first-degree heart block, cardiogenic shock, and overt myocardial failure.

Intraocular Sulfur Hexafluoride

For a patient with a retinal detachment, intraocular sulfur hexafluoride⁷⁹ or other gases such as certain perfluorocarbons may be injected into the vitreous to facilitate reattachment mechanically. These recommendations do not apply to open-eye procedures during which volume and pressure changes are readily compensated for by fluid and gas leak.

Stinson and Donlon⁸⁰ suggest terminating nitrous oxide 15 minutes before gas injection to prevent significant changes in the size of the intravitreal gas bubble. The patient is then given virtually 100% oxygen or a combination of oxygen and air (admixed with a small percentage of volatile agent) for the balance of the operation without adversely affecting intravitreal gas dynamics. Furthermore, if a patient requires reoperation and general anesthesia after intravitreal gas injection, nitrous oxide should be avoided for 5 days subsequent to air injection and for 10 days after sulfur hexafluoride injection⁸¹ (Table 34-3).

| | Blood:Gas Partition Coefficients |
|---------------------|----------------------------------|
| Sulfur hexafluoride | 0.004 |
| Nitrogen | 0.015 |
| Nitrous oxide | 0.468 |

Table 34-3. DIFFERENTIAL SOLUBILITIES OF GASES

Perfluoropropane and octafluorocyclobutane may also be used in vitreoretinal surgery to support the retina. Like sulfur hexafluoride, these gases are relatively insoluble and require discontinuance of nitrous oxide at least 15 minutes before injection. Should the patient require reoperation, it must be remembered that perfluoropropane lingers in the eye for longer than 30 days.⁸²

Systemic Ophthalmic Drugs

In addition to topical and intraocular therapies, various ophthalmic drugs given systemically may result in complications of concern to the anesthesiologist. These systemic drugs include glycerol, mannitol, and acetazolamide. For example, oral glycerol may be associated with nausea, vomiting, and risk of aspiration. Hyperglycemia or glycosuria, disorientation, and seizure activity may occur after oral glycerol.

The recommended iv dose of mannitol is 1.5–2 g · kg⁻¹ given over a 30- to 60-minute interval. However, serious systemic problems may result from rapid infusion of large doses of mannitol. These complications include renal failure, congestive heart failure, pulmonary congestion, electrolyte imbalance, hypotension or hypertension, myocardial ischemia, and, rarely, allergic reactions. Clearly, the patient's renal and cardiovascular status must be thoroughly evaluated before mannitol therapy.

Acetazolamide, a carbonic anhydrase inhibitor with renal tubular effects, should be considered contraindicated in patients with marked hepatic or renal dysfunction or in those with low sodium levels or abnormal potassium values. As is well known, severe electrolyte imbalances can trigger serious cardiac dysrhythmias during general anesthesia. Furthermore, people with chronic lung disease may be vulnerable to the development of severe acidosis with long-term acetazolamide therapy. Topically active carbonic anhydrase inhibitors have been developed⁸³ and are now commercially available. Such topical agents might well be expected to be relatively free of clinically significant systemic effects.

PREOPERATIVE EVALUATION

Establishing Rapport and Assessing Medical Condition

Preoperative preparation and evaluation of the patient begin with the establishment of rapport and communication among the anesthesiologist, the surgeon, and the patient. Most patients realize that surgery and anesthesia entail inherent risks, and they appreciate a candid explanation of potential complications, balanced with information concerning probability or frequency of permanent adverse sequelae. Such an approach also fulfills the medicolegal responsibilities of the physician to obtain informed consent.

A thorough history of the patient and physical examination are the *sine qua non* of safe patient care. A complete list of medications that the patient is currently taking, both systemic and topical, must be obtained so that potential drug interactions can be anticipated and essential medication will be administered during the hospital stay. Naturally, a history of any allergies to medicines, foods, or tape should be documented. Clearly, knowledge of any personal or family history of adverse reactions to anesthesia is mandatory. The requisite laboratory data vary depending on the age and physical status of the patient. An ECG is often obtained in men older than 40 years of age, in women older than 50 years of age, and in younger patients if their medical history suggests the possibility of cardiovascular disease.

The anesthesiologist must be aware of the anesthetic implications of congenital and metabolic diseases with ocular manifestations. Diabetics often present with ocular

complications, and the anesthesiologist must be knowledgeable about the systemic disturbances of physiology that affect these patients. Indeed, the list of congenital and metabolic diseases associated with ocular pathologic effects that have significant anesthetic implications is lengthy. A partial summary includes such syndromes as Crouzon's, Apert's, Goldenhar's (oculoauriculovertebral dysplasia), Sturge-Weber, Marfan's, Lowe's (oculocerebrorenal syndrome), Down's (trisomy 21), Wagner-Stickler, and Riley-Day (familial dysautonomia). Other diseases in this category are homocystinuria, malignant hyperthermia, myotonia dystrophica, and sickle cell disease.⁸⁴

Furthermore, eye patients are often at the extremes of age—ranging from premature babies to nonagenarians. Hence, special age-related considerations, such as altered pharmacokinetics and pharmacodynamics, apply. In addition, elderly patients not infrequently have thyroid dysfunction and cardiopulmonary and renal diseases.

Selection of Anesthesia

The requirements of ophthalmic surgery include safety, akinesia, profound analgesia, minimal bleeding, avoidance or obtundation of the oculocardiac reflex, prevention of intraocular hypertension, awareness of drug interactions, and a smooth emergence devoid of vomiting, coughing, or retching (see [Table 34-1](#)). Moreover, the exigencies of ophthalmic anesthesia mandate that the anesthesiologist be positioned remote from the patient's airway, and this necessity sometimes creates certain logistic problems.

Most ophthalmic procedures may be performed in adults under either local or general anesthesia. (In children, general anesthesia is almost always selected.) When local anesthesia is elected, the ophthalmologist usually administers the local or regional blockade, and the anesthesiologist is present to monitor the patient's ECG continuously, routinely check vital signs, and administer sedation appropriately. If a mature, cooperative patient and a gentle, communicative surgeon are involved, local anesthesia should provide satisfactory conditions for almost any ophthalmic operation of reasonable length. Local anesthesia is especially popular for anterior segment surgery of 2 hours' duration or less. Many retina operations of similar length, however, may also be done under local anesthesia.

The choice of anesthesia should be individualized according to the nature and duration of the procedure, the patient's coagulation status, the ability of the patient to communicate and cooperate, and the personal preference of the surgeon. Patients who are deaf or who speak a foreign language and those with claustrophobia or excessive anxiety are often poor candidates for local anesthesia. Other relative contraindications include tremors, chronic coughing, and inability to lie flat.

Retrobulbar Block

Retrobulbar block is a practical means to achieve akinesia of the globe. Deep general anesthesia or nondepolarizing muscle relaxants also produce a motionless eye. Retrobulbar block entails injection of local anesthesia behind the eye into the muscle cone. In the past, patients were typically asked to gaze superonasally while the block was being performed. This maneuver theoretically freed the inferior oblique muscle from the course of the needle. More recently, however, Unsold *et al*⁸⁵ found that the eye was more vulnerable to optic nerve or ophthalmic artery injury in this position. Hence, they suggest performing the injection with the eye in neutral position or looking slightly downward and inward because these positions move the optic nerve sheath farther away from the path of the needle. A 25-gauge needle, no longer than 31 mm, is then introduced through the lower lid in the inferotemporal quadrant, at the junction of the lateral and middle thirds of the lower orbital rim. The needle is advanced along the inferotemporal wall of the orbit and is then directed upward and nasally toward the orbital apex. The plunger of the syringe is withdrawn to reveal an unwanted intravascular location, and 4 ml of local anesthetic is then injected. The retrobulbar injection should be followed by gentle massage of the globe to enhance dispersion of the local anesthetic.

Akinesia of the eyelids is then obtained by blocking the branches of the facial nerve supplying the orbicularis muscle. This is performed in conjunction with retrobulbar block to prevent squeezing of the eyelid that could result in extrusion of intraocular contents. Since first used for ophthalmic surgery by Van Lint in 1914,⁸⁶ numerous methods of facial nerve blockade have been described. All these techniques block the facial nerve after its exit point from the skull in the stylomastoid foramen. Moving distally to proximally to the foramen, the techniques include the Van Lint, Atkinson, O'Brien, and Nadbath-Rehman methods. Although each has advantages and disadvantages, the Nadbath-Rehman approach can potentially produce the most serious systemic consequences. With this approach, a 27-gauge, 12-mm needle is inserted between the mastoid process and the posterior border of the mandibular ramus. Owing to the proximity of the jugular foramen (10 mm medial to the stylomastoid foramen) to the injection site, ipsilateral paralysis of cranial nerves IX, X, and XI can occur, producing hoarseness, dysphagia, pooling of secretions, agitation, respiratory distress, or laryngospasm. Moreover, because the Nadbath-Rehman block produces complete hemifacial akinesia that interferes with oral intake, this approach is not recommended for outpatients.

Available data have failed to demonstrate a significant difference in complications such as iris prolapse or vitreous loss between local and general anesthesia for cataract surgery,⁸⁷ and local anesthesia has proved safe for patients with certain types of cardiovascular disease such as a relatively recent myocardial infarction.⁸⁸ The clinician must not be lulled into a false sense of security, however, with local anesthesia, because this technique does not necessarily involve less physiologic trespass than general anesthesia. Complications associated with retrobulbar block may be local or systemic and may result in blindness and even death ([Table 34-4](#)). The most common complication is retrobulbar hemorrhage secondary to puncture of vessels in the retrobulbar space. This misadventure is characterized by the simultaneous appearance of an excellent motor block of the globe, closing of the upper lid, proptosis, and a palpable increase in IOP. If this develops, it is prudent to defer the proposed intraocular procedure and monitor the patient for several hours after the hemorrhage to follow central retinal artery pulsations to rule out retinal artery occlusion, and to watch for the possible appearance of the oculocardiac reflex as blood extravasates from the muscle cone. If external pressure on the globe is sufficient to produce retinal artery compression, then a deep lateral canthotomy should be performed to decompress the orbit rapidly. If this does not reestablish normal retinal blood flow, an anterior chamber paracentesis should be done to decompress the globe.

| Inadvertent intraocular injection |

Table 34-4. COMPLICATIONS OF RETROBULBAR BLOCK

Other complications of retrobulbar block include direct intravascular injection; stimulation of the oculocardiac reflex; inadvertent intraocular injection; inadequate blockade of extraocular muscles with compression of the globe and extrusion of intraocular contents; puncture of the posterior segment of the globe, producing a posterior retinal tear resulting in retinal detachment and vitreous hemorrhage; and penetration of the optic nerve. Furthermore, retinal vascular occlusion, a potentially blinding situation, may result from direct trauma to the central retinal artery behind the globe or from the pharmacologic or compressive effects of the injected solution. Optic atrophy may follow direct injury to the nerve, injection into the nerve sheath with compressive ischemia, and intraneural sheath hemorrhage. An initially insidious but potentially lethal complication may also develop when accidental access to cerebrospinal fluid during performance of a retrobulbar nerve block occurs secondary to perforation of the meningeal sheaths that surround the optic nerve. One case report⁸⁹ described the gradual onset of unconsciousness and apnea over 7 minutes without any accompanying seizures or cardiovascular collapse. Hence, anesthesiologists and ophthalmologists should be exquisitely aware of the possibility of accidental brain stem anesthesia after retrobulbar block. In a series of 6000 retrobulbar blocks, Nicoll *et al*⁹⁰ reported 16 cases of apparent central spread of local anesthesia; respiratory arrest developed in 8 of the 16 patients. Clearly, there is a continuum of sequelae, depending on the amount of drug that gains entrance to the CNS and the specific area to which the drug spreads ([Fig. 34-4](#)). The protean CNS signs may include violent shivering; contralateral amaurosis; eventual loss of consciousness; apnea; and hemiplegia, paraplegia, quadriplegia, or hyper-reflexia. Blockade of cranial nerves VIII–XII results in deafness, vertigo, vagolysis, dysphagia, aphasia, and loss of neck muscle power. It is axiomatic that personnel skilled in airway maintenance and ventilatory and circulatory support should be immediately available whenever retrobulbar block is administered.

Figure 34-4. Base of the brain and the path that local anesthetic agents might follow if inadvertently injected into the subarachnoid space. This route includes the cranial nerves, pons, and midbrain. (Reprinted with permission from Javitt JC, Addiego R, Friedberg HL *et al*: Brain stem anesthesia after retrobulbar block. *Ophthalmology* 94:718, 1987.)

The issue of anticoagulant therapy in the setting of ocular regional anesthesia has been revisited in recent years. Discontinuing anticoagulant can have serious medical consequences, and several studies suggest that cataract surgery can be safely performed under regional anesthesia without discontinuing anticoagulants,^{91,92} and ⁹³ especially if the prothrombin time is approximately 1.5 times control.⁹⁴ Retinal surgery may be another matter, however.

Because the complications of retrobulbar block can be both vision threatening and life threatening, alternative approaches have been developed. Since the late 1980s, peribulbar block has become popular. The advantages of this technique include its safety and the fact that a lid block usually is superfluous because the relatively large volume of injected local anesthetic usually diffuses into the eyelids. Two injections are required; these are placed inferotemporally and then superonasally, between the supraorbital notch and trochlea. For both injections, the needle is held in a plane parallel to the orbit, careful aspiration is performed, and 4–5 ml of anesthetic solution is injected in each site. Onset is usually slower than with retrobulbar blockade and may be delayed for as long as 15–20 minutes. However, pH adjustment of a lidocaine–bupivacaine mixture or of plain bupivacaine with bicarbonate may accelerate the onset.⁹⁵ Another disadvantage includes increased forward pressure on the eyeball consequent to the larger volume of local anesthetic deposited in the orbit compared with retrobulbar block. However, no cases of either retrobulbar hemorrhage or brain stem anesthesia associated with peribulbar block have been documented to date. Indeed, Hamilton *et al*⁹⁶ reported 5714 peribulbar blocks without a single case of brain stem anesthesia or respiratory arrest.

Ophthalmologists have also been returning to a technique that was popularized during the early 1900s—the use of topical anesthetic agents, particularly when the surgical incision is being made through clear cornea. Multiple advances in cataract surgery that have enabled faster operations, with greater control and less trauma, have allowed ophthalmologists to re-examine the use of topical anesthesia for this procedure. Phacoemulsification, with its small incisions, is clearly the procedure of choice in using topical anesthesia; however, planned extracapsular procedures can also be performed under topical anesthesia, thereby circumventing potential complications of peribulbar or retrobulbar block that can result in blindness or death. Potential disadvantages of topical anesthesia include eye movement during surgery, patient anxiety, and, rarely, allergic reactions. Patient selection is critical and should be restricted to individuals who are alert, able to follow instructions, and can control their eye movements. Patients who are demented, photophobic, or cannot communicate are inappropriate candidates, as are those with an inflamed eye. Similarly, patients with small pupils who may require significant iris manipulation or those who need large scleral incisions may be contraindicated for topical anesthesia.

A parabolbar method of sub-Tenon's infusion of anesthetic via a flexible, curved cannula also has been developed.⁹⁷ Because it does not involve the use of a sharp needle, it eliminates the risk of globe penetration, retrobulbar hemorrhage, and optic nerve trauma. Topical anesthetic is applied, and a buttonhole is made through the conjunctiva and Tenon's capsule in the inferior temporal or nasal quadrants. A flexible, curved cannula is passed through the buttonhole and slid 3–5 mm along the globe. Two milliliters of 4% lidocaine and 0.75% bupivacaine in a 50:50 mixture without hyaluronidase is infused. Immediate analgesia occurs; akinesia may require 5 minutes to develop.

Many advocate the administration of approximately 10–30 mg of methohexital iv immediately before performance of ocular regional anesthesia, provided that no contraindications to the use of this drug exist. Such a practice is usually quite satisfactory, affording considerable comfort and amnesia. Alternative approaches include 0.5–1 $\mu\text{g} \cdot \text{kg}^{-1}$ remifentanyl, 0.3–0.5 $\text{mg} \cdot \text{kg}^{-1}$ of propofol iv,⁹⁸ or alfentanil 10–20 $\mu\text{g} \cdot \text{kg}^{-1}$ iv⁹⁹ just before placement of the retrobulbar or peribulbar block. What should be avoided at all costs, however, is the combination of local anesthesia with heavy sedation in the form of high doses of opioids, benzodiazepines, and hypnotics. This polypharmacology is highly unsatisfactory because of the pharmacologic vagaries in the geriatric population and the attendant risks of respiratory depression, airway obstruction, hypotension, CNS aberrations, and prolonged recovery time. This undesirable technique has all the disadvantages of a general anesthetic in the absence of a tracheal tube without the advantage of controllability that general anesthesia offers. The patient should be relaxed but awake to avoid head movement associated with snoring or sudden abrupt movement on awakening. Clearly, patients under conscious sedation must be capable of responding rationally to commands and must be able to maintain airway patency. Undersedation should likewise be avoided because tachycardia and hypertension may have deleterious effects, especially in patients with coronary artery disease. Moreover, patients with orthopedic deformities or arthritis must be meticulously positioned and given comfortable padding on the operating table. Adequate ventilation about the face is essential for all patients to avoid carbon dioxide accumulation, and each must be comfortably warm. (The hazards of shivering in patients with cardiac disease and, for that matter, in any patient having delicate eye surgery are well known.) Continuous ECG monitoring is vital, lest performance of the retrobulbar block, pressure on the orbit, or tugging on the extraocular muscles stimulate the oculocardiac reflex arc and produce dangerous cardiac dysrhythmias. Likewise, pulse oximetry is essential.

A question that is frequently asked is whether, for cardiac patients, epinephrine may be safely combined with local anesthetics to achieve vasoconstriction and increased anesthetic duration. Donlon and Moss¹⁰⁰ emphasize that release of endogenous catecholamines secondary to suboptimal analgesia may greatly exceed the relatively minute amount of injected exogenous catecholamine. Specifically, they mention that 0.06 mg epinephrine (12 ml of 1:200,000) produces some systemic uptake but no untoward clinical effects.¹⁰⁰ However, ocular perfusion may be reduced with epinephrine-containing solutions.

Given the economic pressures and fiscal constraints affecting our contemporary practice of medicine, it is critical to acknowledge that cataract surgery is the number one Medicare expenditure. With more than 1.3 million cataract operations performed annually in the United States, the economic impact of each aspect of cataract surgery, including preoperative preparation, intraoperative monitoring, and actual charges for surgery and supplies, can have a profound impact on the Health Care Finance Administration (HCFA) budget. Studies have confirmed that most cataract operations performed annually in the United States, are conducted with the patient under some form of local anesthesia (either retrobulbar, peribulbar, or parabolbar injection, or topical analgesia), with monitoring equipment used in 97% of cases and an anesthesiologist present in 78% of cases.¹⁰¹ Indeed, many anesthesiologists have long wondered whether HCFA will decide not to reimburse for monitored anesthesia care for “routine” cataract cases.

An important study by Rosenfeld and colleagues¹⁰² is the first to assess the need for monitored anesthesia care in cataract surgery. These investigators prospectively studied the incidence and the nature of interventions required by anesthesia personnel in 1006 consecutive cataract operations (both phacoemulsification and extracapsular techniques were included) performed under peribulbar block. They also analyzed the risk factors for intervention, including patient demographic data, medical history, and preoperative laboratory tests, for reliability in predicting those patients at greatest risk for intervention. They found that 37% of patients required some type of intervention and that, in general, the majority of those interventions could not have been predicted before surgery. The interventions ranged from minor forms, such as verbal reassurance and hand holding, to administering such iv medications as supplemental sedation or antihypertensive, pressor, or antiarrhythmic agents, or to providing respiratory assistance. Although hypertension, lung disease, renal disease, and a diagnosis of cancer were related to interventions, these four conditions combined accounted for only a small portion of the needed interventions. Moreover, although many of the interventions were relatively minor, several were more serious, and 30% of the interventions were considered (by the involved anesthesia personnel) to be critical to the success of the operation. The investigators concluded that monitored anesthesia care by qualified anesthesia personnel is reasonable and justified and contributes to the quality of patient care when cataract surgery is performed with local anesthesia. Although there were few, if any, injection-related problems, one wonders if the conclusion regarding need for anesthesia involvement would be different if the majority of cases had received topical analgesia.

ANESTHETIC MANAGEMENT IN SPECIFIC SITUATIONS

General Concepts and Objectives

Most patients undergoing eye surgery are either younger than 10 years of age or older than 55 years of age. In children, operations on the ocular adnexa, including lid surgery, repair of lacrimal apparatus, and adjustment of extraocular muscles, are common. However, surgery on the anterior segment, such as cataract removal, glaucoma procedures, and trauma repair, is definitely not limited to the adult population. Nor are posterior segment operations such as scleral buckling and vitrectomy

the exclusive domain of geriatrics.

Most ocular procedures demand profound analgesia but minimal skeletal muscle relaxation. The airway must be protected from obstruction, and the anesthesiologist must distance himself or herself—along with anesthetic apparatus—from the surgical field. Depending on whether the patient is a child or an adult and various other factors previously discussed, a decision is reached regarding selection of local or general anesthesia. Additional preparation must include, of course, identification of underlying diseases, such as asthma, diabetes mellitus, or nephropathy. The patient should also be prepared emotionally for the recovery period, when he or she will awaken with one or both eyes closed by bandages. This is important not only to spare him or her fear and anxiety but to prevent much of the thrashing about that fright might produce, to the detriment of the eye.

Preoperative sedation is chosen carefully. Except for strabismus correction, retinal detachment surgery, and cryosurgery, ophthalmic procedures usually are associated with little pain. Thus, the routine use of opioid premedication, replete with emetic potential, is ill advised. Rather, premedication should be prescribed with a view toward amnesia, sedation, and antiemesis. Reasonable selections would include a benzodiazepine, for sedative-hypnotic effect, or the phenothiazine derivative promethazine or the antihistaminic hydroxyzine for their sedative and antiemetic properties.

Analgesia and akinesia are then secured through either local or general anesthesia, with careful attention paid to proper control of IOP and to the possible appearance of the oculocardiac reflex. The anesthesiologist strives to provide a smooth intraoperative course and to prevent coughing, retching, and vomiting, lest harmful increases in IOP transpire that could hinder successful surgery. If general anesthesia is elected, extubation of the trachea should be accomplished before there is a tendency to cough. The administration of iv lidocaine, $1.5\text{--}2\text{ mg} \cdot \text{kg}^{-1}$, before extubation of the trachea is helpful in attenuating coughing. Likewise, prophylactic iv droperidol is valuable in reducing the incidence and severity of nausea and vomiting.^{103,104} Should droperidol be ineffective as a prophylactic agent, then the more expensive ondansetron or dolasetron may be administered as a “rescue” antiemetic.

“Open-Eye, Full-Stomach” Encounters

The anesthesiologist involved in caring for a patient with a penetrating eye injury and a full stomach confronts special challenges. He or she must weigh the risk of aspiration against the risk of blindness in the injured eye that could result from elevated IOP and extrusion of ocular contents.

As in all cases of trauma, attention should be given to the exclusion of other injuries, such as skull and orbital fractures, intracranial trauma associated with subdural hematoma formation, and the possibility of thoracic or abdominal bleeding.

Although regional anesthesia or an awake intubation are often valuable alternatives for the management of trauma patients who have recently eaten, such options are not available for patients with penetrating eye injuries. Retrobulbar blockade is ill advised in this setting because extrusion of intraocular contents may ensue. Moreover, although it is conceivable that a well conducted, extremely smooth awake intubation after topical anesthesia might not increase IOP, it seems much more probable that coughing or straining will occur in this setting, resulting in an increased IOP.

Preoperative prophylaxis against aspiration may involve administering H_2 receptor antagonists to elevate gastric fluid pH and to reduce gastric acid production. Metoclopramide may be given to induce peristalsis and enhance gastric emptying.

Not infrequently, a barbiturate, nondepolarizing neuromuscular blocking drug technique is described as the method of choice for the emergency repair of an open eye injury; the nondepolarizing drug pancuronium in a dose of $0.15\text{ mg} \cdot \text{kg}^{-1}$ has been shown to lower IOP. However, this method has its disadvantages, including risk of aspiration and death during the relatively lengthy period—ranging from 75 to 150 seconds—that the airway is unprotected. Performance of the Sellick maneuver during this interval affords some protection. Furthermore, a premature attempt at intubation of the trachea produces coughing, straining, and a dramatic rise in IOP, emphasizing the need to confirm the onset of drug effect with a peripheral nerve stimulator while appreciating, nonetheless, that muscle groups vary in their response to muscle relaxants. Moreover, the cardiovascular side-effects of tachycardia and hypertension may prove worrisome in patients with coronary artery disease. Also, the long duration of action of intubating doses of pancuronium may mandate postoperative mechanical ventilation of the lungs. Intermediate-acting nondepolarizing drugs such as vecuronium have briefer durations of action, and less dramatic, if any, circulatory effects, but nevertheless have an onset of action similar to that of pancuronium.^{105,106}

Several studies have explored the use of extremely large doses of nondepolarizing muscle relaxants to accelerate the onset of adequate relaxation for endotracheal intubation. Using vecuronium doses of 0.2 and $0.4\text{ mg} \cdot \text{kg}^{-1}$, Casson and Jones¹⁰⁷ found mean onset times of 95 and 87 seconds, respectively. Ginsberg *et al.*¹⁰⁸ found comparable albeit slightly longer onset times. Ginsberg's group reported that the administration of high-dose ($0.4\text{ mg} \cdot \text{kg}^{-1}$) vecuronium reduced the onset from 208 ± 41 seconds, as seen with the usual intubating dose of $0.1\text{ mg} \cdot \text{kg}^{-1}$, to 106 ± 35 seconds. However, the design of this study did not eliminate the possibility of bias being introduced by factors that could influence the quality of intubating conditions. For example, the doses of diazepam, fentanyl, and thiopental given before intubation of the trachea varied greatly among patients.

Succinylcholine offers the distinct advantages of swift onset, superb intubating conditions, and brief duration of action. If administered after careful pretreatment with a nondepolarizing drug and an induction dose of thiopental ($4\text{--}6\text{ mg} \cdot \text{kg}^{-1}$), succinylcholine produces only small increases in IOP.^{109,110} Although the advisability of this technique has been debated vociferously, there are no published reports of loss of intraocular contents from a pretreatment barbiturate–succinylcholine sequence when used in this setting.¹¹¹ On completion of surgery and return of spontaneous ventilation, an awake extubation of the trachea may be performed with the patient in a lateral, head-down position.

In managing certain pediatric patients in this situation, a reasonable approach might be to perform an inhalation induction with cricoid pressure and intubation of the trachea under deep halothane¹¹² or sevoflurane anesthesia. In these cases, attempting to start an iv infusion before induction of anesthesia can trigger struggling, sobbing, and screaming, and optimal visual outcome may be compromised. Moreover, it is important to keep in mind that much damage to the eye may already have occurred as a result of vomiting owing to pain or as a result of eye-rubbing and eye-squeezing by the child. The anesthesiologist cannot be held accountable for every insult to the eye.

What about the so-called priming principle?^{113,114} This concept involves using approximately one tenth of an intubating dose of nondepolarizing drug, followed 4 minutes later by an intubating dose. Then, after waiting an additional 90 seconds, intubation of the trachea may be performed. However, studies in this area demonstrate wide variability and disconcerting scatter of data. Future investigations should use a randomized, double-blind design because studies of intubating conditions are notoriously difficult to interpret. Moreover, priming is not devoid of risk; a case of pulmonary aspiration after a priming dose of vecuronium has been reported.¹¹⁵

Rocuronium, with its purportedly rapid onset, may prove to be a useful drug in this setting provided adequate doses ($1.2\text{ mg} \cdot \text{kg}^{-1}$ iv) are administered. However, additional data are needed before rocuronium can be enthusiastically recommended in this challenging situation. Moreover, rocuronium has an intermediate duration of action that could be disadvantageous, compared with succinylcholine, in a patient with an unrecognized difficult airway. Perhaps rapacuronium (Org 9487) will emerge as a viable alternative to succinylcholine. However, considerably more data are needed in this context.

Perhaps the wisest approach to the management of open-eye, full-stomach situations is summarized by Baumgarten and Reynolds,¹¹⁶ who wrote in 1985:

It may be possible to devise a combination of intravenous anesthetics and nondepolarizing relaxants that totally prevents coughing after rapid intubation. Until this combination is devised and confirmed in a large, controlled double-blind series, clinicians should not apply the priming principle to the open eye-full stomach patient. Use of a blockade monitor to predict intubating conditions may be unreliable, since muscle groups vary in their response to nondepolarizing relaxants. At this time, succinylcholine with precurarization probably remains the most tenable compromise in the open eye-full stomach challenge.

Strabismus Surgery

Approximately 3% of the population has malalignment of the visual axes, which may be accompanied by diplopia, amblyopia, and loss of stereopsis (Table 34-5). Indeed, strabismus surgery is the most common pediatric ocular operation performed in the United States, and it entails a variety of techniques to weaken an extraocular muscle by moving its insertion on the globe (recession) or to strengthen an extraocular muscle by eliminating a short strip of the tendon or muscle (resection).

| Procedure | Concerns |
|----------------------------|--|
| Strabismus repair | Forced duction testing Oculocardiac reflex Oculogastric reflex |
| Intraocular surgery | Malignant hyperthermia Proper control of IOP Akinesia Drug interactions Associated systemic disease |
| Retinal detachment surgery | Oculocardiac reflex Proper control of IOP Nitrous oxide interaction with air, sulfur hexafluoride, or perfluoro- carbons |

IOP = intraocular pressure.

Table 34-5. CONCERNS WITH VARIOUS OCULAR PROCEDURES

Infantile strabismus occurs within the first 6 months of life and is often observed in the neonatal period. Although most patients with strabismus are healthy, normal children, the incidence of strabismus is increased in those with CNS dysfunctions such as cerebral palsy and meningomyelocele with hydrocephalus. Moreover, strabismus may be acquired secondary to oculomotor nerve trauma or sensory abnormalities such as cataracts or refractive aberrations.

In addition to the well known propensity of strabismus surgery to trigger the oculocardiac reflex (previously discussed), there is also an increased incidence of malignant hyperthermia in patients with conditions such as strabismus or ptosis. This observation is consistent with the impression that people susceptible to malignant hyperthermia often have localized areas of skeletal muscle weakness or other musculoskeletal abnormalities.^{117,118} and ¹¹⁹ Other aspects of strabismus surgery of interest to anesthesiologists include succinylcholine-induced interference with the FDT and an increased incidence of postoperative nausea and vomiting.

In formulating a surgical treatment plan for incomitant strabismus, ophthalmologists often find the FDT to be exquisitely helpful in differentiating between a paretic muscle and a restrictive force preventing ocular motion. To perform the FDT, the surgeon grasps the sclera of the anesthetized eye with a forceps near the corneal limbus and moves the eye into each field of gaze, concomitantly assessing tissue and elastic properties. This simple test provides valuable clues to the presence and site of mechanical restrictions of the extraocular muscles and is most valuable in patients who have previously undergone strabismus surgery, in those who may have paralysis of one of the extraocular muscles, and in those who have sustained orbital trauma.

France *et al*¹²⁰ quantitated the magnitude and duration of change of the FDT after succinylcholine administration. They demonstrated that quantitation of the force necessary to rotate the globe remained significantly elevated over control for 15 minutes, even though the rise in IOP and the skeletal muscle paralysis lasted less than 5 minutes. Because succinylcholine interferes with FDT, its use is contraindicated less than 20 minutes before testing. Hence, France *et al* suggest performing the FDT on the anesthetized patient either while mask inhalation anesthesia is being administered, before intubation of the trachea; or after intubation, facilitated by nondepolarizing neuromuscular blocking drugs; or after intubation under moderately deep inhalation anesthesia, unaided by succinylcholine. However, when deep inhalational anesthesia is elected, atropine (0.02 mg · kg⁻¹, administered iv) should be given before or in the early stage of induction of anesthesia to prevent the fall in cardiac output that may accompany the significant dose-dependent depression of left ventricular function in children.¹²⁰ In addition, the use of iv atropine at this time affords some protection against elicitation of the oculocardiac reflex. For these reasons, many anesthesiologists administer iv atropine routinely to children scheduled for strabismus surgery.

Eye movement under general anesthesia is well documented, and in nonaligned eyes this tendency is augmented such that divergent squints diverge more and convergent squints converge less. A recent report discloses that surgeons at a regional eye teaching hospital in the United Kingdom who specialize in strabismus surgery are increasingly requesting that, if the FDT is being used, nondepolarizing neuromuscular blockade be incorporated into the anesthetic management so that muscle tone is minimal or absent during testing.¹²¹

Once intubation of the trachea has been accomplished, anesthesia is commonly maintained with halothane, desflurane, sevoflurane, or isoflurane, nitrous oxide, and oxygen. The patient is carefully monitored with a precordial stethoscope, ECG, blood pressure device, pulse oximeter, end-tidal carbon dioxide measurement, and temperature probe. If bradycardia occurs, the surgeon is asked to discontinue ocular manipulation and the patient's ventilatory status and anesthetic depth are quickly assessed. If additional iv atropine is deemed indicated, it is not given while the oculocardiac reflex is active lest even more dangerous cardiac dysrhythmias be triggered.

The laryngeal mask airway is gaining popularity for strabismus surgery in the United States, provided the patient is not at risk for aspiration. The laryngeal mask can be inserted without the use of muscle relaxants, causes significantly less hemodynamic perturbation, and is associated with less straining and coughing on removal.

Vomiting after eye muscle surgery is common, giving credibility to the existence of the oculogastric reflex. Abramowitz *et al*^{103,104} reported that prophylactic iv administration of 0.075 mg · kg⁻¹ of droperidol 30 minutes before termination of surgery was "highly effective" in reducing the frequency and severity of vomiting in pediatric patients undergoing repair of strabismus. (The incidence was decreased from 85 to 43%.) Fortunately, because strabismus surgery is commonly performed on an ambulatory basis, no significant prolongation of recovery time was observed with this protocol. More recently, the administration of droperidol, 0.075 mg · kg⁻¹ at induction of anesthesia before manipulation of the eye, has been claimed to reduce the incidence of vomiting after strabismus surgery to a more clinically acceptable level of approximately 10%.¹²² Moreover, a low dose of droperidol, 0.02 mg · kg⁻¹ iv, administered immediately after anesthetic induction in patients with strabismus may decrease both the incidence and severity of nausea and vomiting.¹²³

Although Warner and associates¹²⁴ reported an incidence of vomiting of approximately 16% when lidocaine, 2 mg · kg⁻¹, was given iv before tracheal intubation, others have not been able to document such favorable results after lidocaine prophylaxis.¹²⁵

Prophylactic iv administration of metoclopramide¹²⁶ 0.25 mg · kg⁻¹ or ondansetron¹²⁷ 0.15 mg · kg⁻¹ also appears to be efficacious. More studies are needed to document the efficacy of some of the other serotonin receptor antagonists, such as dolasetron, granisetron, tropisetron, and ramosetron in this setting. Combination therapy consisting of a given antiemetic, plus a glucocorticoid such as dexamethasone is also gaining popularity in some venues. Moreover, a total iv technique with propofol has also been associated with a low incidence of emesis after strabismus surgery.¹²⁸ In addition, avoiding narcotics may be helpful. One study demonstrates that the nonopioid analgesic ketorolac, in a dose of 0.75 mg · kg⁻¹ iv, provides analgesia comparable with that of morphine in pediatric patients with strabismus, but with a much lower incidence of nausea and vomiting in the first 24 hours.¹²⁹

Intraocular Surgery

Advances in both anesthesia and in technology now permit a level of controlled intraocular manipulation not possible a quarter of a century ago (see [Table 34-5](#)).

Proper control of IOP is crucial for such intraocular procedures as glaucoma drainage surgery, open sky vitrectomy, penetrating keratoplasty (corneal transplantation), and traditional intracapsular cataract extraction. Before scleral incision (when IOP becomes equal to atmospheric pressure), a low-normal IOP is essential because abrupt decompression of a hypertensive eye could result in iris or lens prolapse, vitreous loss, or expulsive choroidal hemorrhage. Available data⁸⁷ have not demonstrated a major difference in the rate of complications such as vitreous loss and iris prolapse between local anesthesia and general anesthesia, and local anesthesia has proved to be a safe technique for eye patients with a recent myocardial infarction.⁸⁸

Premedication is selected with a view toward antiemesis. Furthermore, atropine may be given safely, if desired, for antisialagogue properties. In the usual systemic premedicating dose, atropine is not harmful to patients with glaucoma.¹³⁰

Many anesthetic techniques may be safely used for elective intraocular surgery. If general anesthesia is selected, virtually any of the inhalation drugs may be given after iv induction of anesthesia with a barbiturate or propofol and neuromuscular blocking drug and topical laryngeal lidocaine. Because complete akinesia is essential for delicate intraocular surgery, nondepolarizing drugs are administered, followed by neuromuscular function monitoring to ensure a 90–95% twitch suppression level during surgery. Because proper control of IOP is critical, controlled ventilation of the lungs is used, along with endtidal carbon dioxide monitoring to ensure avoidance of hypercarbia.

Maximal pupillary dilation is important for many types of intraocular surgery and can be induced by continuous infusion of epinephrine 1:200,000 in a balanced salt solution, delivered through a small-gauge needle placed in the anterior chamber. Almost simultaneous with its administration, the drug is removed by aspirating it from

the anterior chamber. The iris usually dilates immediately on contact with the epinephrine infusion, and drug uptake is presumably limited by the associated intense vasoconstriction of the iris and ciliary body. However, epinephrine may also be potentially absorbed by drainage through Schlemm's canal into the venous system or by spillover of the infusion into the conjunctival vessels or drainage to the nasal mucosa.

Clearly, the extent of systemic absorption of epinephrine is of concern to the anesthesiologist, especially in view of the drug's cardiac dysrhythmogenic potential when given concomitantly with potent inhalation drugs. However, plasma catecholamine levels during epinephrine infusion into the anterior chamber have not been investigated extensively. Nonetheless, under halothane anesthesia, in both children and adults, Smith *et al*⁷² were unable to show any increased incidence of cardiac dysrhythmias or signs of systemic effects after instillation of 1:1000 epinephrine ($0.4\text{--}68\ \mu\text{g} \cdot \text{kg}^{-1}$) directly into the anterior chamber during cataract surgery. However, all patients were given lidocaine, $2\ \text{mg} \cdot \text{kg}^{-1}$, as topical laryngeal anesthesia. The authors postulated that the globe is not a fertile site for systemic absorption. Hence, general guidelines for subcutaneous injection may not be germane for intraocular injection.⁷²

At the completion of surgery, any residual neuromuscular blockade is reversed. On resumption of spontaneous ventilation, the patient's trachea is extubated (often in the lateral position) still deeply anesthetized and after iv administration of lidocaine to prevent coughing. Atropine and neostigmine may be safely used to reverse neuromuscular blockade even in patients with glaucoma because this combination of drugs, in conventional doses, has minimal effects on pupil size and IOP.¹³¹

Retinal Detachment Surgery

Surgery to repair retinal detachments involves procedures affecting intraocular volume, frequently using a synthetic silicone band or sponge to produce a localized or encircling scleral indentation (see [Table 34-5](#)). Furthermore, internal tamponade of the retinal break may be accomplished by injecting an expandable gas such as sulfur hexafluoride into the vitreous. Owing to blood gas partition coefficient differences, the administration of nitrous oxide may enhance the internal tamponade effect of sulfur hexafluoride intraoperatively, only to be followed by a dramatic drop in IOP and volume on discontinuation of nitrous oxide. The injected sulfur hexafluoride bubble, in the presence of concomitant administration of nitrous oxide, can cause a rapid and dramatic rise in IOP, reaching a peak within 20 minutes^{79,80} and ⁸¹ (see [Intraocular Sulfur Hexafluoride](#)). Because the resultant rise in IOP may compromise retinal circulation, Stinson and Donlon⁸⁰ recommend cessation of nitrous oxide administration 15 minutes before gas injection to prevent significant changes in the volume of the intravitreal gas bubble. Furthermore, Wolf *et al*⁸¹ state that if a patient requires anesthesia after intravitreal gas injection, nitrous oxide should be omitted for 5 days after an air injection and for 10 days after sulfur hexafluoride injection. Perfluoropropane, moreover, remains in the eye longer than 30 days.

Alternatively, silicone oil, a vitreous substitute, may be injected to achieve internal tamponade of a retinal break.

Retinal detachment operations are basically extraocular but may briefly become intraocular if the surgeon elects to perforate and drain subretinal fluid. Furthermore, rotation of the globe with traction on the extraocular muscles may elicit the oculocardiac reflex, so the anesthesiologist must be vigilant about potential cardiac dysrhythmias. In addition, because it is desirable to have a soft eye while the sclera is being buckled, iv administration of acetazolamide or mannitol is common during retinal surgery to lower IOP.

These patients are usually managed in the same manner as those having intraocular surgery except that maintenance of intraoperative skeletal muscle paralysis is not as critical as during intraocular surgery. Hence, inhalational anesthetics need not be accompanied during surgery by nondepolarizing neuromuscular blocking drugs.

POSTOPERATIVE OCULAR COMPLICATIONS

The incidence of eye injuries associated with nonocular surgery is low. In a study by Roth and colleagues¹³² of 60,965 patients undergoing nonocular surgery from 1988 to 1992, the incidence of eye injury was 0.056% (34 patients). Twenty-one of these 34 patients sustained corneal abrasion, although other injuries included conjunctivitis, blurry vision, red eye, chemical injury, direct ocular trauma, and blindness. Independent risk factors for greater relative risk of ocular injury were protracted surgical procedures, lateral intraoperative positioning, head or neck surgery, general anesthesia, and (for some unknown reason) surgery on a Monday. A specific mechanism of injury could be identified in only 21% of cases. In the ASA Closed Claims Study (which analyzed only cases involving litigation), eye injuries represented only 3% of all claims, but the serious nature of some of the injuries were reflected in large financial awards.¹³³ Similar to the findings of Roth *et al*, in the Closed Claims Study the specific mechanism of injury could be ascertained in only a minority of cases.

Although infrequent and often transient, eye injuries can result occasionally in blindness or more limited, but nonetheless permanent, visual impairment. Postoperative complications after nonocular surgery include corneal abrasion and minor visual disturbances, chemical injuries, thermal or photic injury, and serious visual disturbances, including blindness. Serious injury may result from such diverse conditions as acute corneal epithelial edema,¹³⁴ glycine toxicity and other visual disturbances associated with transurethral resection of the prostate, retinal ischemia, ischemic optic neuropathy, cortical blindness, and acute glaucoma. It appears that certain types of surgery, including complex spinal surgery in the prone position, operations involving extracorporeal circulation, and nasal or sinus surgery may increase the risk of serious postoperative visual complications.

Corneal Abrasion

Although the most common ocular complication of general anesthesia is corneal abrasion,¹³⁵ the incidence varies widely, depending on the perioperative circumstances. In a prospective study, Cucchiara *et al*¹³⁶ found a 0.17% incidence of corneal abrasion in 4652 neurosurgical patients whose eyes were protected, whereas Batra and Bali¹³⁵ one decade earlier reported a 44% incidence of corneal abrasion when eyes were left unprotected and partly open. A variety of mechanisms can result in corneal abrasion, including damage caused by the anesthetic mask, surgical drapes, and spillage of solutions. During intubation of the trachea, moreover, the end of plastic watch bands or hospital ID cards clipped to the laryngoscopist's vest pocket can injure the cornea. Ocular injury may also occur owing to loss of pain sensation, obtundation of protective corneal reflexes, and decreased tear production during anesthesia. Therefore, it may be prudent to tape the eyelids closed immediately after induction and during mask ventilation and laryngoscopy. In addition to taping the eyelids closed,¹³⁷ applying protective goggles, and instilling petroleum-based ointments (artificial tears) into the conjunctival sac may provide protection. Disadvantages of ointments include occasional allergic reactions; flammability, which may make their use undesirable during surgery around the face and contraindicated during laser surgery; and blurred vision in the early postoperative period.¹³⁷ The blurring and foreign body sensation associated with ointments may actually increase the incidence of postoperative corneal abrasions if they trigger excessive rubbing of the eyes while the patient is still emerging from anesthesia. Moreover, halothane absorption into paraffin-based ointments can damage the cornea,¹³⁸ and even water-based (methylcellulose) ointments may be irritating and cause scleral erythema. It would seem prudent, therefore, to close the eyelids with tape during general anesthesia for procedures away from the head and neck. For certain procedures on the face, ocular occluders or tarsorrhaphy may be indicated. Special attention should also be devoted to frequent checking of the eyes during procedures on a prone patient.

Patients with corneal abrasion usually complain of a foreign body sensation, pain, tearing, and photophobia. The pain is typically exacerbated by blinking and ocular movement. It is wise to have an ophthalmologic consultation immediately. Treatment typically consists of the prophylactic application of antibiotic ointment and patching the injured eye shut. Although permanent sequelae are possible, healing usually occurs within 24 hours.

Chemical Injury

Spillage of solutions during skin preparation may result in chemical damage to the eye. The Food and Drug Administration reported serious corneal damage from eye contact with Hibiclens, a 4% chlorhexidine gluconate solution formulated with a detergent.¹³⁹ Again, with meticulous attention to detail, this misadventure is preventable. Treatment consists of liberal bathing of the eye with balanced salt solution to remove the offending agent. After surgery, it may be desirable to have an ophthalmologist examine the eye to document any residual injury or lack thereof.

Photic Injury

Direct or reflected light beams may permanently damage the eye. The potential for serious injury to the cornea or retina from certain laser beams requires that the patient's eyes be protected with moist gauze pads and metal shields and that operating room personnel wear protective glasses. These goggles must be appropriately tinted for the specific wavelength they are intended to block. Clear goggles may be worn when working with the carbon dioxide laser, whereas for work with the argon, Nd-YAG, or Nd-YAG-KTP laser, the goggles must be tinted orange, green, and orange-red, respectively.

Mild Visual Symptoms

After anesthesia, mild visual disturbances such as photophobia or diplopia are not uncommon. Blurred vision in the early postoperative period may reflect residual effects of petroleum-based ophthalmic ointments or ocular effects of anticholinergic drugs administered in the perioperative period (see [Corneal Abrasion](#)). Dhamee *et*

a)¹⁴⁰ reported a 7–14% incidence of benign, transient visual disturbances after gynecologic procedures.

By contrast, the complaint of postoperative visual loss is rare and is cause for alarm. Several of the following conditions may be associated with visual loss after anesthesia and surgery and should be included in the differential diagnosis: hemorrhagic retinopathy, retinal ischemia, retinal artery occlusion, ischemic optic neuropathy, cortical blindness, and acute glaucoma.

Hemorrhagic Retinopathy

Retinal hemorrhages that occur in otherwise healthy people secondary to hemodynamic changes associated with turbulent emergence from anesthesia or protracted vomiting are termed Valsalva retinopathy.¹⁴¹ Fortunately, these venous hemorrhages are usually self-limiting and resolve completely in a few days to a few months.

Because no visual changes occur unless the macula is involved, most cases are asymptomatic. However, if bleeding into the optic nerve occurs, resulting in optic atrophy, or if the hemorrhage is massive, permanent visual impairment may ensue. In some instances of massive hemorrhage, vitrectomy may offer some improvement.

Retinal venous hemorrhage has been described also after injections of local anesthetics, steroids, or saline into the lumbar epidural space, and these cases have been summarized by Purdy and Ajimal.¹⁴² The patients all received large injections (340 ml) into the epidural space and they subsequently developed blurry vision or headaches. On funduscopic examination, retinal hemorrhage was consistently observed. Eight of the nine patients described had complete recovery. It is thought that the hemorrhage is produced by rapid epidural injection, which causes a sudden increase in intracranial pressure. This increase in cerebrospinal fluid pressure causes an increase of retinal venous pressure, which may cause retinal hemorrhages. It is possible that obesity, hypertension, coagulopathies, pre-existing elevated cerebrospinal fluid pressure (as seen in pseudotumor cerebri), and such retinal vascular diseases as diabetic retinopathy may be risk factors. Caution is recommended when injecting drugs or fluid into the epidural space; a slow injection rate and using the minimal volume necessary to accomplish the desired objective are strongly recommended.

Retinal Ischemia

Retinal bleeding may also originate from the arterial circulation. This bleeding may be associated with extraocular trauma. Funduscopic examination shows cotton-wool exudates,¹⁴³ and this condition is known as Purtscher's retinopathy. Purtscher's retinopathy should be ruled out when a trauma patient complains of postanesthetic visual loss. This condition is associated with a poor prognosis, and most patients sustain permanent visual impairment.

Retinal ischemia or infarction may also result from direct ocular trauma secondary to external pressure exerted by an ill-fitting anesthetic mask, especially in a hypotensive setting, as well as from embolism during cardiac surgery¹⁴⁴ or from the intraocular injection of a large volume of sulfur hexafluoride in the presence of high concentrations of nitrous oxide. It may also result from increased ocular venous pressure associated with impaired venous drainage or elevated IOP.

The importance of carefully positioning patients and scrupulously monitoring external pressure on the eye cannot be overemphasized, especially when the patient is in the prone or jackknife positions. When the head is dependently positioned, venous pressure may be elevated. If external pressure is applied to the globe from improper head support, perfusion pressure to the eye is likely to be reduced. An episode of systemic hypotension in this setting could further decrease perfusion pressure and thereby decrease intraocular blood flow, resulting in possible retinal ischemia.

It is imperative that for procedures in the prone position a padded or foam headrest be used. The patient's eyes must be in the opening of this headrest and they must be checked at frequent intervals for pressure. If the patient's head is too large to fit properly into the headrest, then a pin head-holder should be used. During some spine procedures, a steep head-down position may be used to decrease venous bleeding and enhance surgical exposure. This position, in combination with deliberate hypotension and infusion of large quantities of crystalloid, may increase the risk of compromising the ocular circulation. It seems prudent to avoid combining these three risk factors to any significant degree.

Central retinal arterial occlusion and branch retinal arterial occlusion are important, and frequently preventable, causes of postoperative visual loss. Cases have occurred following spinal, nasal, sinus, or neck surgery as well as after coronary artery bypass graft (CABG) surgery. In addition to external pressure on the eye, causes can include emboli from carotid plaques or other sources, as well as vasospasm or thrombosis after radical neck surgery complicated by hemorrhage and hypotension, and after intranasal injection of α -adrenergic agonists. Several cases have followed intra-arterial injections of corticosteroids or local anesthetics in branches of the external carotid artery, with possible retrograde embolization to the ocular blood supply.¹⁴⁵ Mabry¹⁴⁶ has suggested that, in order to produce retrograde flow into the branches of the ophthalmic artery, the needle must be positioned intra-arterially and the perfusion pressure must be overcome during the injection. Therefore, when injecting in the nasal and sinus areas, topical vasoconstrictors should be applied to decrease the size of the vascular bed, and a small (25-gauge) needle on a low-volume syringe should be used to minimize injection pressure. Moreover, because some cases have followed injections of corticosteroids combined with other drugs, it is thought that this practice may predispose to formation of drug crystals and should therefore be discouraged.

In cases of central retinal arterial occlusion, funduscopic examination discloses a pale, edematous retina and a cherry-red spot. Platelet-fibrin, cholesterol, calcific, or crystalloid emboli may be found in narrowed retinal arterioles. Computed tomography (CT) and magnetic resonance imaging (MRI) studies are negative.

Prevention is much more successful than treatment. It may be possible to apply ocular massage (contraindicated if glaucoma is a possibility) to dislodge an embolus to more peripheral sites, and iv acetazolamide and 5% carbon dioxide inhalation have been used to increase retinal blood flow. The prognosis, however, is typically poor, and approximately 50% of patients with central retinal arterial occlusion eventually have optic atrophy.

Ischemic Optic Neuropathy

Ischemic optic neuropathy (ION) in the nonsurgical setting is the most common cause of sudden visual loss in patients older than 50 years, and it may be either arteritic or nonarteritic. Our discussion will be limited to postoperative ION and will contrast the similarities and differences between anterior ischemic optic neuropathy (AION) and posterior ischemic optic neuropathy (PION).

Anterior Ischemic Optic Neuropathy

Although the multifactorial pathophysiology of AION has not been completely established, it is thought to involve temporary hypoperfusion or nonperfusion of the vessels supplying the anterior portion of the optic nerve, although intra-axonal edema and disturbed autoregulation to the optic nerve head may also play a role.¹⁴⁵ Coexisting systemic disease, especially involving the cardiovascular system and (to a lesser extent) the endocrine system, is common in patients in whom AION develops. Male sex also strongly predominates. Other risk factors for postoperative AION include CABG and other thoracovascular operations, and spinal surgery. Although massive bleeding, anemia, and hypotension are commonly described intraoperative risk factors, a retrospective survey of surgeons who perform spinal fusion surgery disclosed that hypotension and anemia were equally prevalent in patients in whom ION developed and in those in whom it did not.¹⁴⁷ Other possible risk factors are increased IOP or orbital venous pressure. Although emboli may also play a role, AION is not usually caused by emboli because emboli preferentially lodge in the central retinal artery rather than in the short posterior ciliary arteries that supply the anterior optic nerve.

Increased IOP caused by extrinsic compression of the eye decreases retinal blood flow that can produce both retinal and optic nerve injury. Moreover, increased IOP can result from large infusions of crystalloid when the head is steeply dependent, as during many spinal operations.¹⁴⁸ Increased orbital venous pressure results in a decreased perfusion pressure gradient to the optic nerve head. Interestingly, one patient who had ION despite perioperative normotension had marked facial edema after surgery of protracted duration.¹⁴⁸ Similarly, a study in cardiac surgery patients revealed that increases in IOP correlated with the degree of hemodilution and the use of crystalloid priming solution.¹⁴⁹ Patients with AION were more likely to have significant weight gain within 24 hours of open heart surgery, again suggesting the role of elevated ocular venous pressure in impeding blood flow to the optic nerve.

According to Roth and Gillesberg,¹⁴⁵ a complex interaction of factors such as ocular venous pressure, hemodilution, hypotension, release of endogenous vasoconstrictors, and individual risk factors such as atherosclerosis and aberrant optic nerve circulation may be implicated in the development of AION. Therefore, specific recommendations for preventative strategies are elusive. Clearly, however, external pressure on the eyes must be meticulously avoided. It also seems prudent to minimize time in the prone position when the head is notably dependent. In patients with pre-existing cardiovascular disease, significant hypertension, or glaucoma, it seems advisable to maintain systemic blood pressure as close to baseline as possible.¹⁴⁵ Recommendations about specific hematocrit levels are difficult to make at this time and should be individualized based on a constellation of circumstances, but it seems prudent to have a different "transfusion threshold" in high-risk patients.

Patients with AION typically have painless visual loss that may not be noted until the first postoperative day (or possibly later), an afferent pupillary defect, altitudinal

field defects, and optic disc edema or pallor. MRI or CT initially show enlargement of the optic nerve. However, optic atrophy is detected by MRI later.
