Digitalis Glycosides. The most important actions of the digitalis glycosides are those affecting myocardial contractility, conduction, and rhythm. The glycoside most likely to be used by the anesthesiologist is digoxin. The principal uses of digoxin are for the treatment of congestive heart failure and to control supraventricular cardiac dysrhythmia such as atrial fibrillation. Digoxin is one of the few positive inotropes that does not increase HR. Digoxin enhances myocardial inotropism and automaticity but slows impulse propagation through the conduction tissues.²⁶⁸ Despite nearly two centuries of use, its mechanism of action is only modestly certain. Digitalis reciprocally facilitates calcium entry into the myocardial cell by blocking the Na^+, K^+ -adenosine triphosphatase pump.²⁶⁹ This calcium influx may account for its positive inotropic action because this inotropic response is not catecholamine- or β -receptor-dependent and is therefore effective in patients taking β -blocking drugs. The inhibition of this enzyme transport mechanism also results in a net K^+ loss from the myocardial cell. This contributes to digitalis toxicity with hypokalemia. Calcium potentiates the toxic effects of digitalis. Extreme caution should be observed when calcium is given to a patient taking digitalis or when digitalis administration is contemplated in the patient with hypercalcemia.

A common indication for the glycosides is in the chronic management of cardiac tachydysrhythmias. Cardiac dysrhythmias are, paradoxically, their most common side-effect. Synchrony of the cardiac beat is an important determinant of CO, and digoxin can be beneficial when heart failure is caused by a tachydysrhythmia, even in ischemic myocardial disease. However, the use of β or calcium channel blockers is increasing in this regard because they both reduce overall myocardial oxygen consumption. The positive inotropic effects of digoxin are potentially beneficial in selected cases of the low CO syndrome. Digoxin produces a dose-related increase in contractility in both normal and failing hearts. Limits are imposed on the upper reaches of inotropism by the development of serious dysrhythmia.

Confusion has arisen in the past about whether digitalis increases or decreases myocardial oxygen consumption. This was based on the observation that the increased inotropism of digoxin increases MVO_2 in patients with normal hearts but decreases it in patients with heart failure. The tension developed within the ventricular wall is a prime determinant of oxygen consumption. By augmenting contractility, wall tension and MVO_2 at any given afterload will be decreased, with a reduction in ventricular radius and HR.²³⁵ This may underlie the clinical observation that angina is often decreased by digoxin in patients with cardiomegaly, whereas angina may be markedly increased by digitalis in patients with ischemic disease without cardiomegaly.

Digitalis tends to increase the tone of the peripheral resistance vessels in normal subjects by a direct vasoconstrictor effect. Untreated congestive heart failure is accompanied by high peripheral vascular resistance owing to compensatory SNS activation. Successful treatment with digitalis usually reduces resistance as increased contractility improves CO. This is the result of SNS release associated with improved cardiac function. Caution must be exercised, however, in giving iv digoxin or ouabain in a setting in which an increase in afterload would be deleterious. An immediate peripheral vasoconstrictor effect can occur, producing a transient worsening of congestive heart failure. Inconsistent hemodynamic benefit has occurred with digitalis in congestive heart failure following myocardial infarction. It has been of no benefit in cardiogenic shock and has proved potentially injurious in patients with uncomplicated myocardial infarction because of its vasoconstrictive properties and effects on myocardial oxygen consumption in the absence of cardiomegaly.

Digoxin is of potential value in patients with signs and symptoms of congestive heart failure caused by ischemic, valvular, hypertensive, and congenital heart disease. Patients with cardiomyopathies and cor pulmonale may also benefit. Care must be taken to rule out conditions in which the use of digitalis is of no benefit and is potentially harmful. These include mitral stenosis with normal sinus rhythm and constrictive pericarditis with tamponade. Signs and symptoms of idiopathic hypertrophic subaortic stenosis are often exacerbated by digitalis. With increased strength of contraction, the muscular obstruction can be markedly increased. The same is true for the use of digitalis in patients with infundibular pulmonic stenosis, as occurs with tetralogy of Fallot. Any augmentation of contractility may further reduce an already diminished pulmonary blood flow. Beware of digitalis toxic reactions in the older age group and in patients suffering from arterial hypoxemia, acidosis, renal compromise, hypothyroidism, hypokalemia, or hypomagnesemia as well as in patients receiving quinidine or calcium channel blockers. In patients with diminished cardiac reserve who are about to undergo major surgical procedures the issue of prophylactic digitalization remains controversial.^{268,269} Indications for preoperative digitalis in which the prophylactic administration of digoxin should be considered include the following: (1) previous heart failure, (2) increased heart size, (3) coronary flow disturbances according to electrocardiogram, (4) age over 60 years, (5) age over 50 years before lung surgery, (6) anticipated massive blood loss, (7) atrial flutter or fibrillation, (8) cardiovascular surgery, and (9) rheumatic valvular lesions.

When entertaining the possibility of perioperative digitalis administration, the following points must be considered:

1. Myocardial oxygen balance is threatened in the nonfailing, nondilated heart.
2. The therapeutic-to-toxic ratio of digitalis is narrow.
3. Inotropic drugs that are less toxic and may be stopped immediately are readily available.
4. Verapamil or β blockers are more efficacious for supraventricular tachydysrhythmias not initiated by heart failure.
5. Digitalis may cause serious dysrhythmia in the unstable patient.
6. Serum potassium concentrations may fluctuate in the surgical patient who is critically ill.
7. Any cardiac dysrhythmia that occurs in the presence of digitalis must be considered a toxic phenomenon.
8. Digitalis-induced cardiac dysrhythmias are difficult to treat.
9. Renal compromise will result in toxic effects with standard maintenance doses.
10. Cardioversion may be dangerous after digitalis administration.
11. After initiation of digitalis therapy, the administration of alternative drugs becomes more complicated.

Calcium Salts. Ringer established the importance of calcium in cardiac contraction more than 150 years ago. It is of great importance in the genesis of the cardiac action potential and is the key to controlling intracellular energy storage and utilization.²⁷⁰ Movement of extracellular calcium across membranes also governs the function of uterine smooth muscle as well as the smooth muscle of the blood vessels. Only recently have we begun to appreciate the critical role that calcium plays in a wide spectrum of biologic processes, from coagulation to neuromuscular transmission. The sympathomimetic drugs promote the transmembrane influx of calcium, whereas the β blockers and calcium channel blockers inhibit such movement.

Despite its molecular simplicity, calcium is one of the least understood drugs.²⁷¹ Calcium chloride is often part of the treatment of ventricular fibrillation, even though the published data to support this indication are scanty. There are data confirming its capability to initiate ventricular fibrillation in a manner similar to that of EPI. Although many of the effects of EPI are mediated by calcium, the two drugs are clearly not identical. The fact that EPI can improve defibrillation success by strengthening the fibrillatory pattern is the apparent basis for the use of calcium salts in this setting. This assumption has not been experimentally or clinically documented.²⁷² The American Heart Association has recently recommended against the use of calcium during cardiac arrest except when hyperkalemia, hypocalcemia, or calcium-entry inhibitor toxicity is present.²⁷³

Traditionally, calcium gluconate has been preferred in pediatric patients and calcium chloride in adult patients. Previous data suggested that calcium chloride produced consistently higher and more predictable levels of ionized calcium than an equivalent dose of the other preparations.²⁷⁴ Recent studies have shown, however, that ionization of any of the preparations is immediate and equally effective.^{275,276} Intravenous calcium appears effective for the transient reversal of hypotension thought to

be the result of myocardial depression from the potent volatile anesthetic drugs.²⁷⁷ Some clinicians feel that recurrent intraoperative hypotension response to calcium chloride may be an indication for the administration of digoxin. Calcium chloride is also given at the termination of cardiopulmonary bypass to offset the myocardial depression associated with hypothermic potassium cardioplegia. The use of calcium salts is clearly indicated during rapid or massive transfusions of citrated blood.²⁷⁸ Citrate binds calcium, and rapid infusion rates of citrated blood result in myocardial depression which is reversible by calcium.

Three forms of calcium salts are available: calcium chloride, calcium gluconate, and calcium gluceptate. Calcium chloride produces only transient (10–20 minutes) increases in CO.²⁶⁸ If inotropic effects are needed for a longer period of time, other inotropic agents should be selected. Bolus doses of 2–10 $\mu\text{g} \cdot \text{kg}^{-1}$ ($1.5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) of calcium chloride can produce moderate improvement in contractility. The rapid administration of calcium salts, if the heart is beating, can produce bradycardia and must be used cautiously in the patient who is digitalized because of the hazard of producing toxic effects. Calcium gluceptate can be given in a dose of 5–7 ml (4.5–6.3 mEq) and calcium gluconate in a dose of 10–15 ml (4.8–7.2 mEq). These doses are approximately equivalent to that suggested for calcium chloride. Calcium gluconate is unstable and is no longer in frequent use. All of the calcium salts will precipitate as calcium carbonate if mixed with sodium bicarbonate.

Antidepressant Drugs

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) and the tricyclic antidepressants are used to treat psychotic depression. These drugs are not used in the practice of anesthesia but are a source of potentially serious interactions in patients who are taking them chronically. Their use is rapidly declining as the nontricyclic antidepressants such as Prozac are more efficacious and produce fewer side-effects. These drugs were a source of potentially serious interactions in the practice of anesthesia. [Table 12-21](#) lists the antidepressants that have been in use and is offered to be historically complete. Few of the MAO inhibitors or tricyclic antidepressants will be encountered in an anesthesia practice today, with the exceptions of phenelzine (Nardil) and amitriptyline (Amitril, Elavil). Their pharmacologic actions and side-effects are a direct result of their effect on the cascade of catecholamine metabolism. The nontricyclics also produce their antidepressant effects *via* this cascade but linked to their inhibition of CNS neuronal uptake of serotonin.

| Nonproprietary Name | Trade Name |
|-------------------------------------|--|
| Monoamine Oxidase Inhibitors | |
| Isocarboxazid | Marplan |
| Pargyline | Eutonyl |
| Phenelzine | Nardil |
| Tranylcypromine | Parnate |
| Tricyclic Antidepressants | |
| Imipramine | Imovate, Janimine, Proxamine, SK-Pramine, Tofranil |
| Desipramine | Norpramin, Pertofrane |
| Amitriptyline | Amitril, Elavil, Endep |
| Nortriptyline | Avenyl, Pamelor |
| Doxepin | Adapin, Siroquan |
| Protriptyline | Vivactil |
| Azocipine | Ascedin |
| Maprotiline | Ludonil |
| Nontricyclics | |
| Trazodone | Desyrel |
| Fluoxetine | Prozac |
| Bupropion | Wellbutrin |

Table 12-21. ANTIDEPRESSANT DRUGS

MAOIs ([Table 12-21](#)) block the oxidative deamination of endogenous catecholamines into inactive vanillylmandelic acid (see [Fig. 12-12](#)). They do not inhibit synthesis.²⁷⁹ Thus, blockade of monoamine oxidase would produce an accumulation of NE, EPI, dopamine, and 5-hydroxytryptamine in adrenergically active tissues, including the brain. Alleviation of depression may be related to elevations of the endogenous catecholamines. Overdose with MAOIs is expressed as SNS hyperactivity. They may produce agitation, hallucinations, hyperpyrexia, convulsions, hypertension, and hypotension. Orthostatic hypotension is a common complaint in patients taking MAOIs.²⁸⁰

The action of sympathomimetic amines is potentiated in patients taking MAOIs. Indirect-acting sympathomimetics (ephedrine, tyramine) produce an exaggerated response as they trigger the release of accumulated catecholamines. Foods with a high tyramine content (cheese, red Italian wine, pickled herring) can also precipitate hypertensive crises.²⁸⁰ SNS reflex stimulation is also intensified by tyramine. Meperidine has been reported to produce hypertensive crisis, convulsions, and coma with MAO inhibitors. Hepatotoxicity has been reported that does not seem to be related to dosage or duration of treatment. Its incidence is low but remains a factor in selecting anesthesia.

The MAOIs produce long-lasting, irreversible enzyme inhibition that is unrelated to duration of treatment. Regeneration of monoamine oxidase may therefore take weeks and has much the same effect on adrenergic metabolism as organophosphates on the cholinesterase system. MAOIs are known to intensify CNS depression caused by ethanol, analgesics, and general anesthesia. The depressive mechanism is not known.

The anesthetic management of patients taking MAOIs remains controversial, although recent data question the need to discontinue them preoperatively. Currently, recommendations for management include discontinuation of the drugs for at least 2 weeks before surgery. However, this recommendation is not based on controlled studies but rather is the result of limited case reports that suggest potent drug interactions.^{279,281,282} A small number of studies found few adverse effects in humans taking MAOIs given analgesics, opioid anesthesia, or regional blocks. However, opioids that cause release of catecholamines (meperidine) should be avoided in these patients.

Symptoms of SNS overdose or interactions due to MAOIs can be treated effectively with a blockers, ganglionic blockers, or direct-acting vasodilators. Tricyclic antidepressants should not be substituted for the MAOIs in the perioperative period. Adverse CNS interactions similar to those encountered with the indirect sympathomimetic amines have been reported. A 2-week washout period is recommended before introducing tricyclic antidepressants to a patient taking an MAOI.

Tricyclic Antidepressants

This group of antidepressant drugs is referred to as tricyclic antidepressants because of their structure. The important tricyclic antidepressants are listed in [Table 12-21](#). These drugs have almost replaced the MAOIs because they cause fewer side-effects.²⁷⁹ The manner in which the tricyclic antidepressants relieve depression is not clear, but all of these agents block uptake of NE into adrenergic nerve endings. Just as with the MAOIs, high doses of the tricyclic antidepressants can induce seizure activity that is responsive to diazepam.

Neuroleptic drugs may potentiate the effects of tricyclic antidepressants by competition with metabolism in the liver. Chronic barbiturate use increases metabolism of the tricyclic antidepressants by microsomal enzyme induction. Other sedatives, however, potentiate the tricyclic antidepressants in a manner similar to that occurring with the MAOIs. Atropine also has an exaggerated effect because of the anticholinergic effect of tricyclic antidepressants. Prolonged sedation from thiopental has been reported. Ketamine may also be dangerous in patients taking tricyclic antidepressants by producing acute hypertension and cardiac dysrhythmia. Likewise, muscle relaxants that produce tachycardia (pancuronium, gallamine) have been observed to produce serious ventricular cardiac dysrhythmia in humans and dogs pretreated with imipramine.

Despite these serious interactions, discontinuation of these drugs before surgery is probably unnecessary. The latency of onset of these drugs is from 2 to 5 weeks; however, the excretion of tricyclic antidepressants is rapid, with approximately 70% of a dose appearing in the urine during the first 72 hours. One might consider a discontinuation of the drug for 72 hours, but the risk of recurrent depression may be greater than that of any untoward drug reaction. The long latency period for resumption of treatment militates against interrupted treatment. A thorough knowledge of the possible drug interactions and autonomic countermeasures obviates postponement.

Nontricyclic Antidepressants

The nontricyclic antidepressants are listed in [Table 12-21](#). Their mechanism of action is not fully known, but all have in common selective inhibition of neuronal uptake of serotonin. This potentiates the behavioral changes induced by the serotonin precursor, 5-hydroxytryptophan.^{283,284}

Desyrel has been associated with the occurrence of priapism and should not be used in those patients with a propensity for cardiac arrhythmias. Little is known about the interaction between Desyrel and general anesthesia. It has an elimination half-life of 6 hours, posing the question of whether to discontinue its use before elective

surgery. Currently there is no information about potential risk factors of discontinuance versus the benefits of therapy. The availability of sympathetic antagonists for possible side-effects during anesthesia weighs in favor of continuation of therapy versus the risk of exacerbation of a severe depression.²⁸⁵

Prozac (fluoxetine) is a popular oral nontricyclic antidepressant. Unlike Desyrel, Prozac has an elimination half-life of 1–3 days, which can lead to significant accumulation of the drug. Prozac's metabolism, like that of other compounds including tricyclic antidepressants, phenobarbital, ethanol, and pentothal, involves the $P_{450}IID_6$ system; thus, concomitant therapy with drugs also metabolized by this enzyme system may lead to drug interactions and prolongation of effect of the benzodiazepines.

Wellbutrin and Zyban are the same drug—bupropion hydrochloride. Zyban, however, is a sustained-release drug. Wellbutrin is used as an antidepressant whereas Zyban is marketed as a non-nicotine aid to smoking cessation. These drugs should not be used concomitantly. Overdose is possible, with resultant seizures. Seizure activity is dose-related. The neurochemical mechanism of the antidepressant effect of bupropion is not known. It does not inhibit monoamine oxidase and is a weak blocker of the neuronal uptake of serotonin and norepinephrine. It does, however, inhibit the neuronal uptake of dopamine to some extent. No systematic data have been collected on the interactions of bupropion with other drugs. The mechanism by which Zyban enhances the ability to abstain from smoking is unknown but perhaps it assists the patient through the mental vicissitudes of nicotine withdrawal. The primary untoward side-effects of therapeutic levels of Zyban are insomnia and a dry mouth. Doses higher than 300 mg can result in seizures.²⁸⁶

Adrenergic Antagonists

a Antagonists

Drugs that bind selectively to α -adrenergic receptors block the action of endogenous catecholamines at effector sites and alter the autonomic response. The resultant effects may be ascribed to unopposed β -adrenergic receptors and are dependent upon the prevailing adrenergic tone. In the vasculature, for example, the response to the a blocker phenoxybenzamine may vary over a wide range in a single vascular bed, depending on its intrinsic state of constriction. Vessels with higher initial tone have a greater response to a blockade. Classically, a blockers are defined as drugs that convert the vascular response to EPI from constriction to vasodilation.²⁸⁷ Prominent clinical effects of a blockers include hypotension, tachycardia, and miosis. Nasal stuffiness, diarrhea, and inhibition of ejaculation are common side-effects.

The a blockers may be classified according to binding characteristics (Table 12-22). Phenoxybenzamine is a drug that binds covalently to the receptors and produces an irreversible blockade. It is relatively nonspecific and has antagonistic activity at several other receptor types as well.²⁸⁸ Phentolamine, tolazoline, and prazosin are characterized by reversible binding and antagonism.

| | Type of Antagonism | Selectivity |
|------------------|--------------------|-------------------------|
| Phenoxybenzamine | Noncompetitive | $\alpha_1 > \alpha_2$ |
| Phentolamine | Competitive | $\alpha_1 = \alpha_2$ |
| Tolazoline | Competitive | $\alpha_1 = \alpha_2$ |
| Prazosin | Competitive | $\alpha_1 \gg \alpha_2$ |
| Yohimbine | Competitive | $\alpha_2 \gg \alpha_1$ |

Table 12-22. α -ADRENERGIC BLOCKING DRUGS

There are also important differences between the individual drugs with regard to relative receptor specificity. As with the β blockers, some show greater affinity for one subset of a receptors than another. Phenoxybenzamine, for example, is 100 times more potent on α_1 than on α_2 receptors. Prazosin is also markedly specific for α_1 receptors, whereas phentolamine has nearly equal blocking activity on both subsets. Phentolamine, therefore, by blocking presynaptic inhibitory α_2 receptors, causes greater NE release from the presynaptic terminal. The tachycardia and the reflex response to hypotension seen commonly with phentolamine are thought to be secondary to this enhanced NE release.

The a blockers in use today include prazosin and phentolamine (see Table 12-22). Phentolamine is used almost exclusively in the diagnosis and treatment of pheochromocytoma. Prazosin is now commonly used to treat essential hypertension. When patients taking these drugs are to undergo anesthesia, one should keep in mind that the normal ANS response to stress and inhalation anesthetic drugs may be completely blocked at the vascular effector site; therefore, elevations of catecholamines will not reflexly increase peripheral vascular resistance and may actually decrease it if vascular β receptors are left unopposed. In the presence of a blockade, we suggest preloading with iv fluids to ensure adequate central volume and careful titration of halogenated anesthetic drugs.

Phenoxybenzamine. Phenoxybenzamine is a haloalkylamine with predominantly α_1 antagonist activity. Because of the noncompetitive nature of the block, as discussed above, it has a relatively long duration of 24 hours. In the past it was the drug of choice for treating patients with pheochromocytoma in preparation for surgery. It has now been replaced with shorter-acting, more specific drugs such as phentolamine.

Phentolamine. Phentolamine is an imidazoline, which is a competitive antagonist at α_1 and α_2 receptors. The imidazolines also have some antihistaminic and cholinomimetic activity. The cholinomimetic activity may result in abdominal cramping and diarrhea, both of which are blocked by atropine. Tachycardia and hypotension are also common side-effects.²⁸⁷ It also is commonly used in the diagnosis and treatment of pheochromocytoma. It is usually given in 2–5-mg iv boluses until adequate control of blood pressure is obtained.

Tolazoline. Tolazoline is also an imidazoline derivative and acts like phentolamine. It is less potent on peripheral α receptors, however, and some of its vasodilatory action has been ascribed to histamine-like activity. It effectively decreases pulmonary vascular resistance and has been used in neonates with respiratory distress syndrome to improve pulmonary blood flow. The effects, however, were detrimental and inconsistent.^{289,290}

Prazosin. Prazosin is a piperazine derivative that has relative selectivity for α_1 receptors and, as a result, does not cause the tachycardia seen with phentolamine. Cardiovascular effects include decreased peripheral vascular resistance and venous return with little change in HR or CO. When used alone, it is not remarkably effective in treatment of essential hypertension resulting from fluid retention. When combined with a diuretic, however, it is an effective antihypertensive drug. It should not be used with clonidine or α -methyl dopa (discussed below), as it appears to decrease their effectiveness. Prazosin also may cause bronchodilation, and it decreases serum cholesterol and triglyceride levels.²⁹¹

Yohimbine. Yohimbine is an α_2 antagonist (see Table 12-5). It blocks the action of clonidine on presynaptic receptors and increases NE release. It is mostly used as a research tool but has been used in the treatment of impotence and orthostatic hypotension.²⁹²

b Antagonists

The use of β -blocking drugs has markedly escalated in the last 10 years as more indications for their use have been found and more compounds have been developed.²⁹³ They are among the most common drugs used in the treatment of cardiovascular disease, and frequently the anesthesiologist must deal with their effects and side-effects during anesthesia. There are now a variety of drugs available with β -blocking activity that may be distinguished by differing pharmacokinetic and pharmacodynamic characteristics.^{294,295} Examples of drugs available for clinical use in the United States and their characteristics are listed in Table 12-23. Their structures are shown in Figure 12-33.

| Drug | Code | Relative β_1 Selectivity | Relative β_2 Selectivity | Intrinsic Sympathomimetic Activity | Phase 0 Activity | Plasma Half-life (hr) | Oral Availability (%) | Lipid Solubility | Elimination | Preparation |
|-------------|----------|--------------------------------|--------------------------------|------------------------------------|------------------|-----------------------|-----------------------|------------------|-------------|-------------|
| Propranolol | Isobut | 1 | + | 0 | 1-4 | 3h | 100 | +++ | Renal | Oral, iv |
| Sotalolol | Ciprod | 1 | 0 | 0 | 18-21 | 3h | 100 | 0 | Renal | Oral |
| Timolol | Resorin | 1 | 0 | 0 | 4-5 | 3h | 100 | 0 | Renal | Oral, eye |
| Ebolol | Flaxin | 1 | + | ++ | 1-4 | 3h | 100 | + | Renal | Oral |
| Betalolol | Berblock | ++ | 0 | 0 | 0-16 | — | 1 | 0 | EC-stim | iv |
| Atenolol | Schol | + | + | 0 | 1-4 | 7h | 100 | 0 | Renal | Oral |
| Iprenolol | Teromol | ++ | 0 | 0 | 1-8 | 7h | 100 | 0 | Renal | Oral |
| Moxalolol | Lipromol | ++ | 0 | 0 | 1-4 | 3h | 100 | + | Renal | Oral |
| Bucindolol | Kelone | ++ | + | 0 | 18-22 | 3h | 100 | 0 | Renal | Oral |
| Betaxolol | Local | 1 | 0 | + | 1 | 15 | 100 | 0 | Renal | Oral |
| Carvedilol | Carval | 1 | 0 | + | 4 | 15 | 100 | 0 | Renal | Oral |

* Usually hepatic, but active metabolites are formed that may be totally excreted.

Table 12-23. β -ADRENERGIC BLOCKING DRUGS

Figure 12-33. The structures of the commonly used β blockers are compared with the pure β agonist isoproterenol, and the partial agonist dichloroisoproterenol.

Several of these drugs are marketed on the basis of cardioselectivity, *i.e.*, antagonist activity is greater at β_1 than β_2 receptors in an isolated muscle preparation. Theoretically, this implies that these agents would be of greater benefit in treatment of patients with obstructive airway disease, diabetes mellitus, or peripheral vascular disease.²⁹⁶ The practitioner must keep in mind, however, that this means relative selectivity, not specificity, and that β -blocking effects may be seen in all tissues if higher blood levels are reached (see Fig. 12-3). Clinical studies have not shown greater effectiveness of cardioselective β blockers in treatment of hypertension²⁹⁷ or diabetes mellitus,²⁹⁸ and their relative effectiveness in the case of peripheral vascular disease is still controversial.²⁹⁶

Figure 12-13. Relative dose-response relationship on target and other organs. Relative selectivity is illustrated by showing the relationship between two dose-response curves. The curve on the left represents the desired response of bronchodilation using a relatively selective β_2 agonist. The unwanted effects on other organs that occur at higher doses are represented by the curve on the right. For example, an increased HR (β_1 effect) may occur with higher doses of a relatively select β_2 agonist. The optimal range is that concentration of drug that will give the maximal desired response with minimal effects on other organs. The size of the optimal range is dependent on the therapeutic index, or the distance between the two curves. These are usually established *in vitro* where drug concentration can be precisely controlled. For many cardiovascular drugs, the optimal range is small, and wide fluctuations in serum level of the drug are common; therefore, secondary or side-effects are often seen during drug therapy.

The use of β_1 -selective blockers in patients with obstructive airway disease is also controversial. The degree of bronchoreactivity is an important consideration in their use. Patients with reactive airway disease may develop serious reductions in ventilatory function even with β -selective drugs.²⁹⁹ No β blocker can be considered safe in patients with obstructive airway disease, and other types of drugs are available for treatment of supraventricular arrhythmias and hypertension.

SNS activation generally results in increased circulating glucose levels secondary to enhanced glycogenolysis, lipolysis, and gluconeogenesis. Administration of β blockers to insulin-dependent diabetics reduces their ability to recover from hypoglycemic episodes, primarily due to β_2 -adrenoceptor antagonism. Thus, β blockers must be used with caution in diabetic patients on insulin therapy, to avoid potentially life-threatening hypoglycemic episodes. When necessitated, β_1 -selective antagonists are preferable.

β -Adrenergic receptor blockers are also commonly used now in the treatment of hypertension. They have been discussed in detail above, but certain comments about their perioperative use are pertinent here (see Table 12-23). Following the introduction of propranolol, several deleterious interactions (in particular, the enhanced negative inotropic and chronotropic effects of halothane) were noted with anesthetics. This resulted in a debate over whether or not the blocker should be discontinued preoperatively. β -Blocker therapy should be continued up until the time of operation. A withdrawal syndrome has been noted after acute discontinuation of chronic β -blocker therapy.^{300,301} Also, the control of HR and blood pressure perioperatively is easier if chronic medications are continued and the anesthetic plan is altered rather than acutely stopping the chronic medications and administering a routine anesthetic plan.³⁰² HR is a major determinant of myocardial oxygen demand. Tachycardia has recently been shown to increase the risk of poor outcome in patients with ischemic heart disease.³⁰³ Therefore, the control of HR and blood pressure is important perioperatively, and β -blocker therapy should be continued to maximize this control.

Some β antagonists have partial agonist activity at low doses. This is referred to as intrinsic sympathomimetic activity. Drugs with intrinsic sympathomimetic activity decrease resting HR less than those without it.³⁰⁴ In the presence of similar degrees of β blockade, however, all β blockers blunt exercise-induced increases in HR to a similar extent.²⁹⁸ The clinical relevance of this is unclear, but it has been implied that intrinsic sympathomimetic activity would be advantageous in patients treated with nonselective β blockers who are troubled by bradycardia or worsening ventricular failure.³⁰⁵ A distinct advantage to intrinsic sympathomimetic activity in β blockers has not been clearly shown in clinical studies.

Several of the β blockers listed in Table 12-23 also have a local anesthetic-like effect on myocellular membranes at high doses. This effect is similar to that of quinidine in that Phase 0 of the cardiac action potential is depressed, slowing conduction. This membrane-stabilizing activity is caused by the D-isomer, whereas the L-isomer is responsible for β -blocking activity. The clinical significance of membrane-stabilizing activity is also unclear.²⁹⁵

Propranolol. Propranolol is the prototypical β -blocking drug against which all others are compared. It is nonselective and has no intrinsic sympathomimetic activity but does have membrane-stabilizing activity at higher doses. It is available in both iv and oral forms. It is highly lipophilic and is metabolized by the liver to more water-soluble metabolites, one of which, 17-OH propranolol, has weak β -blocking activity. There is a significant first-pass effect by the liver after oral administration of

the drug. It is highly protein-bound, and the free drug level may be altered by other highly bound drugs. The elimination half-life is approximately 4 hours, but the pharmacologic half-life is around 10 hours.

Hemodynamic effects include decreased HR and contractility. The major factors contributing to the decrease in blood pressure by propranolol are decreased CO and renin release. Systemic vascular resistance may increase upon acute administration owing to blockade of β_2 receptors in the peripheral vasculature. With chronic administration, however, peripheral vascular resistance decreases. This is thought to be secondary to decreased renin release and, possibly, decreased central SNS outflow.^{292,306} Complications with the use of propranolol include bradycardia, heart block, worsening of congestive heart failure, bronchospasm, and sedation. During anesthesia with halothane, it may cause severe bradydysrhythmias.

Nadolol. Nadolol is a noncardioselective β blocker with no membrane-stabilizing activity or intrinsic sympathomimetic activity. It is approximately equipotent to propranolol, but its effects are prolonged owing to slower elimination. It is relatively lipid-insoluble and is excreted 70% unchanged in urine and 20% in the feces. The elimination half-life is 24 hours. Because it is lipid-insoluble, it does not cross the blood-brain barrier, and sedation is less of a problem than with propranolol. Hemodynamic effects are the same as for propranolol. The main advantage of the drug is the capability for once per day dosing.

Timolol. Timolol is also noncardioselective with little intrinsic sympathomimetic activity and no membrane-stabilizing activity. It is the only β blocker used as the L-isomer rather than the racemic mixture. It is 5–10 times as potent as propranolol. Hepatic metabolism accounts for approximately 66% of its elimination, and another 20% is found unchanged in the urine. The elimination half-life is 5.6 hours, and the pharmacologic half-life is approximately 15 hours. It was first used topically for treatment of glaucoma but is now used in hypertension and has been shown to decrease the risk of reinfarction and death following myocardial infarction.³⁰⁷ Its hemodynamic effects and side-effects are similar to those of other β blockers. The anesthesiologist should also be aware that timolol eye drops may be absorbed systemically and cause bradycardia and hypotension that are refractory to treatment with atropine.³⁰⁸

Pindolol. Pindolol is a nonselective β blocker with membrane-stabilizing activity and intrinsic sympathomimetic activity. It is 10–40 times as potent as propranolol. It is lipid-soluble and metabolized by the liver but not as avidly extracted; therefore, its biologic availability after oral administration is more predictable. It is excreted 40% unchanged in the urine. The elimination half-life is 3.5 hours. It is useful in the treatment of angina pectoris, cardiac dysrhythmia, and hypertension. As discussed above, the clinical usefulness of the intrinsic sympathomimetic activity property is unclear.

Oxprenolol. Oxprenolol is similar to pindolol except for less intrinsic sympathomimetic activity and lower potency.

Metoprolol. Metoprolol is a relatively selective β -blocking drug with β -blocking effects at moderate and high doses. It has neither intrinsic sympathomimetic activity nor membrane-stabilizing activity. It has a possible advantage in patients with reactive airway disease at oral doses up to 100 mg \cdot day⁻¹.³⁰⁹ In this case, it should probably be used with a β_2 -mimetic drug. It is mostly metabolized in the liver, with only about 5% excreted unchanged in the urine. The elimination half-life is 3.5 hours. It has recently become available in iv as well as oral form; therefore, it may be useful during anesthesia.

Atenolol. Atenolol is similar to metoprolol in that it is relatively cardioselective and has no intrinsic sympathomimetic activity or membrane-stabilizing activity. It is less lipophilic, however, and is eliminated primarily by renal excretion. The elimination half-life is 6–7 hours. The lack of first-pass metabolism results in more predictable blood levels after oral dosing.

Acebutolol. Acebutolol is a cardioselective β blocker with intrinsic sympathomimetic activity and membrane-stabilizing activity.³¹⁰ It is metabolized in the liver and is subject to extensive first-pass metabolism. The primary metabolite is diacetolol, which has a pharmacologic profile similar to that of the parent drug and is excreted renally.³¹¹ The pharmacologic effects of the drug, therefore, are dependent on both hepatic transformation and renal excretion. The elimination half-life of acebutolol is 3–4 hours and of diacetolol 8–13 hours. Elimination is prolonged in the elderly and patients with renal disease. Acebutolol, like pindolol, has intrinsic sympathetic activity that makes it more advantageous than the other β blockers in patients with bradydysrhythmias or myocardial failure.

Esmolol. Esmolol has several uses in the perioperative period.^{312,313} The most distinctive feature of the drug is the ester function that is incorporated into the phenoxypropanolamine structure. This allows for rapid degradation by esterases in the red blood cells and a resultant pharmacologic half-life of 10–20 minutes.³¹³ Esmolol is cardioselective and appears to have little effect on bronchial or vascular tone at doses that decrease HR in humans. It has been used successfully in low doses in patients with asthma,³¹⁴ but caution is again advised when using β blockers in these patients.²⁹⁶ Esmolol is metabolized rapidly in the blood by an esterase located in the red blood cell cytoplasm. It is different from the plasma cholinesterase and is not inhibited to a significant degree by physostigmine or echothiophate but is markedly inhibited by sodium fluoride. There are no apparent important clinical interactions between esmolol and other ester-containing drugs. At the highest infusion rates (500 μ g \cdot kg⁻¹ \cdot min⁻¹), esmolol does not prolong neuromuscular blockade by succinylcholine.³¹⁵

Esmolol has proved useful in the perioperative period because of its capability to be administered intravenously and its short half-life.³¹⁶ This feature permits a trial of β blockade in doubtful situations. Esmolol has been shown to blunt the response to intubation of the trachea^{313,317} and is moderately effective in treating postoperative hypertension.^{317,318} Most reported studies in humans have used doses of 50–500 μ g \cdot kg⁻¹ \cdot min⁻¹. The most beneficial approach seems to be a loading dose of 500 μ g \cdot kg⁻¹ over 30 seconds, followed by continuous infusion of 50–300 μ g \cdot kg⁻¹ \cdot min⁻¹. Peak blockade appears to occur within 5 minutes. On discontinuation of the infusion, serum levels decline with an elimination half-life of 9 minutes. The HR response to isoproterenol returns to control in 20 minutes.

Betaxolol. Betaxolol hydrochloride is a β_1 -selective (cardioselective) adrenergic receptor antagonist and is freely soluble in water. It has weak membrane-stabilizing activity and no intrinsic sympathomimetic (partial agonist) activity. The preferential effect on β_1 receptors is not absolute. Some β_2 -inhibitory activity can be expected in the bronchial and vascular musculature at higher doses. Absorption of an oral dose is complete, with an absolute bioavailability of 90% that is unaffected by ingestion of food or alcohol. The mean elimination half-life is from 11 to 22 hours. It is eliminated primarily by the liver but secondarily through the kidneys. Betaxolol is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents.

Penbutolol. Penbutolol is a synthetic β -receptor antagonist for oral administration. It is a nonselective β -receptor antagonist with some intrinsic sympathomimetic activity. Penbutolol does not appear to have any membrane-stabilizing properties, as does propranolol. Plasma elimination half-life is 5 hours in normal subjects. Ninety percent of radioactive penbutolol was found to be excreted in the urine. There is no change in the effective half-life of penbutolol in healthy patients versus those on renal dialysis. It is indicated primarily for the treatment of hypertension and may be used in combination with other antihypertensives.

Carteolol. Carteolol is a synthetic, nonselective, β -adrenergic receptor-blocking agent with intrinsic sympathetic activity. It possesses no significant membrane-stabilizing (local anesthetic) activity and is without value in treating intrinsic arrhythmias. Carteolol has equivocal effects on renin secretion because of its intrinsic sympathomimetic activity, in contrast to β blockers without such activity, which inhibit renin. Carteolol is well absorbed with a half-life of approximately 6 hours. About 50–75% of the drug is eliminated by the kidneys; thus, renal impairment increases its half-life in proportion to the reduction in creatinine clearance. Carteolol is primarily indicated for the management of hypertension but may be used in combination with other potent drugs.

Mixed Antagonists

Labetalol. Labetalol is an antihypertensive drug with blocking activity at both α and β receptors. The relative α/β -blocking effects are dependent upon the route of administration. After oral administration, the ratio of α/β effectiveness is 1:3; however, when given intravenously, it is 1:7 (*i.e.*, it is 3 and 7 times more potent on β than on α receptors, respectively). The α effects are primarily on α_1 receptors, whereas the β effects are nonselective.

Hemodynamic effects consist primarily of decreased peripheral resistance and decreased or unchanged HR with little change in CO.³¹⁶ Serum renin activity is decreased. Maintenance of lower HRs in the presence of decreased systemic blood pressure is beneficial in controlling the myocardial oxygen supply/demand ratio and is a major benefit of labetalol in patients with coronary artery disease.³¹⁹

Labetalol is eliminated by hepatic glucuronide conjugation. The elimination half-life after iv administration is 5.5 hours and 6–8 hours after oral use. Elimination is not markedly prolonged in patients with hepatic or renal failure. Another advantage of the drug is the ability to convert from iv to oral forms of the same drug after the patient is stable.^{320,321} For treatment of hypertension when used as a bolus, the initial dose is 0.25 mg \cdot kg⁻¹ iv over 2 minutes, then repeat every 10 minutes to a total of 300 mg. When used as a continuous infusion, it is usually started at 2 mg \cdot min⁻¹ and titrated to effect. Because there is an enhanced effect by inhalation anesthetics, these doses should be decreased when used intraoperatively.

Complications and contraindications are similar to those for the β blockers. Labetalol should be used with caution in patients with compromised myocardial function because it may worsen heart failure. Also, owing to β -blocking activity, the drug may induce bronchospasm in asthmatics. As with other β blockers, abrupt withdrawal is

not recommended.

Calcium Entry Blockers

Calcium is regarded as the universal messenger in cells and plays a critical role in a number of biologic processes.²⁴⁵ It is involved in blood coagulation, a broad array of enzymatic reactions, the metabolism of bone, neuromuscular transmission, the electrical activation of various excitable membranes and endocrine secretion, and muscle contraction. Calcium initiates several physiologic events in the specialized automatic and conducting cells in the heart.³²² It is involved in the genesis of the cardiac action potential, and it links excitation to contraction and controls energy stores and utilization. Movement of extracellular calcium across membranes also governs the function of smooth muscle in bronchi and in coronary, pulmonary, and systemic arterioles. Its role in adrenergic effector response has been outlined in detail (see [Molecular Pharmacology and Effector Response](#)).

There are membrane calcium channels that provide a pathway for calcium influx across cell membranes that differs from that of calcium efflux movements associated with active pumps or exchange.³²³ The inward calcium channel exhibits two distinguishing properties: (1) selectivity, in that they have the ability to distinguish between ion species; (2) excitability, in that they have the property of responding to changes in membrane potential.³²⁴ Separate, ion-specific channels for sodium and calcium influx are thought to exist. The status of these channels can vary to produce three kinetic states: resting, activated, and inactivated. Sodium channels are referred to as fast channels because the transition among resting, activated, and inactivated states is more rapid than among the calcium channels. Thus, calcium channels are often referred to as membrane "slow channels."¹⁹³

Classification of calcium entry blockers has been difficult since their discovery. They were initially thought to be β -adrenergic blocking drugs because of their sympatholytic action. Later they were called calcium antagonists.³²⁵ It is clear, however, that these drugs are not true pharmacologic antagonists of calcium. Instead, they interact with the cell membrane to control the intracellular concentration of calcium. The correct terminology for this group of drugs appears to be calcium entry blockers.³²⁶ Slow channel inhibitors or calcium channel blockers are alternative terms.

The molecular structures of three clinically useful calcium entry blockers are shown in [Figure 12-34](#). Calcium entry blockers are a heterogeneous group of drugs with dissimilar structures and electrophysiologic and pharmacologic properties.¹⁹² Despite structural dissimilarities, this group shares some important actions that are consistent with the known importance of extracellular calcium and adrenergic function. Any drug that alters slow-channel kinetics could be expected to produce vasodilatation, to depress cardiac conduction velocity (dromotropism), to depress contractility (inotropism), and to decrease HR (chronotropism). All calcium entry blockers do this, but with varying degrees of potency in the intact human and *in vitro* ([Table 12-24](#)).^{327,328} Thus, despite their similarities, these drugs cannot be considered therapeutically interchangeable. Clinically, nifedipine is a potent coronary artery vasodilator with little direct effect on cardiac conduction. It may reduce dysrhythmia secondarily when increased coronary blood flow is of benefit. Verapamil is valued for its specific antidysrhythmic activity, but it is a myocardial depressant with little vasodilator activity. Verapamil also has slightly greater local anesthetic activity (fast-channel inhibition) than procaine on an equimolar basis.³²⁹ The significance of this observation in humans has not been established. The structural heterogeneity of this group of drugs also suggests more than one site and mechanism of action. Although the molecular basis of the action of these compounds is unknown, they are lipophilic, and it appears likely that they work by producing conformational changes in the cell membranes (see [Molecular Pharmacology and Effector Response](#)).

Figure 12-34. Structural formulas of the calcium entry blockers demonstrate dissimilar structures consistent with their dissimilar electrophysiologic and pharmacologic properties. They also share some similarities but cannot be considered therapeutically interchangeable. Nifedipine and nitrendipine are structurally similar and are both potent vasodilators; BAY K 8644 is also similar but is a calcium channel agonist.

| | Verapamil | Diltiazem | Nifedipine | Lidoflazine |
|-----------------------|-----------|-----------|------------|-------------|
| Negative inotropic | + | 0/+ | 0 | 0 |
| Negative chronotropic | + | 0/+ | 0 | 0 |
| Negative dromotropic | +++ | +++ | 0 | 0 |
| Coronary vasodilation | ++ | +++ | +++ | +++ |
| Systemic vasodilation | ++ | ++ | +++ | +++ |
| Bronchodilation | 0/+ | | 0/+ | |

Table 12-24. AUTONOMIC EFFECTS OF CALCIUM ENTRY BLOCKERS IN INTACT HUMANS

The useful pharmacologic effects of the calcium entry blockers have been confined almost solely to the cardiovascular system, although the list of uses will likely grow.¹⁹³ [Table 12-25](#) lists some of the areas of investigation in which they appear to be of clinical benefit.^{123,330} Calcium entry blockers have been described, perhaps erroneously, as selective slow-channel blockers. A review of the literature, however, suggests that these agents are not selective, but rather that the slow-channel effects on the cardiovascular system are just more apparent. Their lack of selectivity should not be surprising considering the critical role calcium plays in a wide variety of biologic processes. The sensitivity of a given tissue to the calcium entry blockers is related to that tissue's dependence on extracellular calcium for its function. This would explain the sensitivity of the calcium-dependent myocardium and smooth muscle to these blockers on the one hand and the apparent insensitivity of striated muscle on the other.³³¹ Extracellular calcium is relatively insignificant in the function of striated muscle, where the SR is the major storage organelle of calcium. Striated muscle can recycle intracellular calcium for prolonged periods, which is in keeping with its function of sustained contraction as opposed to the rhythmic or cyclic contraction of the myocardium and smooth muscle.

| Vascular Disorders | Nonvascular Disorders |
|-------------------------|-----------------------|
| Systemic hypertension | Bronchial asthma |
| Pulmonary hypertension | Esophageal spasm |
| Cerebral arterial spasm | Dysmenorrhea |
| Raynaud's phenomenon | Premature labor |
| Migraine | |

Table 12-25. USES OF CALCIUM CHANNEL BLOCKERS

The drugs are all absorbed *via* the gastrointestinal tract, but the extensive first-pass hepatic extraction of verapamil limits its bioavailability orally (Table 12-26). Onset of action is equivalent for all three drugs and is consistent with rapid membrane transport. All three drugs are extensively protein-bound and subject to the effect of changes in plasma protein concentration and competition from other protein-bound drugs and metabolites, but final elimination of verapamil and nifedipine is primarily renal.

| | Verapamil | Diltiazem | Nifedipine |
|----------------------|--|--|--|
| Dose | 80-160 mg bid | 60-90 mg bid | 30-60 mg bid |
| Oral bioavailability | 20-30% (po) | 70-80% (po) | 50-60% (po) |
| Protein binding | ~90% | ~80% | ~95% |
| Half-life | 2-4 hr | 3-5 hr | 2-5 hr |
| Elimination | Renal (50%) | Renal (50%) | Renal (50%) |
| Contraindications | Heart failure, aortic stenosis, bradycardia, hypotension | Heart failure, aortic stenosis, bradycardia, hypotension | Heart failure, aortic stenosis, bradycardia, hypotension |

Table 12-26. COMPARATIVE PHARMACOLOGY OF CALCIUM ENTRY BLOCKERS

Verapamil. Verapamil is a calcium entry blocker that is administered intravenously for terminating supraventricular tachydysrhythmias.^{332,333} Nearly all forms of supraventricular tachydysrhythmias are caused by re-entry using either the sinoatrial or the AV node as part of the circuit. Verapamil terminates these cardiac dysrhythmias by decreasing nodal conductivity, converting the unidirectional block of re-entry to a bidirectional block. In this regard, its action on supraventricular dysrhythmia is similar to that of quinidine on ventricular re-entry cardiac dysrhythmia.

Verapamil does not alter the action potential upstroke in fibers whose resting membrane potential is more negative than -60 mV, *i.e.*, fast action potentials.³³⁴ It does slow or prevent depolarization in cardiac tissue with a resting membrane potential that is less negative than -50 mV, *i.e.*, calcium-dependent upstroke. Verapamil, therefore, has profound effects on pacemaker cells, which depend on the calcium current for depolarization.³³⁵ It depresses the rate of sinus discharge, reduces conduction velocity, and increases refractoriness of the AV node. A dose-dependent increase in the PR interval and AV interval is produced on the electrocardiogram. This has been described as a quinidine-like effect similar to that produced by Class IA antidysrhythmic drugs (*e.g.*, procainamide), which are also effective for supraventricular dysrhythmia. In contrast to the procainamide, verapamil does not increase the QRS or Q-T interval because it lacks activity on the sodium-dependent action potentials.

Verapamil is a first-line drug for treatment of supraventricular tachydysrhythmias (Table 12-27). The incidence of successful termination of paroxysmal atrial tachycardia with verapamil in adults has approached 90%.³³⁶ It is also effective in treating atrial fibrillation and atrial flutter by either converting to a sinus rhythm or slowing the ventricular response. The ventricular rate will slow as a result of decreased conduction velocity through the AV node even when conversion is not produced. Caution must be exercised in treating patients when the underlying cause of the atrial tachycardia, atrial fibrillation, or atrial flutter is the Wolff-Parkinson-White syndrome.³³⁷ An accessory bypass tract lies near the AV node that participates in the re-entry of these tachydysrhythmias. Verapamil may terminate the tachydysrhythmia by its specific depressant effects on the AV node, which is one limb of the re-entrant pathway. It may also increase conduction velocity in the accessory tract, in which case the HR may actually increase.

| |
|--|
| Verapamil |
| Vasodilator |
| ↓ systemic vascular resistance → ↓ heart rate |
| → ↓ ejection fraction and cardiac output |
| Small decrease in left ventricular dP/dt |
| Little or no change in coronary resistance |
| ↓ conduction through atrioventricular node (↑ P-R interval) |
| Should not be given with digitalis or β blockers |
| Diltiazem |
| More like verapamil than nifedipine |
| Effect on coronary more than systemic vessels and has less marked |
| hemodynamic effects than diltiazem or verapamil |
| Little effect on cardiac output |
| Does not cause tachycardia |
| Effect on conduction system similar to those of verapamil |
| Less inotropic effect than verapamil |
| Nifedipine |
| Rapid onset of action, may be used sublingually |
| Powerful peripheral vasodilator, may be useful in treatment of hyper- |
| tension |
| Has little clinically important negative inotropic activity |
| Low tendency to produce cardiac decompensation than verapamil |
| Little effect on nodal activity and no antiarrhythmic activity; there- |
| fore causes no electrocardiographic changes |
| Increased coronary blood flow in normal and ischemic myo- |
| cardium |

Table 12-27. ACTIONS OF CALCIUM ENTRY BLOCKERS

Verapamil has no adverse effects on bronchial asthma or obstructive lung disease and may be selected over propranolol in patients with these conditions.¹²³ It should be avoided in patients with sick sinus syndrome, AV block, and the presence of heart failure, unless the heart failure is the result of a supraventricular tachycardia.

Studies further support the hypothesis that Ca²⁺ participates directly in the genesis of ventricular dysrhythmia.^{337,338} When sodium channels are inactivated by hypoxia, stretch, or hyperkalemia, the remaining Ca²⁺ can produce a depolarizing current in these abnormal cells, especially in the presence of catecholamines. The conversion of a fast response cell to a cell with slow response characteristics presents all the necessary ingredients for the re-entry phenomenon: slow depolarization and delayed conduction. The resulting ventricular dysrhythmia can usually be terminated with one of the Class I drugs as long as the resting membrane potential of the slow response is between -80 and -60 mV. Verapamil has been effective in terminating ventricular tachycardias and premature depolarizations in about two thirds of the treatment trials when other drugs have failed. The resting membrane potential of these abnormal "slow response" foci has been postulated to be less negative than -60 mV, a range in which lidocaine would be ineffective on the calcium current conduction and depolarization. More information is needed before recommendations can be made for verapamil in treating dysrhythmia other than supraventricular tachydysrhythmias. Other drugs are significantly more effective for the initial treatment of ventricular dysrhythmia.

The important side-effects of verapamil are directly related to its predominant pharmacologic action (see Table 12-27). It may produce unwanted AV conduction delays and bradycardia, resulting in cardiovascular collapse. Verapamil must be used carefully, if at all, in the presence of propranolol. The combined effect has produced complete heart block in animals and humans. It must be used carefully in digitalized patients for the same reason. No such interactions exist with nifedipine. The combination of β blockade and nifedipine may be beneficial in patients with ischemic heart disease because the reflex tachycardia seen with nifedipine can be countered with β blockade.

Nifedipine. Nifedipine is the most potent calcium entry blocker when tested in isolated tissue preparations. It is an equipotent cardiac depressant and vasodilator. Depression of inotropism and cardiac conduction, however, is not evident in the intact human. It does not effect baroreflex mechanisms and, as a result, the marked vasodilation is accompanied by increased SNS tone and afterload reduction (see Table 12-27).¹⁹³ A compensatory tachycardia may result, and CO may actually increase as a result of the afterload reduction.

The most specific therapeutic application for nifedipine is coronary vasospasm (variant of Prinzmetal's angina).^{192,328} It has been more successful than nitroglycerin for this purpose because it produces a more profound and predictable coronary vasodilation. It has also been extremely useful in other types of ischemic heart disease ranging from unstable angina to myocardial infarction. The decrease in myocardial oxygen demand that results from the reduced afterload and reduced left ventricular volume appears to be the mechanism for the relief of angina. Coronary vasodilation is another factor, but it is not known if this is the antianginal effect in patients with

coronary artery disease. The dilating effect may last only 5 minutes, but the antianginal effect may last more than 1 hour.

Nifedipine is not available for iv use, but clinical practice has demonstrated that sublingual nifedipine is an effective therapeutic application with a nearly immediate onset of action.¹⁹² One need only puncture the end of a nifedipine capsule and squirt it under the patient's tongue. Use of this technique is particularly applicable for the anesthesiologist in situations in which oral medication cannot be given. We have also used sublingual nifedipine effectively in situations in which perioperative hypertension and evidence of acute coronary ischemia coexist. In these circumstances, a reduction in afterload, coronary vasodilation, and reduced blood pressure are all achieved with the same drug.³³⁹ Reflex tachycardia, if it occurs, can be managed with β blockade without significant interaction with nifedipine.

Diltiazem. The hemodynamic effects of diltiazem lie somewhere between those of verapamil and nifedipine.¹⁹³ It is less potent than either of these two agents.³⁴⁰ Diltiazem is a good coronary artery dilator but a poor peripheral vasodilator. It often produces bradycardia and delayed conduction, and reflex tachycardia is not a problem.³³⁷ It appears to be an effective oral drug for the treatment of coronary disease in which cardiac dysrhythmias are troublesome. Cardiac dysrhythmias are noticeably a part of the clinical picture in patients suffering from coronary spasm. Intravenous administration of diltiazem is effective therapy for supraventricular tachycardias including PSVT, atrial fibrillation, atrial flutter, and re-entrant tachycardias such as Wolff-Parkinson-White syndrome.³⁴¹ Like verapamil, diltiazem acts by prolonging AV nodal conduction. The peripheral vascular effects of diltiazem, though, are less severe, making it a more desirable therapeutic choice in most cases. A bolus dose of $0.25 \text{ mg} \cdot \text{kg}^{-1}$ is administered over 2 minutes and may be repeated at $0.35 \text{ mg} \cdot \text{kg}^{-1}$ if necessary after 15 minutes. An infusion of $5\text{--}15 \text{ mg} \cdot \text{hr}^{-1}$ may be necessary to maintain the reduction of HR.

Nicardipine. Nicardipine hydrochloride is a calcium channel blocker that can be administered orally and intravenously. It is the only calcium channel blocker that can be titrated intravenously to achieve blood pressure response. Nicardipine is a smooth muscle relaxant producing vasodilation of peripheral and coronary arteries. It has a rapid onset of action, and the major effects last 10–15 minutes. Toxic metabolic products are not produced.³⁴² It has minimal cardiodepressant effects and does not decrease the rate of the sinus node pacemaker or slow conduction through the AV node. Renal failure does not affect the dosage, but the dosage should be reduced in the elderly and those with hepatic dysfunction. It is compatible with most crystalloid solutions. Side-effects of nicardipine include headache, lightheadedness, flushing, and hypotension. Reflex tachycardia is not a frequent finding with nicardipine, as is the case with nitroprusside, hydralazine, or nifedipine.

Nimodipine. Nimodipine is highly lipophilic. It has a greater vasodilating effect on cerebral arteries than on vessels elsewhere because of its lipophilism, which promotes crossing the blood–brain barrier. Clinical studies demonstrate a favorable effect on the severity of neurologic deficits caused by cerebral vasospasm following subarachnoid hemorrhage. However, no radiographic evidence has been presented that nimodipine either prevents or relieves spasm of these arteries. The mechanism for clinical improvement is not known. It is primarily an oral drug that is rapidly absorbed, with a T-terminal half-life of approximately 8–9 hours. Earlier elimination rates are much more rapid, which results in a need to redose every 4 hours. The bioavailability of an oral dose is only 13%. Dosage should be reduced in patients with hepatic dysfunction. The primary indication for nimodipine is for the improvement of neurologic deficits caused by spasm following subarachnoid hemorrhage from a ruptured congenital aneurysm.

Felodipine. Felodipine is a second-generation calcium channel inhibitor that is currently under investigation by the Federal Drug Administration. Nimodipine and felodipine have demonstrated selectivity for vascular tissue beds. Whereas nimodipine preferentially dilates cerebral vessels, felodipine preferentially dilates peripheral resistance vessels. Neither has significant effects on cardiac muscle. This has important clinical implications in the treatment of hypertension. Early studies indicate that 10–20 mg of felodipine daily will reduce blood pressure without reducing CO or HR. Coronary blood flow increases, but no effect on ventricular contraction or relaxation has been reported. This would make the drug appropriate for the active hypertensive patient.

Calcium Entry Blockers and Anesthesia

Evidence indicates that halothane depresses slow-channel kinetics. All of the potent inhalation anesthetics behave in a similar fashion in that they depress myocardial contractility and vascular tone in a dose-related manner.^{343,344} Most studies indicate that the calcium entry blockers and inhalation anesthetics exert additive effects on the inward calcium current.^{192,328} Opioid anesthetics do not appear to add anything to the effects of the calcium entry blockers. Several recent studies indicate an interaction between the calcium entry blockers and the neuromuscular blocking drugs similar to that seen with the mycin antibiotics.¹⁹³ This interaction is not well defined, but *in vitro* and *in vivo* studies indicate a reduced margin of safety with these drug combinations. Calcium entry blockers appear to augment the effects of both depolarizing and nondepolarizing muscle relaxants.³⁴⁵ These observations serve as a word of caution because their clinical significance has not been defined. Prolonged apnea and relaxation have been reported when verapamil was used to treat a supraventricular tachycardia in a patient with Duchenne's muscular dystrophy.³⁴⁶

Calcium entry blockers should be continued until the time of surgery to maintain control of angina pectoris, hypertension, or cardiac dysrhythmia.¹⁹³ It could be anticipated that sudden discontinuation of these drugs theoretically could produce a rebound of symptoms, although this phenomenon has not been reported. Upregulation of calcium receptors would probably occur during periods of entry blockade.³⁴⁷

Verapamil may increase the toxicity of digoxin, the benzodiazepines, carbamazepine, oral hypoglycemics, and possibly quinidine and theophylline.³⁴⁸ Cardiac failure, AV conduction disturbances, and sinus bradycardia may be more frequent with concurrent use of β blockers, and severe hypotension and bradycardia may occur with bupivacaine. Decreased lithium effect and lithium neurotoxicity have both been reported with the concurrent use of verapamil.³⁴⁹ The effects of verapamil may also be increased by cimetidine.³⁵⁰

Antihypertensives

Increased awareness and treatment of hypertension over the last 20 years has resulted in increasing numbers of patients presenting for anesthesia and surgery who are taking one or more antihypertensive medications. These drugs are numerous, affect multiple organ systems, and have the potential for many deleterious interactions in the perioperative period. Most antihypertensive drugs blunt the ANS or its effector organs or cause reflex increases in ANS outflow. Most anesthetic agents also inhibit ANS tone to some degree³⁴⁸ and may therefore have additive effects with antihypertensive drugs. In addition, patients with hypertension may exhibit greater lability in blood pressure intraoperatively and rebound hypertension in the postoperative period.^{351,352} The anesthesiologist should therefore maintain a thorough understanding of the commonly used antihypertensive drugs. A rational approach to their perioperative use includes decisions as to holding or continuing them preoperatively, possible interactions with anesthetic drugs, and resumption of treatment postoperatively. The commonly used antihypertensive drugs are grouped below according to their primary mechanism of action and discussed briefly with emphasis on consideration for the anesthesiologist.

Diuretics

Diuretics are the most common prescribed drugs for hypertension. Their basic mechanisms of action are decreased plasma and extracellular volumes. Although the thiazides and furosemide have been shown to have vasodilating properties, the clinical significance of this effect is unclear. Chronic diuretic therapy results in decreased intravascular volume. The cardiovascular response to induction of anesthesia may therefore be accentuated, resulting in hypotension and tachycardia. Other problems associated with diuretic use include hypokalemia, hyponatremia, hypocalcemia, and hyperglycemia. Chronic hypokalemia is common with diuretic therapy and may predispose the patient to cardiac arrhythmias.³⁵³ The clinical relevance of perioperative hypokalemia is unclear and has stirred considerable debate among anesthesiologists as to whether surgery should be postponed until plasma potassium levels are treated.^{354,355}

Sympatholytics

Sympatholytic drugs include those that block central SNS outflow or NE release from the presynaptic neuron at the effector site. Currently included in this group are *a*-methyl dopa and clonidine.

***a*-Methyl dopa.** *a*-Methyl dopa is a catechol derivative that is enzymatically converted to active compounds by enzymes in the catecholamine synthesis chain (see Fig. 12-9). *a*-Methyl dopamine and *a*-methylnorepinephrine are the primary metabolites. The precise mechanism responsible for decreased SNS tone is unclear, but it is thought that *a*-methylnorepinephrine, which is stored in presynaptic vesicles, is released and stimulates presynaptic α_2 receptors, thereby inhibiting NE release.²⁹² Because of the unique metabolism of *a*-methyl dopa to the active compound and the storage of the metabolite in presynaptic vesicles, both the time to onset and duration of action are long. Even after iv administration, the peak effect may not be seen for several hours. Although the elimination half-life is 2 hours, the effect of an oral dose may last up to 24 hours.

Clonidine. Clonidine stimulates presynaptic α_2 receptors and inhibits NE release from both central and peripheral adrenergic terminals. It also has some α_1 -agonist activity and in high oral doses may cause paradoxical hypertension by stimulating vascular α_1 receptors. Under normal circumstances, the α_2 effects predominate. The prominent antihypertensive effect is thought to be secondary to stimulation of α_2 receptors in the vasomotor centers of the medulla oblongata.²⁹² Whether these are

presynaptic or postsynaptic receptors remains controversial²⁸⁷; however, the end result is decreased SNS and enhanced vagal tone. Peripherally, there is decreased plasma renin activity as well as decreased EPI and NE levels.³⁵⁶

Cardiovascular effects of clonidine include decreased peripheral vascular resistance and HR.³⁵⁷ The cardiovascular response to exercise is usually maintained. Prominent side-effects include hypotension, sedation, and dry mouth.^{358,359} One of the more worrisome complications of clonidine use is the occurrence of a withdrawal syndrome on acute discontinuation of the drug. This usually occurs about 18 hours after discontinuation and consists of hypertension, tachycardia, insomnia, flushing, headache, apprehension, sweating, and tremulousness. It lasts for 24–72 hours and is most likely to occur in patients taking more than 1.2 mg · day⁻¹ of clonidine. The withdrawal syndrome has been noted postoperatively in patients who were taken off clonidine for surgery.³⁶⁰ It can be confused with anesthesia emergence symptoms, particularly in a patient with uncontrolled hypertension. Clonidine is not available for iv use, but symptoms of the withdrawal syndrome as well as routine postoperative hypertension can be treated with clonidine administered transdermally or rectally.³⁶¹ Withholding clonidine prior to surgery is not recommended.

Dexmedetomidine. Dexmedetomidine is a more selective α_2 agonist than clonidine.³⁶² It has a much shorter half-life (about 1.5 hours) and a more rapid onset of action (<5 minutes). The time to peak effect is 15 minutes. Intravenous dexmedetomidine provides excellent sedation, lowering of blood pressure and HR, and profound decreases in plasma catecholamines. Little respiratory depression is evident. Other studies have shown it to be an effective anxiolytic and sedative when used as premedication for anesthesia for minor gynecologic surgery. In an animal model, dexmedetomidine produces stereospecific and dose-dependent decreases in MAC.³⁶³

Flacke listed the potential uses of sympatholytic drugs in the future. In addition to the reducing effect of MAC and the absent respiratory depression, the following properties seem particularly valuable to the anesthesiologist³⁶³:

1. They are potent analgesics.
2. They are sedatives and anxiolytics.
3. They are antisialogogues.
4. They may promote hemodynamic stability.
5. Homeostatic reflexes remain intact.
6. They attenuate opioid rigidity (in animals).
7. Their circulatory actions can be reversed.

Clonidine has also been used successfully as a substitute for opiates and nicotine during withdrawal. It reduces sympathetic hyperactivity with head injury and can be used as an analgesic in the subarachnoid and epidural spaces for the treatment of pain.

Converting Enzyme Inhibitors

The renin-angiotensin system is integrally related to the ANS in controlling blood pressure (see Fig. 12-18). The central role of the renin-angiotensin-aldosterone system in the regulation of fluid balance and hemodynamics was not fully appreciated until the discovery and clinical application of inhibitors of the angiotensin-converting enzyme (ACE).^{126,127} Captopril, enalapril, and lisinopril inhibit converting enzyme and thereby prevent the conversion of angiotensin I to the active angiotensin II. These drugs have been highly effective in the treatment of all levels of essential hypertension as well as renovascular and malignant hypertension.^{128,129} The cardiovascular effects normally involve only decreased peripheral vascular resistance. CO may remain normal or increase while the filling pressure remains unchanged. Thus, these drugs have been effective in the management of congestive heart failure as well.^{364,365,366} and ³⁶⁷ There is usually no increase in SNS tone in response to the lowered blood pressure. ACE inhibition generally results in reductions in angiotensin-aldosterone, NE, and plasma antidiuretic hormone. This suppression is accompanied by a decrease in aldosterone and an improvement in cumulative plasma potassium levels, which are beneficial in both congestive heart failure and hypertension. It can be concluded that the major humoral responses to chronic congestive heart failure, even overlooking the effects of the diuretics, are affected by the release of angiotensin, aldosterone, and increased SNS tone.

Captopril, the first orally active compound, has proved highly effective in the treatment of all levels of hypertension and congestive heart failure (Table 12-28). Enalapril is a second-generation (nonsulfhydryl) ACE inhibitor. The omission of the sulfhydryl group possibly diminishes side-effects. Both captopril and enalapril combine a high degree of clinical efficacy with a low rate of side-effects. Both are eliminated via renal excretion and should be given in reduced doses in patients with renal dysfunction. Captopril has a shorter half-life and requires more frequent dosing than enalapril. Enalapril has to be converted by esterase in the liver and other tissues into the active compound enalaprilat. Many new ACE inhibitors are being developed that are eliminated via hepatic routes and may prove advantageous in renal failure. Lisinopril is one of these ACE inhibitors that is absorbed as the active form and is very long-acting.

| Agent | Major Studies | Characteristics |
|--------------|---|---|
| Captopril | Quality of life (SHE), diabetic nephropathy (SBD), and Stage A (ACE trial negative) | The first ACE inhibitor, overall the best studied |
| Enalapril | CONSENSUS, SOLVD (prevention and treatment arms), TIPPET and II | Long-acting, the best studied in heart failure |
| Benazepril | None | Long plasma half-life (20 hr) |
| Cilazapril | None | Long plasma half-life |
| Perindopril | None | Renal and hepatic elimination may allow safe use in renal or hepatic failure |
| Benazepril | None | Long plasma half-life (20 hr), low initial hypertension |
| Quinapril | QUEST (Quinapril Ischemic Stroke Trial postoperative), and years A (ACE, sudden death, study 199) | First leading to lower ACE, postoperative half-life |
| Benazepril | ACE (acute infarction) (acute efficacy) | Long plasma half-life (>20 hr), proven use in postinfarction CHF |
| Trandolapril | TRANCE (Trandolapril Cardiovascular Study) in hypertensive (ACE) patients, study 195 | Long plasma half-life (20 hr), highly lipophilic with poor % in lower binding |
| Lisinopril | CONSENSUS (ACE), mortality reduced by 25% | Active as is, water-soluble, long-acting |

CHF = congestive heart failure.

Table 12-28. THE ANGIOTENSIN-CONVERTING ENZYME (ACE)

The ACE inhibitors are associated with few side-effects and are increasingly popular in treating hypertension. Captopril may produce reversible neutropenia, dermatitis, and angioedema. Enalapril produces syncope, headache, and dizziness in about 1% of elderly patients. All ACE inhibitors may cause hypotension in patients who are hypovolemic and taking diuretic therapy. Diuretic therapy should be discontinued 1 week before starting ACE inhibitor therapy. The hypotensive effects are also enhanced by the concomitant use of calcium channel blockers. The ACE inhibitors blunt the hypokalemic effects of thiazide diuretics and may magnify the potassium-sparing effects of spironolactone, triamterene, and amiloride. In addition, nonsteroidal anti-inflammatory drugs, including aspirin, may magnify the potassium-retaining effects of ACE inhibitors.

Vasodilators

The drugs that directly relax smooth muscle to cause vasodilation reflexively increase ANS tone and are included here for the sake of a complete discussion of antihypertensive drugs.¹³⁴ These are discussed with emphasis on perioperative use.

Hydralazine. Hydralazine is the most commonly used vasodilator and can be given by the im, iv, and oral routes. It relaxes smooth muscle tone directly, without interacting with adrenergic or cholinergic receptors. The mechanism of action is unknown. It is most potent in coronary, splanchnic, renal, and cerebral vessels, causing increased blood flow in each of these organs. The decrease in cardiac afterload is beneficial, but, unfortunately, there is usually a concomitant reflex tachycardia that may be severe. It is commonly combined with a β blocker such as propranolol. It may also cause fluid retention and is usually given chronically with a diuretic.²⁹² Hydralazine is metabolized by hepatic acetylation, and oral bioavailability may be low owing to first-pass metabolism. The elimination half-life is about 4 hours, but the pharmacologic half-life is much longer as a result of avid binding of the drug to smooth muscle. The effective half-life is approximately 100 hours.³⁶⁸ Side-effects include a lupus-like syndrome, drug fever, skin rash, pancytopenia, and peripheral neuropathy. The iv dose we recommend for perioperative use is 5–10 mg in an iv bolus every 15–20 minutes until blood pressure control is achieved. It may also be given 10–40 mg im, but the response is slower.

Sodium Nitroprusside. Sodium nitroprusside is an extremely potent vasodilator that is available only for iv administration. It acts directly on smooth muscle, causing both arterial and venous dilation.^{134,369} The mechanism of action is not entirely clear but appears to involve binding to a receptor on the surface of the myocyte, followed by activation of an intracellular vasodilator intermediate. The action of sodium nitroprusside on both venous and arterial sides of the circulation causes decreases in cardiac preload as well as afterload. This results in decreased cardiac work; however, it has been suggested that sodium nitroprusside may further compromise

ischemic myocardium in the presence of occlusive coronary artery disease by shunting blood away from the ischemic zone.³⁷⁰

Sodium nitroprusside is useful during the perioperative period. It lowers blood pressure within 1–2 minutes, with the effect dissipating within 2 minutes after infusion is stopped. It is extremely potent and should be administered through a central venous line by infusion pump while continuously monitoring arterial pressure. The starting dose is $0.25\text{--}0.5\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. It can be increased slowly as needed to control blood pressure, but chances for toxicity are greater if the dose of $10\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ is exceeded. The dose required for steady-state-induced hypotension is variable.

Chemically, sodium nitroprusside consists of a ferrous iron atom bound with five cyanide molecules and one nitric group. The ferrous iron reacts with sulfhydryl groups in red blood cells and releases cyanide.³⁷¹ Cyanide is reduced to thiocyanate in the liver and excreted in the urine. The half-life of thiocyanate is 4 days, and it accumulates in the presence of renal failure.³⁷² There is no evidence, however, that pre-existing hepatic or renal failure increases the likelihood of cyanide toxicity. Administration of high doses of sodium nitroprusside can result in cyanide toxicity. The cyanide molecule binds to cytochrome oxidase, interfering with electron transport and causing cellular hypoxia. This can be recognized by increasing tolerance to the drug, elevated mixed venous $P_{a_{O_2}}$, and metabolic acidosis. The treatment of cyanide toxicity consists of (1) administration of amyl nitrate (by inhalation or directly into the anesthesia circuit), (2) infusion of sodium nitrite $5\ \text{mg} \cdot \text{kg}^{-1}$ over 4–5 minutes, and (3) administration of sodium thiosulfate $150\ \text{mg} \cdot \text{kg}^{-1}$ in 50 ml water over 15 minutes.

The hypotensive effects of sodium nitroprusside may be potentiated by inhalation anesthetics and blood loss; therefore, close perioperative monitoring is essential. It is commonly used to induce hypotension for decreasing blood loss in patients predisposed to major hemorrhage. Administration of sodium nitroprusside causes a reflex increase in sympathetic tone and renin release.³⁷³ Drugs that blunt these reflexes markedly enhance its effects. Preoperative treatment with propranolol or captopril decreases the amount of sodium nitroprusside required for producing hypotension and thus decreases the potential for toxicity.^{374,375}

Glyceril Trinitrate. Glyceril trinitrate, or nitroglycerin, is a venodilator used to treat myocardial ischemia. Its predominant action is on venules, causing increased venous capacitance and decreased cardiac preload. Effects on the arterial side are minimal except at very high doses. Upon iv administration, effects can be seen within 2 minutes, and they usually resolve within 5 minutes of discontinuing the drug. Side-effects are minimal, and there is no potential for cyanide toxicity as with nitroprusside. Use of nitroglycerin for control of perioperative hypertension has been reported,³⁷⁶ but because of its relatively weak arteriolar action it is not as useful as other drugs as an antihypertensive agent. In obstetric patients with pre-eclampsia, however, it may be chosen over nitroprusside to circumvent potential cyanide toxicity to the fetus.³⁷⁷

Diazoxide. Diazoxide is a direct-acting vasodilator that may be given iv and is useful in hypertensive emergencies. It has a greater effect on resistance than capacitance vessels, thus decreasing cardiac afterload with little effect on preload. It also causes fluid retention and induces a reflex sympathetic response.²⁹² The hypotensive effect is potentiated by diuretics, sympatholytics, and hypovolemia. Diazoxide is usually administered as an iv bolus of 300 mg for a 70-kg adult. It is 90% bound to serum albumin; therefore, a substantial portion of the initial bolus may not reach the site of action. Rapid boluses (30 seconds) of 100 mg every 5 minutes are often recommended as an alternative to allow more free drug to reach the arterioles.²⁹² The hypotensive effect is usually obtained in 5–10 minutes and lasts 5–12 hours.

Calcium Entry Inhibitors

The calcium entry blockers verapamil, nifedipine, and nitrendipine may also be useful for treating hypertension in the perioperative period^{378,379} (see [Adrenergic Antagonists: Calcium Channel Blockers](#)).

Treatment of Postoperative Hypertension

The wide variety of antihypertensive agents discussed previously makes the treatment of hypertension in the recovery room easier because we can now choose from among multiple routes of administration and variable onsets and durations of action of the different agents.^{380,381} However, treatment may become confusing unless the basic pharmacology of each drug is understood. Those drugs available for only oral administration are not routinely used because of unreliable gastrointestinal function during this period. The etiology of postoperative hypertension in each case should be considered. A determination should be made as to whether this requires emergency therapy or is just urgent. Pain should be eliminated by assurance of adequate analgesia prior to therapy with antihypertensive agents. Also, because of the complex pathophysiology of hypertension, a thorough knowledge of each patient and his or her condition is mandatory in choosing a treatment regimen. The medications required for preoperative control may provide the most information in determining what will be necessary postoperatively. In particular, the use of drugs that may have an associated withdrawal syndrome, such as clonidine or β blockers, should be noted as well as if they were withheld prior to surgery. The volume status of the patient is also important. Fluid overload may require diuretic therapy. Volume depletion or hemorrhagemay predispose to severe hypotension in response to routine doses of sympatholytics or vasodilators.

For severe elevations of blood pressure that require immediate treatment, sodium nitroprusside is the drug of choice. Diazoxide and nifedipine (sublingual) are also useful but may take 5–10 minutes to work. Intravenous nicardipine can be given and effective before a sodium nitroprusside infusion can be prepared. Labetalol, metoprolol, and esmolol may also be used intravenously. Esmolol has the advantage of being rapidly titratable.³⁸² α -Methyldopa may be used intravenously but takes much longer to work than clonidine. Clonidine can be given per rectum and begins to act in 10–20 minutes.³⁶¹ If conditions permit, it is helpful to use the drugs the patient was taking preoperatively to ease the transition in the postoperative period. Caution must be exercised if the hypertension is the result of excessive exogenous catecholamines, pheochromocytoma, or thyrotoxicosis. α Blockade should be started before β blockade. The hypertension may, in fact, worsen if β receptors are blocked first, leaving the α receptors unopposed.

*Uptake 3 is used as a clinical term to describe uptake of exogenous drug administration.

[Summary](#)
[Chapter References](#)

The concept of intravenous (iv) anesthesia has evolved from primarily induction of anesthesia to that of total iv anesthesia (TIVA). This change has been spurred by the development of rapid, short-acting iv hypnotic, analgesic, and muscle relaxant drugs; by pharmacokinetic and pharmacodynamic-based “closed-loop” infusion delivery systems; and by the development of the electroencephalogram (EEG) bispectral index (BIS) monitor, which measures the hypnotic component of the anesthetic state. This chapter focuses on the pharmacologic properties and clinical uses of the currently available nonopioid iv anesthetics.

Since its introduction into clinical practice in 1934, thiopental has become the “gold standard” of iv anesthetics against which all newer drugs must be compared. Many different hypnotic drugs are currently available for use during iv anesthesia (Fig. 13-1). However, the “ideal” iv anesthetic has not yet been developed. The most important physical and pharmacologic properties that an iv anesthetic should possess include the following:

Figure 13-1. Chemical structures of currently available nonopioid iv anesthetics.

1. Drug compatibility and stability in solution
2. Lack of pain on injection, venoiritation, or tissue damage from extravasation
3. Low potential to release histamine or precipitate hypersensitivity reactions
4. Rapid and smooth onset of action without excitatory activity
5. Rapid metabolism to pharmacologically inactive metabolites
6. A steep dose–response relationship that enhances titratability and minimizes accumulation
7. Lack of acute cardiovascular and respiratory depression
8. Decreases in cerebral metabolism and intracranial pressure
9. Rapid and smooth return of consciousness and cognitive skills
10. Absence of postoperative nausea and vomiting, amnesia, psychomimetic reactions, dizziness, headache, or prolonged sedation (“hangover”)

Despite thiopental's proven clinical usefulness, safety, and widespread acceptance, it is far from the “ideal” iv anesthetic. Many of the sedative-hypnotic drugs that have been introduced into clinical practice over the last few decades have proved extremely valuable in specific clinical situations. These newer compounds combine many of the characteristics of the ideal iv anesthetic but fail in aspects where other drugs succeed. For some of these sedative-hypnotics, disadvantages have led to restricted indications (e.g., ketamine, etomidate) or withdrawal from clinical use (e.g., althesin, propanidid, eltanolone). Because the desired pharmacologic properties are not equally important in every clinical situation, the anesthesiologist must make the choice that best fits the needs of the individual patient and the operative procedure. Not surprisingly, the search for better iv sedative-hypnotics continues.

GENERAL PHARMACOLOGY OF INTRAVENOUS HYPNOTICS

Mechanism of Action

A widely accepted theory of anesthetic action is that both iv and inhalational anesthetics exert their primary sedative and hypnotic effects through an interaction with the inhibitory γ -aminobutyric acid (GABA) neurotransmitter system.¹ GABA is the principal inhibitory neurotransmitter within the central nervous system (CNS). The GABA and adrenergic neurotransmitter systems counterbalance the action of excitatory neurotransmitters. The GABA type A ($GABA_A$) receptor is a receptor complex consisting of up to five glycoprotein subunits. When the $GABA_A$ receptor is activated, transmembrane chloride conductance increases, resulting in hyperpolarization of the postsynaptic cell membrane and functional inhibition of the postsynaptic neuron. Sedative-hypnotic drugs interact with different components of the GABA receptor complex (Fig. 13-2). However, the allosteric (structural) requirements for activation of the receptor are different for iv and volatile anesthetics.²

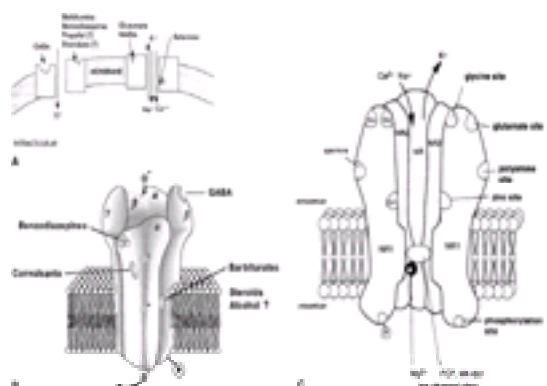

Figure 13-2.(A) A model depicting the postsynaptic site of GABA and glutamate within the CNS. GABA decreases the excitability of neurons by its action at the GABA_A receptor complex. When GABA occupies the binding site of this complex, it allows inward flux of chloride ion, resulting in hyperpolarization of the cell and subsequent resistance of the neuron to stimulation by excitatory transmitters. Barbiturates, benzodiazepines, propofol, and etomidate decrease neuronal excitability by enhancing the effect of GABA at this complex, facilitating this inhibitory effect on the postsynaptic cell. Glutamate and its analog *N*-methyl-D-aspartate (NMDA) are excitatory amino acids. When glutamate occupies the binding site on the NMDA subtype of the glutamate receptor, the channel opens and allows Na⁺, K⁺, and Ca²⁺ to enter or leave the cell. Flux of these ions leads to depolarization of the postsynaptic neuron and initiation of an action potential and activation of other pathways. Ketamine blocks this open channel and prevents further ion flux, thus inhibiting the excitatory response to glutamate. Benzodiazepines bind to specific receptor sites that are part of the GABA_A receptor complex. The binding of benzodiazepines to their receptor site increases the efficiency of the coupling between the GABA receptor and the chloride ion channel. The degree of modulation of the GABA-receptor function is limited, which explains the “ceiling effect” produced by benzodiazepines with respect to CNS depression. The CNS properties of benzodiazepines (e.g., hypnosis, sedation, anxiolysis, anticonvulsant effects) are presumed to be associated with the stimulation of different receptor subtypes and/or concentration-dependent receptor occupancy. It has been suggested that a benzodiazepine receptor occupancy of 20% provides anxiolysis, while 30–50% receptor occupancy is associated with sedation and >60% receptor occupancy is required for hypnosis (unconsciousness).

The interaction of barbiturates (and propofol) with specific membrane structures appears to decrease the rate of dissociation of GABA from its receptor, thereby increasing the duration of the GABA-activated opening of the chloride ion channel (Fig. 13-2). Barbiturates can also mimic the action of GABA by directly activating the chloride channels. Etomidate augments GABA-gated chloride currents (*i.e.*, indirect modulation) and, at higher concentrations, evokes chloride currents in the absence of GABA (*i.e.*, direct activation). Although the mechanism of action of propofol is similar to that of the barbiturates (*i.e.*, enhancing the activity of the GABA-activated chloride channel), it also possesses ion channel blocking effects in cerebral cortex tissue and nicotinic acetylcholine receptors, as well as an inhibitory effect on lysophosphatidate signaling in lipid mediator receptors.³

Ketamine produces a functional dissociation between the thalamocortical and limbic systems, a state that has been termed “dissociative” anesthesia. Ketamine depresses neuronal function in the cerebral cortex and thalamus, while simultaneously activating the limbic system. Ketamine's effect on the medial medullary reticular formation may be involved in the affective component of its nociceptive activity. The CNS effects of ketamine appear to be primarily related to its antagonistic activity at the *N*-methyl-D-aspartate (NMDA) receptor (Fig. 13-2). Unlike the other iv anesthetics, ketamine does not interact with GABA receptors; however, it binds to non-NMDA glutamate receptors and to nicotinic, muscarinic, monoaminergic, and opioid receptors. In addition, it also inhibits neuronal sodium channels (accounting for a modest local anesthetic action) and calcium channels (causing cerebral vasodilatation).

Pharmacokinetics and Metabolism

An understanding of basic pharmacokinetic principles is integral to the understanding the pharmacologic actions and interactions of iv anesthetic and adjunctive drugs, and will allow the anesthesiologist to develop more optimal dosing strategies when using iv techniques. Although lipid solubility facilitates diffusion of iv anesthetics across cellular membranes including the blood–brain barrier, only the nonionized form is able to readily cross neuronal membranes. The ratio of the nonionized-to-ionized fraction depends on the pK_a of the drug and the pH of the body fluids.

The rapid onset of the CNS effect of most iv anesthetics can be explained by their high lipid solubility and the relatively high proportion of the cardiac output (20%) perfusing the brain. However, a substantial degree of hysteresis may exist between the blood concentration of the hypnotic drug and its onset of action on the CNS. The hysteresis is related in part to diffusion of these drugs into brain tissue and nonspecific CNS receptor binding. However, the number of CNS binding sites is usually saturable, and only a small fraction of the available binding sites needs to be occupied to produce clinical effects. Although the total amount of drug in the blood is available for diffusion, the diffusion rate will be more limited for iv anesthetics with a high degree of plasma protein binding (>90%) because only the “free” unbound drug can diffuse across membranes and exert central effects. When several drugs compete for the same binding sites, or when the protein concentration in the blood is decreased by pre-existing disease (e.g., hepatic failure), a higher fraction of the unbound drug will be available to exert effects on the CNS. Since only unbound drug is available for uptake and metabolism in the liver, highly protein-bound drugs may have a lower rate of hepatic metabolism as a result of their decreased hepatic extraction ratio (*i.e.*, the fraction of the hepatic blood flow that is cleared of the drug).

The pharmacokinetics of iv hypnotics are characterized by rapid distribution and subsequent redistribution into several hypothetical compartments, followed by elimination (Table 13-1). The initial pharmacologic effects are related to the activity of the drug in the central compartment. The primary mechanism for terminating the central effects of iv anesthetics administered for induction of anesthesia is redistribution from the central highly perfused compartment (brain) to the larger but less well perfused “peripheral” compartments (muscle, fat). Even for drugs with a high hepatic extraction ratio, elimination does not usually play a major role in terminating the drug's CNS effects because elimination of the drug can only occur from the central compartment. The rate of elimination from the central compartment, the amount of drug present in the peripheral compartments, and the rate of redistribution from the peripheral compartments “back” into the central compartment determine the time necessary to eliminate the drug from the body.

| Drug Name | Distribution Half-life (min) | Brain Binding (%) | Distribution Volume at Steady State (L/kg) | Clearance (ml/kg·min) | Elimination Half-life (hr) |
|--------------|------------------------------|-------------------|--|-----------------------|----------------------------|
| Thiopental | 3-4 | 85 | 15 | 54 | 11 |
| Methohexital | 5-6 | 85 | 22 | 71 | 8 |
| Propofol | 3-4 | 88 | 2.80 | 38-50 | 4-20 |
| Midazolam | 1-5 | 84 | 13-17 | 64-80 | 15-24 |
| Oxazepam | 10-25 | 88 | 67-107 | 62-105 | 30-50 |
| Lorazepam | 3-10 | 88 | 68-115 | 68-118 | 10-22 |
| Etomidate | 3-4 | 75 | 15-45 | 38-25 | 14-13 |
| Ketamine | 11-18 | 12 | 25-35 | 12-17 | 3-4 |

Table 13-1. PHARMACOKINETIC VALUES FOR THE CURRENTLY AVAILABLE INTRAVENOUS SEDATIVE-HYPNOTIC DRUGS

Most iv anesthetic agents are eliminated *via* hepatic metabolism followed by renal excretion of more water-soluble metabolites. Some metabolites have pharmacologic activity and can produce prolonged drug effects (e.g., oxazepam, desmethyldiazepam, norketamine). Moreover, there is considerable interpatient variability in the clearance rates for commonly used iv anesthetic drugs. The elimination clearance is the distribution volume cleared of drug over time and is a measure of the efficacy of the elimination process. The slow elimination of some anesthetics is due in part to their high degree of protein binding, which reduces their hepatic extraction ratio. Other drugs may have a high hepatic extraction ratio and elimination clearance despite extensive plasma protein binding (e.g., propofol), indicating that protein binding is not always a rate-limiting factor.

For most drugs, the hepatic enzyme systems are not saturated at clinically relevant drug concentrations, and the rate of drug elimination will decrease as an exponential function of the drug's plasma concentration (first-order kinetics). However, when high steady-state plasma concentrations are achieved with prolonged infusions, hepatic enzyme systems can become saturated and the elimination rate becomes independent of the drug concentration (zero-order kinetics). The elimination half-life (t_{1/2}b) is the time required for the anesthetic concentration to decrease by 50% during the terminal phase of the plasma decay curve. The t_{1/2}b is dependent on the volume to be cleared (the distribution volume) and the efficiency of the metabolic clearance system. Because their volumes of distribution are similar, the wide variation in elimination half-life values for the iv anesthetics is a reflection of differences in their clearance values.

When a drug infusion is administered without a loading dose, 3–5 times the t_{1/2}b value may be required to reach a “steady-state” plasma concentration. The

steady-state concentration obtained during an anesthetic infusion depends on the rate of drug administration and its clearance rate. When an infusion is discontinued, the rate at which the plasma concentration decreases is largely dependent on the clearance rate (as reflected by the terminal elimination half-life value). For drugs with shorter elimination half-lives, plasma concentration will decrease at a rate that allows for a more rapid recovery (e.g., propofol). Drugs with long elimination half-life values (e.g., thiopental and diazepam) are usually only administered by continuous iv infusion when the medical condition requires long-term treatment [elevated intracranial pressure (ICP), prolonged sedation in the ICU, or anticonvulsive treatment].

Careful titration of an anesthetic drug to achieve the desired clinical effect is necessary to avoid drug accumulation and the resultant prolonged CNS effects after the infusion has been discontinued. Although the value of the terminal half-life indicates how fast a drug is eliminated from the body, a more useful indicator of the acceptability of an hypnotic infusion for maintenance of anesthesia or sedation is the context-sensitive half-time, a value derived from computer simulations of drug infusions.⁴ The context-sensitive half-time is defined as the time necessary for the effect-compartment concentration to decrease by 50% in relation to the duration of the infusion. The context-sensitive half-time becomes particularly important in determining recovery after variable-length infusions of sedative-hypnotic drugs. Drugs (e.g., propofol) may have a relatively short context-sensitive half-time despite the fact that a large amount of drug remains present in the "deep" (less well perfused) compartment. The slow return of the anesthetic from the deep compartment contributes little to the concentration of drug in the central compartment from which it is rapidly cleared. Therefore, the concentration in the central compartment rapidly declines below the hypnotic threshold after discontinuation of the infusion, contributing to short emergence times despite the fact that a substantial quantity of anesthetic drug may remain in the body.

Marked interpatient variability exists in the pharmacokinetics of iv sedative-hypnotic drugs. Factors that can influence anesthetic drug disposition include the degree of protein binding, the efficiency of hepatic and renal elimination processes, physiologic changes with aging, pre-existing disease states, the operative site, body temperature, and drug interactions (e.g., co-administration of volatile anesthetics). For example, with increasing age, lean body mass, and total body water decrease, resulting in an increase in the steady-state volume of distribution of most iv anesthetics. The increased distribution volume and decreased hepatic clearance lead to a prolongation of their $t_{1/2}$ values. Moreover, a decrease of the volume of the central compartment may result in higher initial drug concentrations, and can at least partially explain the decreased induction requirement in the elderly. Additionally, the slower redistribution from the vessel-rich tissues to intermediate compartments (muscles) also contributes to the age-related decrease in the induction dose requirements.⁵ Although prolongation of the elimination half-time does not provide an explanation for the decreased induction dose requirement, it is responsible for producing higher steady-state plasma concentrations at any given infusion rate.

The hepatic clearance of iv anesthetics with a high (etomidate, propofol, ketamine) or intermediate (methohexital, midazolam) extraction ratio is largely dependent on hepatic blood flow, with most of the drug being removed from the blood as it flows through the liver (so-called perfusion-limited clearance). The elimination rate of drugs with low hepatic extraction ratios (thiopental, diazepam, lorazepam) is dependent upon the enzymatic activity of the liver and is less dependent of hepatic blood flow (so-called capacity-limited clearance). Hepatic blood flow decreases during upper abdominal surgery, and as a result, higher blood levels of drugs with perfusion-limited clearance are achieved at any given infusion rate. With aging, a decreased cardiac output and a redistribution of blood flow can partly explain the lower clearance rate for drugs with perfusion-limited clearance. While concomitant administration of volatile anesthetics (which are known to decrease liver blood flow) has little influence on the elimination of thiopental, they can decrease the clearance of etomidate, ketamine, methohexital, and propofol. Other factors that decrease hepatic blood flow include hypocapnia, congestive heart failure, intravascular volume depletion, circulatory collapse, β -adrenergic blockade, and norepinephrine administration.

Hepatic disease can influence the pharmacokinetics of drugs by the following: (1) altering the plasma-protein content and changing the degree of protein binding, (2) decreasing hepatic blood flow and producing intra-hepatic shunting, and (3) depressing the metabolic enzymatic activity of the liver. Therefore, the influence of hepatic disease on the pharmacokinetics and dynamics of iv anesthetics is difficult to predict. Renal disease can also alter the concentration of plasma and tissue proteins, as well as the degree of protein binding, thereby producing changes in free drug concentrations. Because iv anesthetic agents are primarily metabolized by the liver, renal insufficiency has little influence on their rate of metabolic inactivation or elimination of the primary compound.

Pharmacodynamics

The principal pharmacologic effect of iv anesthetics is to produce sedation and hypnosis as a result of dose-dependent CNS depression. However, all sedative-hypnotics also directly or indirectly affect other major organ systems. The relationship between the dose of a sedative-hypnotic and its CNS effects can be defined by dose-response curves. Although most iv anesthetics are characterized by steep dose-response curves, they are not always parallel (Fig. 13-3). The characteristics of a dose-response curve can only be interpreted in relation to the specific response for which it was constructed.

Figure 13-3. Dose-response relationships for sedation with midazolam (l) and diazepam (o). The level of sedation (2 = awake and alert to 6 = asleep and unarousable) was assessed 5 min after bolus doses of midazolam (0.05, 0.1, or 0.15 mg · kg⁻¹) or diazepam (0.1, 0.2, or 0.3 mg · kg⁻¹). Values represent mean values ± SEM. (Reprinted with permission from White PF, Vascones LO, Mathes SA, Way WL, Wender LA: Comparison of midazolam and diazepam for sedation during plastic surgery. *J Plast Reconstruct Surg* 81:703, 1988.)

When steady-state plasma concentrations are achieved, it can be presumed that the plasma concentration is in equilibrium with the effect-site concentration. Under these circumstances, it is possible to describe the relationship between drug and effect using a concentration-effect curve (Fig. 13-4). Because of the pharmacodynamic variability that exists among individuals, the plasma drug concentration necessary to obtain a particular effect is often described in terms of an effective concentration range, the so-called therapeutic window. Efficacy of an iv anesthetic relates to the maximum effect that can be achieved with respect to some measure of CNS function. Depending on the drug effect under consideration, the efficacy of sedative-hypnotics may appear to be less than 100%. For example, it is virtually impossible to produce a burst-suppressive EEG pattern with a benzodiazepine. Potency, on the other hand, relates to the quantity of drug necessary to obtain the maximum CNS effect. The relative potency of sedative-hypnotics also varies depending on the end point chosen. In the presence of an antagonist drug (e.g., flumazenil), the maximal response that can be obtained with a benzodiazepine agonist is reduced due to competition for the same CNS receptor binding sites.

Figure 13-4. The concentration of thiopental versus time and spectral edge in an elderly patient (top) and in a younger patient (bottom). Solid horizontal bars represent the length of thiopental infusion. Filled circles represent the measured thiopental concentration (linear scale), and the solid line next to them represents the fitted data from the pharmacokinetic model. The axis for spectral edge has been inverted for visual clarity. The influence of sedative-hypnotics on cerebral metabolism, cerebral hemodynamics, and ICP is of particular importance during neuroanesthesia. In patients with reduced cerebral compliance, a small increase in cerebral blood volume can cause a life-threatening increase in ICP. Most sedative-hypnotic drugs cause a proportional reduction in cerebral metabolism (CMRO₂) and cerebral blood flow (CBF), resulting in a decrease in ICP. Although a decrease in CMRO₂ probably provides only a modest degree of protection against CNS ischemia or hypoxia, some hypnotics appear to possess cerebroprotective potential. Explanations for the alleged neuroprotective effects of these compounds include a biochemical role as free-radical scavengers and membrane stabilizers (barbiturates and propofol), or NMDA-receptor antagonists (ketamine). With the exception of ketamine, all sedative-hypnotics also lower intraocular pressure (IOP). The changes in IOP generally reflect the effects of the iv agent on systemic arterial pressure and intracranial hemodynamics. However, none of the available sedative-hypnotic drugs protects against the transient increase in IOP that occurs with laryngoscopy and intubation.

Most iv hypnotics have similar electroencephalographic (EEG) effects. Activation of high-frequency EEG activity (15–30 Hz) is characteristic of low concentrations (so-called sedative doses) of iv anesthetics. At higher concentrations, an increase in the relative contribution of the lower-frequency higher-amplitude waves is observed. At high concentrations, a burst-suppressive pattern develops with an increase in the isoelectric periods. Most sedative-hypnotic drugs have been reported to cause occasional EEG seizure-like activity. Interestingly, the same drugs also possess anticonvulsant properties.⁶ When considering possible epileptogenic properties of CNS depressant drugs, it is important to differentiate between true epileptogenic activity and myoclonic-like phenomena. Epileptic activity refers to a sudden alteration in CNS activity resulting from a high-voltage electrical discharge at either cortical or subcortical sites, with subsequent spreading to the thalamic and brainstem centers. Myoclonus can have an epileptic or nonepileptic origin, depending on the EEG findings. Myoclonic activity is generally considered to be the result of an imbalance between excitatory and inhibitory subcortical centers, produced by an unequal degree of suppression of these brain centers by low concentrations of hypnotic drugs.

Although some induction drugs can increase airway sensitivity, coughing and airway irritation (bronchospasm) are usually due to manipulation of the airway during "light" levels of anesthesia rather than to a direct drug effect. With the exception of ketamine (and to a lesser extent etomidate), iv anesthetics produce dose-dependent respiratory depression which is enhanced in patients with chronic obstructive pulmonary disease. The respiratory depression is characterized by a decrease in tidal volume and minute ventilation, as well as a transient rightward shift in the CO₂ response curve. Following the rapid injection of a large bolus dose of an iv anesthetic, transient apnea lasting 30–90 sec is usually produced. Ketamine causes minimal respiratory depression when administered in the usual induction doses, while etomidate is associated with less respiratory depressant effects than the barbiturate compounds or propofol.

Many different factors contribute to the hemodynamic changes associated with iv induction of anesthesia, including the patient's pre-existing cardiovascular and fluid status, resting sympathetic nervous system tone, chronic cardiovascular drugs, preanesthetic medication, the speed of drug injection, and the onset of unconsciousness. In addition, cardiovascular changes can be attributed to the direct pharmacologic actions of anesthetic and analgesic drugs on the heart and peripheral vasculature. Intravenous anesthetics can depress the CNS and peripheral nervous system responses, blunt the compensatory baroreceptor reflex mechanisms, produce direct myocardial depression, and lower peripheral vascular resistance (and/or dilate venous capacitance vessels), thereby decreasing venous return. Profound hemodynamic effects occur at induction in the presence of hypovolemia because a higher than expected drug concentration is achieved in the central compartment. Not surprisingly, the acute cardiocirculatory depressant effects of all iv anesthetics are accentuated in the elderly, as well as in the presence of pre-existing cardiovascular disease.

The effects of intravenous anesthetics on neuroendocrine function are influenced by the surgical stimuli. For example, although iv anesthetics are alleged to increase antidiuretic hormone (vasopressin) secretion, it is probably secondary to the surgical stress. Increases in this stress hormone can result in increased peripheral vascular resistance and a reduction of urine output. Similarly, glucose tolerance appears to be decreased by surgical stress, resulting in hyperglycemia. Most iv sedative-hypnotic drugs lack intrinsic analgesic activity. In fact, thiopental has been alleged to possess so-called antianalgesic activity (*i.e.*, it appears to lower the pain threshold, but this is unproven). On the other hand, ketamine has analgesic-like activity.

Hypersensitivity (Allergic) Reactions

Allergic reactions to iv anesthetics and/or their solubilizing agents can be severe and even life-threatening. Intravenous drug administration bypasses the normal "protective barriers" against entrance of foreign molecules into the body. With the exception of etomidate, all iv induction agents have been alleged to cause some histamine release. However, the incidence of severe anaphylactic reactions is low with the currently available induction agents. The high frequency of allergic reactions to the cremophor EL-containing formulations led to the early withdrawal of several iv anesthetics containing this solubilizing agent (*e.g.*, propofol EL, propanidol, Althesin). The possible mechanisms for immunologic reactions include the following: (1) direct action on mast cells, (2) classic complement activation after previous exposure and antibody formation, (3) complement activation through the alternative pathway without previous antigen exposure, (4) antigen-antibody reactions, and (5) the "mixed type" of anaphylactoid reactions.

Following thiopental administration, the plasma level of histamine increases to ~350% of normal and decreases to the normal range after ~10 min. A transient urticarial skin rash can be associated with the use of barbiturates. Although severe anaphylactic reactions are extremely uncommon, profound hypotension attributed to non-immunologically mediated histamine release has been reported with thiopental use. The incidence of allergic reactions to the emulsion formulation of propofol, ketamine, and benzodiazepines also appears to be extremely low. Although anaphylactic reactions to etomidate have been reported, it does not appear to release histamine and is considered to be the most "immunologically safe" iv anesthetic. While propofol does not normally trigger histamine release, life-threatening anaphylactoid reactions have been reported most often in patients with a previous history of drug allergies. Barbiturates may precipitate episodes of acute intermittent porphyria (AIP) and their use is contraindicated in patients who are predisposed to AIP. Although benzodiazepines, ketamine, and etomidate are reported to be safe in humans, these drugs have been shown to be porphyrinogenic in animal models. Propofol has been used with no evidence of porphyrinogenicity in AIP-susceptible patients.

PHARMACOLOGY OF INTRAVENOUS SEDATIVE-HYPNOTICS

Barbiturates

The most commonly used barbiturates are thiopental [5-ethyl-5-(1-methylbutyl)-2-thiobarbituric acid], methohexital [1-methyl-5-allyl-5-(1-methyl-2-pentynyl)barbituric acid], and thiamylal [5-allyl-5-(1-methylbutyl)-2-thiobarbituric acid]. Thiopental (Pentothal) and thiamylal (Surital) are thiobarbiturates, while methohexital (Brevital) is an oxybarbiturate. Thiamylal is slightly more potent than thiopental but has a similar pharmacologic profile. Although the L-isomers of thiopental and thiamylal are twice as potent as the D-isomers, both hypnotics are commercially available as racemic mixtures. Because methohexital has two asymmetric centers, it has four stereoisomers. The b-L-isomer is 4–5 times more potent than the a-L-isomer, but it produces excessive motor responses. Therefore, methohexital is marketed as the racemic mixture of the two a-isomers.

All three barbiturates are available as sodium salts and must be dissolved in isotonic sodium chloride (0.9%) or water to prepare solutions of 2.5% thiopental, 1–2% methohexital, and 2% thiamylal. If refrigerated, solutions of the thiobarbiturates are stable for up to 2 weeks. Solutions of methohexital are stable for up to 6 weeks. When barbiturates are added to Ringer's lactate or an acidic solution containing other water-soluble drugs, precipitation will occur and can occlude the iv catheter. Although the typical solution of thiopental (2.5%) is highly alkaline (pH >19) and can be irritating to the tissues if injected extravascularly, it does not cause pain on injection and veno-irritation is rare. In contrast, a 1% methohexital solution frequently causes discomfort when injected into small veins. Intra-arterial injection of thiobarbiturates is a serious complication as crystals can form in the arterioles and capillaries, causing intense vasoconstriction, thrombosis, and even tissue necrosis. Accidental intra-arterial injections should be treated promptly with intra-arterial administration of papaverine and lidocaine (or procaine), as well as a regional anesthesia-induced sympathectomy (stellate ganglion block, brachial plexus block) and heparinization.

Thiopental is metabolized in the liver to hydroxythiopental and the carboxylic acid derivative, which are more water-soluble and have little CNS activity. When high doses of thiopental are administered, a desulfuration reaction can occur with the production of pentobarbital, which has long-lasting CNS-depressant activity. The low elimination clearance of thiopental (3.4 ml.kg⁻¹.min⁻¹) contributes to a long elimination half-life (t_{1/2b} of 12 h). Pre-existing hepatic and renal disease results in decreased plasma protein binding, thereby increasing the free fraction of thiopental and enhancing its CNS and cardiovascular-depressant properties. During prolonged continuous administration of thiopental, the concentration in the tissues approaches the concentration in the central compartment, with termination of its CNS effects becoming solely dependent on elimination by nonlinear hepatic metabolism. Methohexital is metabolized in the liver to inactive hydroxy derivatives. The clearance of methohexital (11 ml.kg⁻¹.min⁻¹) is higher and more dependent on hepatic blood flow than thiopental, resulting in a shorter elimination half-life (t_{1/2b} 3–6 h).

The usual induction dose of thiopental is 3–5 mg · kg⁻¹ in adults, 5–6 mg · kg⁻¹ in children, and 6–8 mg · kg⁻¹ in infants. Because methohexital is approximately 2.7 times more potent than thiopental, a dose of 1.5 mg · kg⁻¹ is equivalent to 4 mg · kg⁻¹ of thiopental in adults. The dose of barbiturates necessary to induce anesthesia is reduced in premedicated patients, patients in early pregnancy (7–13 weeks' gestation) and those of more advanced ASA physical status (III or IV). Geriatric patients require a 30–40% reduction in the usual adult dose because of a decrease of the volume of the central compartment and slowed redistribution of thiopental from the vessel-rich tissues to lean muscle.⁵ When the calculation of the induction dose is based on the lean body mass rather than total body weight, dosage adjustments for age, sex, or obesity are not necessary. Thiopental infusion is seldom used to maintain anesthesia because of the long context-sensitive half-time and prolonged

recovery period. Plasma thiopental levels necessary to maintain a hypnotic state range between 10 and 20 mg·ml⁻¹. A typical infusion rate necessary to treat intracranial hypertension or intractable convulsions is 2–4 mg · kg⁻¹·h⁻¹. The plasma concentration of methohexital needed to maintain hypnosis during anesthesia ranges between 3 and 5 mg·ml⁻¹ and can be achieved with an infusion rate of 50–120 mg·kg⁻¹·min⁻¹.

Barbiturates produce a proportional decrease in CMRO₂ and CBF, thereby lowering ICP. The maximal decrease in CMRO₂ (55%) occurs when the EEG becomes isoelectric (burst-suppressive pattern). An isoelectric EEG can be maintained with a thiopental infusion rate of 4–6 mg · kg⁻¹·h⁻¹ (resulting in plasma concentrations of 30–50 mg·ml⁻¹). Because the decrease in systemic arterial pressure is usually less than the reduction in ICP, thiopental should improve cerebral perfusion and compliance. Therefore, thiopental is widely used to improve brain relaxation during neurosurgery and to improve cerebral perfusion pressure (CPP) after acute brain injury. Although barbiturate therapy is widely used to control ICP after brain injury, the results of outcome studies are no better than with other aggressive forms of cerebral antihypertensive therapy.

It has been suggested that barbiturates also possess “neuroprotective” properties secondary to their ability to decrease oxygen demand. Alternative explanations that have been suggested, including a reverse steal (“Robin Hood effect”) on CBF, free-radical scavenging, stabilization of liposomal membranes, as well as excitatory amino acid (EAA) receptor blockade. Based on evidence from experimental studies and a large randomized prospective multi-institutional study,⁷ it has been concluded that barbiturates have no place in the therapy following resuscitation of a cardiac arrest patient. In contrast, barbiturates are frequently used for cerebroprotection during incomplete brain ischemia (e.g., carotid endarterectomy, temporary occlusion of cerebral arteries, profound hypotension, cardiopulmonary bypass). By improving the brain’s tolerance of incomplete ischemia in patients undergoing open heart surgery with cardiopulmonary bypass, barbiturates are alleged to decrease the incidence of post-bypass neuropsychiatric disorders.⁸ However, during valvular open heart cardiac surgery, a protective effect of barbiturate loading could not be demonstrated.⁹ The routine use of barbiturates during cardiac surgery is not recommended because recent evidence would suggest that the use of moderate degrees of hypothermia (33–34 °C) may provide superior neuroprotection without prolonging the recovery phase.

Barbiturates cause predictable, dose-dependent EEG changes and possess potent anticonvulsant activity. Continuous infusions of thiopental have been used to control refractory status epilepticus. However, low doses of thiopental may induce spike wave activity in epileptic patients. Methohexital has well-established epileptogenic effects in patients with psychomotor epilepsy. Low-dose methohexital infusions are frequently used to activate cortical EEG seizure discharges in patients with temporal lobe epilepsy. Yet, the frequency of epileptiform EEG activity during induction of anesthesia with methohexital is significantly less than that which occurs during normal periods of sleep in epileptic patients, suggesting that even methohexital has some anticonvulsant activity.⁶ Methohexital frequently causes myoclonic-like muscle tremors and other signs of excitatory activity (hiccoughing).

Barbiturates cause dose-dependent respiratory depression.¹⁰ However, bronchospasm or laryngospasm following induction with thiopental is usually the result of airway manipulation in “lightly” anesthetized patients. Laryngeal reflexes appear to be more active after induction with thiopental than with propofol. The cardiovascular effects of thiopental and methohexital include decreases in cardiac output, systemic arterial pressure, and peripheral vascular resistance. The depressant effects of thiopental on cardiac output are primarily due to a decrease in venous return caused by peripheral pooling, as well as to a direct myocardial depressant effect, which assumes increasing importance in the presence of hypovolemia and myocardial disease.¹¹ An equipotent dose of methohexital produces somewhat less hypotension than thiopental due to a greater tachycardic response to the blood pressure-lowering effects of the drug. If the blood pressure remains stable, the myocardial oxygen demand–supply ratio remains normal despite the increase in heart rate because of a concurrent decrease in coronary vascular resistance.

Propofol

Propofol [2,6-diisopropylphenol], an alkylphenol compound, is virtually insoluble in aqueous solution. The initial cremophor EL formulation of propofol was withdrawn from clinical testing because of the high incidence of anaphylactic reactions. Subsequently, propofol (10 mg · ml⁻¹) has been reintroduced as an egg lecithin emulsion formulation (Diprivan), consisting of 10% soybean oil, 2.25% glycerol, and 1.2% egg phosphatide. Pain on injection occurs in 32–67% of patients when injected into small hand veins, but can be minimized by injection into larger veins and by prior administration of either 1% lidocaine or a potent opioid analgesic. Diluting the formulation with additional solvent (Intralipid) or changing the lipid carrier (Lipofundin) also reduced injection pain, probably due to a decrease in the concentration of free propofol in the aqueous phase of the emulsion. A new propofol formulation with sodium metabisulfite (instead of disodium edetate) as an antimicrobial, has recently been shown to be associated with less pain on injection. However, the presence of the metabisulfite has raised concerns regarding its use in sulfite-allergic patients. Of interest, a 2% formulation is available for long-term sedation to decrease the volume infused as well as the lipid load.

Propofol’s pharmacokinetics have been studied using single-bolus dosing and continuous infusions.¹² In studies using a two-compartment kinetic model, the initial distribution half-life is 2–8 min and the elimination half-life is 1–3 h. Using a three-compartment model the initial and slow distribution half-life values are 1–8 min and 30–70 min, respectively. The elimination half-life depends largely on the sampling time after discontinuing the administration of propofol and ranges from 2 to 24 h. This long elimination half-life is indicative of the existence of a poorly perfused compartment from which propofol slowly diffuses back into the central compartment. Propofol is rapidly cleared from the central compartment by hepatic metabolism and the context-sensitive half-life for propofol infusions up to 8 h is less than 40 min.⁴ Propofol is rapidly and extensively metabolized to inactive, water-soluble sulfate and glucuronic acid metabolites, which are eliminated by the kidneys. Propofol’s clearance rate (1.5–2.2 l·min⁻¹) exceeds hepatic blood flow, suggesting that an extrahepatic route of elimination (lungs) also contributes to its clearance. Nevertheless, changes in liver blood flow would be expected to produce marked alterations in propofol’s clearance rate. Surprisingly, few changes in propofol’s pharmacokinetics have been reported in the presence of hepatic or renal disease.

The induction dose of propofol in healthy adults is 1.5–2.5 mg · kg⁻¹, with blood levels of 2–6 mg·ml⁻¹, producing unconsciousness depending on the associated medication, the patient’s age and physical status, and the extent of the surgical stimulation.¹³ The recommended maintenance infusion rate of propofol varies between 100 and 200 mg·kg⁻¹·min⁻¹ for hypnosis and 25–75 mg·kg⁻¹·min⁻¹ for sedation. Awakening typically occurs at plasma propofol concentrations of 1–1.5 mg·ml⁻¹.¹⁴ Because a 50% decrease in the plasma propofol concentration is usually required for awakening, emergence following anesthesia is rapid, even following prolonged infusions. Analogous to the barbiturates, children require higher induction and maintenance doses of propofol on a milligram-per-kilogram basis as a result of their larger central distribution volume and higher clearance rate. Elderly and patients in poor health require lower induction and maintenance doses of propofol as a result of their smaller central distribution volume and decreased clearance rate. Although subhypnotic doses of propofol produce sedation and amnesia,¹⁴ awareness has been reported even at higher infusion rates when propofol is used as the sole anesthetic.¹⁵ Propofol often produces a subjective feeling of well-being and even euphoria,¹⁶ and may have abuse potential as a result of these effects.

Propofol decreases CMRO₂ and CBF, as well as ICP.¹⁷ However, when larger doses are administered, the marked depressant effect on systemic arterial pressure can significantly decrease CPP. Cerebrovascular autoregulation in response to changes in systemic arterial pressure and reactivity of the cerebral blood flow to changes in carbon dioxide tension are not affected by propofol. Evidence for a possible neuroprotective effect has been reported in *in vitro* preparations, and the use of propofol to produce EEG burst suppression has been proposed as a method for providing neuroprotection during aneurysm surgery. Its neuroprotective effect may at least partially be related to the antioxidant potential of propofol’s phenol ring structure, which may act as a free-radical scavenger, decreasing free-radical-induced lipid peroxidation. Although total iv anesthesia with propofol and an opioid analgesic is a safe and effective alternative to standard “balanced” techniques for maintenance of neuroanesthesia, concerns have been raised regarding the cost-effectiveness of this technique.

Propofol produces cortical EEG changes that are similar to those of thiopental. However, sedative doses of propofol increase b-wave activity analogous to the benzodiazepines. Induction of anesthesia with propofol is occasionally accompanied by excitatory motor activity (so-called nonepileptic myoclonia). In a study involving patients without a history of seizure disorders, excitatory movements following propofol were not associated with EEG seizure activity.¹⁸ Propofol appears to possess profound anticonvulsant properties.¹⁹ Propofol has been reported to decrease spike activity in patients with cortical electrodes implanted for resection of epileptogenic foci and has been used successfully to terminate status epilepticus. The duration of motor and EEG seizure activity following electroconvulsive therapy is shorter with propofol than with methohexital anesthesia. Propofol produces a decrease in the early components of somatosensory and motor-evoked potentials but does not influence the early components of the auditory-evoked potentials.

Propofol produces dose-dependent respiratory depression, with apnea occurring in 25–35% of patients after a typical induction dose. A maintenance infusion of propofol decreases tidal volume and increases respiratory rate. The ventilatory response to carbon dioxide and hypoxia is also significantly decreased by propofol.¹⁰ Propofol can produce bronchodilation in patients with chronic obstructive pulmonary disease and does not inhibit hypoxic pulmonary vasoconstriction.

Propofol’s cardiovascular depressant effects are generally considered to be more profound than those of thiopental.¹¹ Both direct myocardial depressant effects and decreased systemic vascular resistance have been implicated as important factors in producing cardiovascular depression. Direct myocardial depression and peripheral vasodilation are dose- and concentration-dependent. In addition to arterial vasodilation, propofol produces venodilation (due both to a reduction in sympathetic activity and to a direct effect on the vascular smooth muscle), which further contributes to its hypotensive effect. The relaxation of the vascular smooth muscle may be due to an effect on intracellular calcium mobilization or to an increase in the production of nitric oxide. Experiments in isolated myocardium suggest that the negative inotropic effect of propofol results from a decrease in intracellular calcium availability secondary to inhibition of trans-sarcolemmal calcium influx. Propofol alters the baroreflex mechanism, resulting in a smaller increase in heart rate for a given decrease in arterial pressure.²⁰ The smaller increase in heart rate with propofol may account for the larger decrease in arterial pressure than with an equipotent dose of thiopental. Recent research suggests that induction of anesthesia with propofol

attenuates desflurane-mediated sympathetic activation.²¹ Age enhances the cardiodepressant response to propofol and dosage adjustments are required in the elderly. Patients with limited cardiac reserve seem to tolerate the cardiac depression and systemic vasodilation produced by carefully titrated doses of propofol, and maintenance infusions are increasingly used during coronary artery surgery when early extubation is desired.

Propofol appears to possess antiemetic properties that contribute to a low incidence of emetic sequelae after propofol anesthesia. In fact, subanesthetic doses of propofol (10–20 mg) have also been successfully used to treat nausea and emesis in the early postoperative period.²² The postulated mechanisms include antidopaminergic activity, depressant effect on the chemoreceptor trigger zone and vagal nuclei, decreased release of glutamate and aspartate in the olfactory cortex, and reduction of serotonin concentrations in the area postrema. Interestingly, propofol also decreases the pruritus associated with spinal opioids, as well as with cholestatic liver disease.

Propofol does not trigger malignant hyperthermia (MH) and may be considered the induction agent of choice in MH-susceptible patients. The use of propofol infusions for sedation in the pediatric intensive care unit has been linked to several deaths following prolonged administration. Although clinical doses of propofol do not affect cortisol synthesis or the response to adrenocorticotropic hormone (ACTH) stimulation, propofol has been reported to inhibit phagocytosis and killing of bacteria *in vitro* and to reduce proliferative responses when added to lymphocytes from critically ill patients.²³ Because fat emulsions are known to support the growth of microorganisms, contamination can occur as a result of dilution or fractionated use.²⁴

Benzodiazepines

The benzodiazepines of primary interest to anesthesiologists are diazepam (Valium), lorazepam (Ativan), and midazolam (Versed), as well as the antagonist flumazenil (Romazicon). Diazepam and lorazepam are insoluble in water and their formulation contains propylene glycol, a tissue irritant that causes pain on injection and venous irritation. Diazepam is available in a lipid emulsion formulation (Diazemuls or Dizac), which does not cause pain or thrombophlebitis but is associated with a slightly lower bioavailability. Midazolam is a water-soluble benzodiazepine that is available in an acidified (pH 3.5) aqueous formulation that produces minimal local irritation after iv or im injection.²⁵ At physiologic pH, an intramolecular rearrangement changes the physicochemical properties of midazolam such that it becomes more lipid-soluble.

Benzodiazepines undergo hepatic metabolism *via* oxidation and glucuronide conjugation. Oxidation reactions are susceptible to hepatic dysfunction and co-administration of other anesthetic drugs. Diazepam is metabolized to active metabolites (desmethyldiazepam, 3-hydroxydiazepam), which can prolong its residual sedative effects. These metabolites undergo secondary conjugation to form inactive water-soluble glucuronide conjugates. Drugs that inhibit the oxidative metabolism of diazepam include the H₂-receptor blocking drug cimetidine. Severe liver disease reduces diazepam's protein-binding and hepatic clearance rate, increases its volume of distribution, and thereby prolongs the $t_{1/2\beta}$ value. Chronic renal disease decreases protein binding and increases the free drug fraction, resulting in enhanced hepatic metabolism and a shorter $t_{1/2\beta}$ value. In elderly patients, the clearance rate of diazepam is significantly decreased, prolonging its $t_{1/2\beta}$ to 75–150 h.

Lorazepam is directly conjugated to glucuronic acid to form pharmacologically inactive metabolites. Age and renal disease have little influence on the kinetics of lorazepam; however, severe hepatic disease decreases its clearance rate.

Midazolam undergoes extensive oxidation by hepatic enzymes to form water-soluble hydroxylated metabolites, which are excreted in the urine. However, the primary metabolite, 1-hydroxymethylmidazolam, has some CNS-depressant activity. The hepatic clearance rate of midazolam is 5 times greater than that of lorazepam and 10 times greater than that of diazepam. Although changes in liver blood flow can affect the clearance of midazolam, age has relatively little influence on midazolam's elimination half-life.

The benzodiazepines used in anesthesia are classified as either short- (midazolam, flumazenil), intermediate- (diazepam), or long-acting (lorazepam). Because the distribution volumes are similar, the large difference in the elimination half-times is due to differences in their clearance rates (see [Table 13-1](#)). The context-sensitive half-times for diazepam and lorazepam are very long; therefore, only midazolam should be used for continuous infusion.

All benzodiazepines have anxiolytic, amnestic, sedative, hypnotic, anticonvulsant, and spinally mediated muscle relaxant properties. Benzodiazepines differ in potency and efficacy with regard to their distinctive pharmacologic properties.²⁵ The dose-dependent pharmacologic activity implies that the CNS effects of various benzodiazepine compounds depend on the affinity for receptor subtypes and their degree of receptor binding. Although benzodiazepines can be used as hypnotics, they are primarily used as premedicants and adjuvant drugs because of their anxiolytic, sedative, and amnestic properties. For example, midazolam (0.04–0.08 mg · kg⁻¹ iv/im) is a commonly used premedicant. In addition, midazolam, 0.4–0.8 mg · kg⁻¹ administered orally 10–15 min before parental separation is an excellent premedicant in children. In contrast to lorazepam, both diazepam and midazolam can be used to induce anesthesia because they have a relatively short onset time after iv administration. The half-life of equilibration between the plasma concentration of midazolam and its maximal EEG effect is only 2–3 min. The therapeutic window to maintain unconsciousness with midazolam is reported to be 100–200 ng · ml⁻¹, with awakening occurring at plasma concentrations below 50 ng · ml⁻¹. However, significant hypnotic synergism occurs when midazolam and opioid analgesics are administered in combination.

The usual induction dose of midazolam in premedicated patients is 0.1–0.2 mg · kg⁻¹ iv, with infusion rates of 0.25–1 mg · kg⁻¹ · min⁻¹ required to maintain hypnosis and amnesia in combination with inhalational agents and/or opioid analgesics. Higher maintenance infusion rates and prolonged administration will result in accumulation and prolonged recovery times. Lower infusion rates are sufficient to provide sedation and amnesia during local and regional anesthesia.²⁶ Patient-controlled administration of midazolam during procedures under local anesthesia is well accepted by patients and associated with few perioperative complications.²⁷

Benzodiazepines decrease both CMRO₂ and CBF analogous to the barbiturates and propofol. However, in contrast to these compounds, midazolam is unable to produce a burst-suppressive (isoelectric) pattern on the EEG. Accordingly, there is a “ceiling” effect with respect to the decrease in CMRO₂ produced by increasing doses of midazolam. Midazolam induces dose-dependent changes in regional cerebral perfusion in the parts of the brain that subserve arousal, attention, and memory. Cerebral vasomotor responsiveness to carbon dioxide is preserved during midazolam anesthesia. In patients with severe head injury, a bolus dose of midazolam may decrease CPP with little effect on ICP. Although midazolam may improve neurologic outcome after incomplete ischemia in animal experiments, benzodiazepines have not been shown to possess neuroprotective activity in humans. Like the other sedative-hypnotic drugs, the benzodiazepines are potent anticonvulsants that are commonly used to treat status epilepticus.

Benzodiazepines produce dose-dependent respiratory depression. In healthy patients, the respiratory depression associated with benzodiazepine premedication is insignificant. However, the depressant effect is enhanced in patients with chronic respiratory disease, and synergistic depressant effects occur when benzodiazepines are co-administered with opioid analgesics. Benzodiazepines also depress the swallowing reflex and decrease upper airway reflex activity.

Both midazolam and diazepam produce decreases in systemic vascular resistance and blood pressure when large doses are administered for induction of anesthesia. However, the cardiovascular depressant effects of benzodiazepines are frequently “masked” by the stimulus of laryngoscopy and intubation. The cardiovascular depressant effects are directly related to the plasma concentration; however, a plateau plasma concentration appears to exist above which little further change in arterial blood pressure occurs. In the presence of heart failure, the decrease in preload and afterload produced by benzodiazepines may be beneficial in improving cardiac output. However, the cardiodepressant effect of benzodiazepines may be more marked in hypovolemic patients.

Ro 48-6791, 3-(5-dipropylaminomethyl-1,2,4-oxadiazol-3-yl)-8-fluoro-5-methyl-5,6-dihydro-4H-imidazo[1,5-a][1,4]benzodiazepin-6-one) is a new water-soluble benzodiazepine that has full agonistic activity at CNS benzodiazepine receptors. Compared with midazolam, it is 2 to 2.5-fold more potent, has a higher plasma clearance rate, and a similar onset and duration of action.²⁸ In a recent study involving outpatients undergoing endoscopy procedures, the times to ambulation and to recovery from psychomotor impairment were decreased compared to midazolam, although the later recovery end points (e.g., “fitness-for-discharge”) were similar.²⁹

In contrast to all other sedative-hypnotic drugs, there is a specific antagonist for benzodiazepines. Flumazenil, a 1,4-imidazobenzodiazepine derivative, has a high affinity for the benzodiazepine receptor but minimal intrinsic activity.³⁰ Flumazenil's molecular structure is similar to that of other benzodiazepines except for the absence of a phenyl group, which is replaced by a carbonyl group. It is water-soluble and possesses moderate lipid solubility at physiologic pH. Flumazenil is rapidly metabolized in the liver, and its metabolites are excreted in the urine as glucuronide conjugates. Flumazenil acts as a competitive antagonist in the presence of benzodiazepine agonist compounds. The residual activity of the benzodiazepines in the presence of flumazenil depends on the relative concentrations of the agonist and antagonist drugs. As a result, it is possible to reverse benzodiazepine-induced anesthesia (or deep sedation) either completely or partially depending on the dose of flumazenil. Flumazenil is short-acting, with an elimination half-life of ~1 h.

Recurrence of the central effects of benzodiazepines (resedation) may occur after a single dose of flumazenil due to residual effects of the more slowly eliminated agonist drug.³¹ If sustained antagonism is desired, it may be necessary to administer flumazenil as repeated bolus doses or a continuous infusion. In general, 45–90 min of antagonism can be expected following flumazenil 1–3 mg iv. However, the respiratory depression produced by benzodiazepines is not completely reversed by

flumazenil.³² Reversal of benzodiazepine sedation with flumazenil is not associated with adverse cardiovascular effects or evidence of an acute stress response.³³ Although flumazenil does not appear to change CBF or CMRO₂ following midazolam anesthesia for craniotomy, acute increases in ICP have been reported in head-injured patients receiving flumazenil.

Etomidate

Etomidate is a carboxylated imidazole-containing anesthetic compound [*R*-1-ethyl-1-(*a*-methylbenzyl) imidazole-5-carboxylate] which is structurally unrelated to any other iv anesthetic. Only the *D*-isomer of etomidate possesses anesthetic activity. Analogous to midazolam (which also contains an imidazole nucleus), etomidate undergoes an intramolecular rearrangement at physiologic pH, resulting in a closed-ring structure with enhanced lipid solubility. The aqueous solution of etomidate (Amidate) is unstable at physiologic pH and is formulated in a 0.2% solution with 35% propylene glycol (pH 6.9), contributing to a high incidence of pain on injection, venoiritation, and hemolysis. A new lipid emulsion formulation (Etomidate-Lipuro) has recently been introduced in Europe and appears to be associated with a lower incidence of side effects compared to the original propylene glycol formulation.

The standard induction dose of etomidate (0.2–0.4 mg · kg⁻¹ iv) produces a rapid onset of anesthesia. Involuntary myoclonic movements are common during the induction period as a result of subcortical disinhibition, and are unrelated to cortical seizure activity. The frequency of this myoclonic-like activity can be attenuated by prior administration of opioid analgesics, benzodiazepines, or small sedative doses of etomidate (0.03–0.05 mg · kg⁻¹) prior to induction of anesthesia.³⁴ Emergence time after etomidate anesthesia is dose-dependent but remains short even after administration of repeated bolus doses or continuous infusions. For maintenance of hypnosis, the target concentration is 300–500 ng · ml⁻¹ and can be rapidly achieved by administering a two- or three-stage infusion (e.g., 100 mg · kg⁻¹ · min⁻¹ for 10 min followed by 10 mg · kg⁻¹ · min⁻¹ or 100 mg · kg⁻¹ · min⁻¹ for 3–5 min, followed by 20 mg · kg⁻¹ · min⁻¹ for 20–30 min, and then 10 mg · kg⁻¹ · min⁻¹). The pharmacokinetics of etomidate are optimally described by a three-compartment open model.³⁵ The high clearance rate of etomidate (18–25 ml · kg⁻¹ · min⁻¹) is a result of extensive ester hydrolysis in the liver (forming inactive water-soluble metabolites). A significant decrease in plasma protein binding has been reported in the presence of uremia and hepatic cirrhosis. Severe hepatic disease causes a prolongation of the elimination half-life secondary to an increased volume of distribution and a decreased plasma clearance rate.

Analogous to the barbiturates, etomidate decreases CMRO₂, CBF, and ICP. However, the hemodynamic stability associated with etomidate will maintain adequate CPP. Etomidate has been used successfully for both induction and maintenance of anesthesia for neurosurgery. Etomidate's well-known inhibitory effect on adrenocortical synthetic function³⁶ limits its clinical usefulness for long-term treatment of elevated ICP. Although clear evidence for a neuroprotective effect in humans is lacking, etomidate is frequently used during temporary arterial occlusion and intraoperative angiography (for the treatment of cerebral aneurysms). Etomidate produces an EEG pattern that is similar to thiopental except for the absence of increased β activity at lower doses. Etomidate can induce convulsion-like EEG potentials in epileptic patients without the appearance of myoclonic or convulsant-like motor activity, a property that has been proven useful for intraoperative mapping of seizure foci. Etomidate also possesses anticonvulsant properties, and it has been used to terminate status epilepticus.⁶ Etomidate produces a significant increase of the amplitude of somatosensory evoked potentials while only minimally increasing their latency. Consequently, etomidate can be used to facilitate the interpretation of somatosensory evoked potentials when the signal quality is poor.

Etomidate causes minimal cardiorespiratory depression even in the presence of cardiovascular and pulmonary disease.³⁷ The drug does not induce histamine release and can be safely used in patients with reactive airway disease. Consequently, etomidate is considered to be the induction agent of choice for poor-risk patients with cardiorespiratory disease, as well as in those situations in which preservation of a normal blood pressure is crucial (e.g., cerebrovascular disease). However, etomidate does not effectively blunt the sympathetic response to laryngoscopy and intubation unless combined with a potent opioid analgesic.

Etomidate is associated with a high incidence of postoperative nausea and emesis when used in combination with opioids for short outpatient procedures. In addition, the increased mortality in critically ill patients sedated with an etomidate infusion has been attributed to its inhibitory effect on cortisol synthesis.³⁸ Etomidate inhibits the activity of 11- β -hydroxylase, an enzyme necessary for the synthesis of cortisol, aldosterone, 17-hydroxyprogesterone, and corticosterone. Even after a single induction dose of etomidate,³⁸ adrenal suppression persists for 5–8 h. Although the clinical significance of short-term blockade of cortisol synthesis is not known, the use of etomidate for maintenance of anesthesia has been questioned. In spite of its side-effect profile, etomidate remains a valuable induction drug for specific indications (in patients with severe cardiovascular and cerebrovascular disease).

Ketamine

Ketamine (Ketalar or Ketaject) is an arylcyclohexylamine that is structurally related to phencyclidine.³⁹ Ketamine is a water-soluble compound with a p*K*_a of 7.5, and is available in 1%, 5%, and 10% aqueous solutions. The ketamine molecule contains a chiral center producing two optical isomers. The *S*(+) isomer of ketamine possesses more potent anesthetic and analgesic properties despite having a similar pharmacokinetic and pharmacodynamic profile to that of the racemic mixture [or the *R*(-) isomer].⁴⁰ However, apart from some European countries where *S*(+)-ketamine is approved for clinical use, the commercially available solution is a racemic mixture of the two isomers and the preservative is benzethonium chloride. Ketamine is extensively metabolized by hepatic microsomal cytochrome P-450 enzymes, and its primary metabolite, norketamine, is one-third to one-fifth as potent as the parent compound. The metabolites of norketamine are excreted by the kidney as water-soluble hydroxylated and glucuronidated conjugates. Analogous to the barbiturates and propofol, ketamine has relatively short distribution and redistribution half-life values. Ketamine also has a high hepatic clearance rate (1 l · min⁻¹) and a large distribution volume (3 l · kg⁻¹), resulting in an elimination half-life of 2–3 h. The high hepatic extraction ratio suggests that alterations in hepatic blood flow can significantly influence ketamine's clearance rate.

Ketamine produces dose-dependent CNS depression leading to a so-called dissociative anesthetic state characterized by profound analgesia and amnesia, even though patients may be conscious and maintain protective reflexes. The proposed mechanism for this cataleptic state includes electrophysiologic inhibition of thalamocortical pathways and stimulation of the limbic system. Although it is most commonly administered parenterally, oral and intranasal administration of ketamine (6 mg · kg⁻¹) has been used for premedication of pediatric patients. Following benzodiazepine premedication, ketamine 1–2 mg · kg⁻¹ iv (or 4–8 mg · kg⁻¹ im) can be used for induction of anesthesia. The duration of ketamine-induced anesthesia is in the range of 10–20 min after a single induction dose; however, recovery to full orientation may require an additional 60–90 min. Emergence times are even longer following repeated bolus injections or a continuous infusion. *S*(+)-Ketamine has a shorter recovery time compared with the racemic mixture. The therapeutic window for maintenance of unconsciousness with ketamine is between 0.6 and 2 mg · ml⁻¹ in adults and between 0.8 and 4 mg · ml⁻¹ in children. Analgesic effects are evident at subanesthetic doses of 0.1–0.5 mg · kg⁻¹ iv and plasma concentrations of between 85 and 160 ng · ml⁻¹. A low-dose infusion of 4 mg · kg⁻¹ · min⁻¹ iv was reported to result in equivalent postoperative analgesia as an iv morphine infusion of 2 mg · h⁻¹.

As a result of its NMDA receptor blocking activity, it has been suggested that ketamine should be highly effective for pre-emptive analgesia and opioid-resistant chronic pain states.⁴¹ Unfortunately, a recent well-controlled study failed to demonstrate a pre-emptive effect when ketamine was administered prior to the surgical incision.⁴²

An important consideration in the use of ketamine anesthesia relates to the high incidence of psychomimetic reactions (namely, hallucinations, nightmares, altered short-term memory and cognition) during the early recovery period. The incidence of these reactions is dose-dependent and can be reduced by co-administration of benzodiazepines, barbiturates, or propofol. Ketamine has been traditionally contraindicated for patients with increased ICP or reduced cerebral compliance because it increases CMRO₂, CBF, and ICP. However, there is recent evidence that iv induction doses of ketamine actually decreases ICP in traumatic brain injury patients during controlled ventilation with propofol sedation.⁴³ Prior administration of thiopental or benzodiazepines can blunt ketamine-induced increases in CBF. Since ketamine has antagonistic activity at the NMDA receptor, it has been suggested that it possesses some inherent protective effects against brain ischemia. Nevertheless, ketamine can adversely affect neurologic outcome in the presence of brain ischemia despite its NMDA-receptor blocking activity. Cortical EEG recordings following ketamine induction are characterized by the appearance of fast β activity (30–40 Hz) followed by moderate-voltage α activity, mixed with high-voltage δ waves recurring at 3–4 sec intervals. At higher dosages, ketamine produces a unique EEG burst suppression pattern (Fig. 13-5). Although ketamine-induced myoclonic and seizure-like activity has been observed in normal (nonepileptic) patients, ketamine appears to possess anticonvulsant activity.⁶

Figure 13-5. Progressive changes in the EEG produced by ketamine. Stages I–III are achieved with racemic ketamine and its S(+) isomer. With R(-)ketamine, Stage II was the maximal EEG depression produced. (Reprinted with permission from Schüttler J, Stanski DR, White PF *et al*: Pharmacodynamic modeling of the EEG effect of ketamine and its enantiomers in man. *J Pharmacokinet Biopharm* 15:241, 1987.)

Ketamine has well-characterized bronchodilatory activity. In the presence of active bronchospasm, ketamine is considered to be the iv induction agent of choice. Ketamine has been used in subanesthetic dosages to treat persistent bronchospasm in the operating room and ICU. It is also used in combination with midazolam to provide sedation and analgesia for asthmatic patients. In contrast to the other iv anesthetics, protective airway reflexes are more likely to be preserved with ketamine. However, it must be emphasized that the use of ketamine does not obviate the need for tracheal intubation in the patient with a full stomach (because tracheal soiling has been reported in this situation). Ketamine causes minimal respiratory depression in clinically relevant doses and can facilitate the transition from mechanical to spontaneous ventilation after anesthesia. However, its ability to increase oral secretions can lead to laryngo-spasm during “light” anesthesia.

Ketamine has prominent cardiovascular stimulating effects secondary to direct stimulation of the sympathetic nervous system. Induction of anesthesia with ketamine often produces significant increases in arterial blood pressure and heart rate. Although the mechanism of the cardiovascular stimulation is not entirely clear, it appears to be centrally mediated. There is evidence to suggest that ketamine attenuates baroreceptor activity via an effect on NMDA receptors in the nucleus tractus solitarius. Owing to the increased cardiac work and myocardial oxygen consumption, ketamine negatively affects the balance between myocardial oxygen supply and demand. Consequently, its use is not recommended in patients with severe coronary artery disease. In contrast to the secondary cardiovascular stimulation, ketamine has intrinsic myocardial depressant properties that become apparent only in the seriously ill patient with depleted catecholamine reserves. Because ketamine can also increase pulmonary artery pressure, its use is contraindicated in adult patients with poor right ventricular reserve. Interestingly, the effect on the pulmonary vasculature seems to be attenuated in children.

The anesthetic and analgesic potency of S(+)-ketamine is 3 times greater than that of R(-)-ketamine and twice that of the racemic mixture (Fig. 13-6), reflecting its 4-fold greater affinity at the phencyclidine binding site on the NMDA receptor compared with the R(-) isomer.⁴⁰ The therapeutic index of S(+)-ketamine is 2.5 times greater than both the R(-) and the racemic forms. In addition, hepatic biotransformation of S(+)-ketamine occurs 20% faster than that of the R(-) enantiomer, contributing to shorter emergence times and a faster return of cognitive function. Both isomers produce similar cardiovascular stimulating effects and hormonal responses during surgery. Although the incidence of dreaming is similar with S(+)-ketamine and the racemic mixture, subjective mood and patient acceptance are higher with the S(+) isomer. Of interest is the fact that S(+)-ketamine has been reported to have possible neuroregenerative properties.⁴⁴

Figure 13-6. Concentration–response relationship for racemic ketamine and S(+)-ketamine in relation to specific clinical end points. The slowing of the median EEG frequency was used as the effect (end point) and was related to the arterial blood concentrations of ketamine. (Reprinted with permission from Schüttler J, Kloos S, Ihmsen H, Pelzer E: Pharmacokinetic–pharmacodynamic properties of S(+)-ketamine versus racemic ketamine: A randomized double-blind study in volunteers. *Anesthesiology* 77:A330, 1992.)

CLINICAL USES OF INTRAVENOUS ANESTHETICS

Use of Intravenous Anesthetics as Induction Agents

The induction characteristics and recommended dosages of the available iv anesthetic agents are summarized in Table 13-2. As a result of differences in pharmacokinetic (*e.g.*, altered clearance and distribution volumes) and pharmacodynamic (altered brain sensitivity) variables, the induction dosages of all iv anesthetics need to be adjusted to meet the needs of individual patients. For example, advanced age, pre-existing diseases (*e.g.*, hypothyroidism, hypovolemia), premedication (*e.g.*, benzodiazepines), and co-administration of adjuvant drugs (*e.g.*, opioids, α_2 -agonists) decrease the induction dose requirements. When there is concern regarding a possible abnormal response, assessing the effect of a small “test dose” (equal to 10–20% of the usual induction dose) will often identify those patients for whom a dosage adjustment is required. Before administering additional medication, adequate time should be allowed for the anesthetic to exert its effect, especially when using drugs with a slow onset of action (midazolam) or in the presence of a “slow” circulation time in elderly patients and those with congestive heart failure.

| Drug Name | Induction Dose (mg/kg) | Onset (sec) | Duration (min) | Excitatory Activity* | Effect on Heart Rate† | Blood Pressure† |
|--------------|------------------------|-------------|----------------|----------------------|-----------------------|-----------------|
| Thiopental | 3-4 | <10 | 3-10 | + | 0-++ | ↓ |
| Methohexital | 1-2 | <10 | 3-10 | ++ | + | ↓ |
| Propofol | 1.5-2.5 | 15-40 | 3-10 | + | 0-++ | ↓ |
| Midazolam | 0.2-0.4 | 30-60 | 30-100 | 0 | 0 | 0 |
| Diazepam | 0.5-1.0 | 45-90 | 15-30 | 0 | +/-+++ | 0 |
| Lorazepam | 0.05-0.10 | 60-120 | 60-120 | 0 | ++ | 0 |
| Etomidate | 0.2-0.3 | 15-40 | 3-10 | +++ | +++ | 0 |
| Ketamine | 1-2 | 60-90 | 30-120 | + | 0 | ↑↑ |

*0 = none; + = minimal; ++ = moderate; +++ = severe

†↓ = decrease; ↑ = increase

Table 13-2. INDUCTION CHARACTERISTICS AND DOSAGE REQUIREMENTS FOR THE CURRENTLY AVAILABLE SEDATIVE-HYPNOTIC DRUGS

The clinical uses of propofol have expanded greatly since its introduction into clinical practice in 1989.⁴⁵ Intravenous administration of propofol results in a rapid loss of consciousness (usually within one arm-to-brain circulation) comparable to that of barbiturates. Although an induction dose of 2.5 mg · kg⁻¹ was initially recommended, the use of smaller induction doses of propofol (1–2 mg · kg⁻¹) has minimized its acute cardiovascular and respiratory depressant effects. Recovery from propofol's sedative-hypnotic effects is rapid, with less residual sedation, fatigue (“hangover”), and cognitive impairment than with other available sedative-hypnotic drugs after short surgical procedures. Consequently, propofol has become the iv drug of choice for outpatients undergoing ambulatory surgery.

With benzodiazepines, there is wide variation in the dose–response relationships in unpremedicated elective surgery patients. Compared to midazolam, diazepam and lorazepam have slower onset times to achieve a peak effect and their dose–effect relationship is less predictable. As a result, diazepam and lorazepam are rarely used for induction of general anesthesia. In addition, the slow hepatic clearance of diazepam and lorazepam may contribute to prolonged residual effects (sedation, amnesia, fatigue) when they are used for premedication. Midazolam has a slightly more rapid onset and may be a useful induction agent for special indications (when nitrous oxide is contraindicated, or as part of a total iv anesthetic technique). However, when midazolam is used for induction and/or maintenance of anesthesia, return of consciousness takes substantially longer than with other sedative-hypnotic drugs. In spite of its extensive hepatic metabolism, recovery of cognitive function is still slower after midazolam compared with thiopental, methohexital, etomidate, or propofol.

In an effort to optimize the clinical use of midazolam during the induction period, it is utilized increasingly as a co-induction agent with other sedative-hypnotic drugs (propofol, ketamine). Midazolam 2–5 mg iv can provide for increased sedation, amnesia, and anxiolysis during the preinduction period. When midazolam is used in combination with propofol, 1.5–2 mg · kg⁻¹ iv, or ketamine, 0.75–1 mg · kg⁻¹ iv, it facilitates the onset of anesthesia without delaying emergence times.⁴⁶ Midazolam attenuates the cardiostimulatory response to ketamine, as well as its psychomimetic emergence reactions. Use of midazolam, 2–3 mg iv, with propofol reduces recall during the induction period; however, larger doses of midazolam (>15 mg iv) will delay emergence after brief surgical procedures.

Owing to their side-effect profiles, the clinical use of etomidate and ketamine for induction of anesthesia is restricted to specific situations where their unique pharmacologic profiles offer advantages over other available iv anesthetics. For example, etomidate can facilitate maintenance of a stable blood pressure in high-risk patients with critical stenosis of the cerebral vasculature and in patients with severe cardiac impairment or unstable angina. Ketamine is a useful induction agent for hypovolemic patients, as well as in patients with reactive airway disease or a compromised upper airway.

Use of Intravenous Drugs for Maintenance of Anesthesia

The continued popularity of volatile anesthetics for maintenance of anesthesia is due primarily to their rapid reversibility and ease of administration when using conventional vaporizer delivery system for titrating to the desired end point. The availability of iv drugs with more rapid onset and shorter recovery profiles, as well as user-friendly infusion delivery systems, has facilitated the maintenance of anesthesia with continuous infusions of iv drugs, producing an anesthetic state (namely, TIVA) that compares favorably with that of the volatile anesthetics.

The traditional intermittent bolus administration of iv drugs results in a “depth” of anesthesia (and analgesia) that oscillates above and below the desired level.⁴⁷ Owing to rapid distribution and redistribution of the iv anesthetics, the high peak blood concentration after each bolus is followed by a rapid decrease, producing fluctuating drug levels in the blood, and hence the brain. The magnitude of the drug level fluctuation is dependent on the size of the bolus dose and the frequency of its administration. Wide variation in the plasma drug concentrations can result in hemodynamic and respiratory instability due to changes in the depth of anesthesia or sedation. By providing more stable blood (and brain) concentrations with a continuous iv infusion, it might be possible to improve anesthetic conditions and hemodynamic stability, as well as decreasing side effects and recovery times with iv anesthetics.⁴⁸ Administration of iv anesthetics by a variable-rate infusion is a logical extension of the incremental bolus method of drug titration, as a continuous infusion is equivalent to the sequential administration of infinitely small bolus doses.

Although an iv anesthetic can be titrated to achieve and maintain the desired clinical effect, a knowledge of basic pharmacokinetic principles is helpful in more accurately predicting the optimal dosage requirements. The required plasma concentration depends on the desired pharmacologic effect (hypnosis, sedation), the concomitant use of other adjunctive drugs (opioid analgesics, muscle relaxants, cardiovascular drugs), the type of operation (superficial, intra-abdominal, intracranial), and the patient's sensitivity to the drug (age, drug history, pre-existing diseases). Pre-existing diseases (cirrhosis, congestive heart failure, renal failure) can markedly alter the pharmaco-kinetic variables of the highly protein-bound, lipophilic iv anesthetic drugs. In general, children have higher clearance rates, while the elderly have reduced clearance values. Various intraoperative interventions (laryngoscopy, tracheal intubation, skin incision, entry into body cavities) transiently increase the anesthetic and analgesic requirements. Therefore, the infusion scheme should be tailored to provide peak concentrations during the periods of most intense stimulation. For specific surgical interventions, the so-called therapeutic window of an iv anesthetic is defined as the blood concentration range required to produce a given effect (Table 13-3). It must be emphasized that the therapeutic window for sedative-hypnotics is markedly influenced by the presence of adjunctive drugs (opioids, α₂-agonists, nitrous oxide).

| Drug Name | Major Surgery Concentration | Minor Surgery Concentration | Sedative Concentration | Awakening Concentration |
|-----------|--------------------------------|--------------------------------|---------------------------|----------------------------|
| Propofol | 10–20 µg ml ⁻¹ | 10–20 µg ml ⁻¹ | 4–8 µg ml ⁻¹ | 4–8 µg ml ⁻¹ |
| Etomidate | 4–5 µg ml ⁻¹ | 5–10 µg ml ⁻¹ | 1–2 µg ml ⁻¹ | 1–2 µg ml ⁻¹ |
| Propofol | 4–8 µg ml ⁻¹ | 4–8 µg ml ⁻¹ | 1–2 µg ml ⁻¹ | 1–2 µg ml ⁻¹ |
| Ketamine | 10–20 µg ml ⁻¹ | 10–20 µg ml ⁻¹ | 4–8 µg ml ⁻¹ | 4–8 µg ml ⁻¹ |
| Etomidate | 10–20 µg ml ⁻¹ | 10–20 µg ml ⁻¹ | 10–20 µg ml ⁻¹ | 10–20 µg ml ⁻¹ |
| Ketamine | 1–4 µg ml ⁻¹ | 16–2 µg ml ⁻¹ | 11–2 µg ml ⁻¹ | NA |

NA = not available.

Table 13-3. THERAPEUTIC BLOOD CONCENTRATIONS WHEN INTRAVENOUS ANESTHETICS ARE INFUSED FOR HYPNOSIS OR SEDATION

The use of iv anesthetic techniques requires continuous titration of the drug infusion rate to the desired pharmacodynamic end point. Most anesthesiologists rely on somatic and autonomic signs for assessing depth of iv anesthesia, analogous to the manner in which they titrate the volatile anesthetics. The most sensitive clinical signs of depth of anesthesia appear to be changes in muscle tone and ventilatory pattern.⁴⁹ However, if the patient has been given muscle relaxants, the anesthesiologist must rely on signs of autonomic hyperactivity (tachycardia, hypertension, lacrimation, diaphoresis). Unfortunately, the anesthetic drugs (ketamine), as well as adjunctive agents (α₂-agonists, β-blockers, adenosine, calcium-channel blockers), can influence the cardiovascular response to surgical stimulation. Although the cardiovascular signs of autonomic nervous system hyperactivity may be masked, other autonomic signs (e.g., diaphoresis) and purposeful movements are more reliable indicators of depth of anesthesia than blood pressure because the latter depends upon the ability of the heart to maintain the cardiac output in the face of acute changes in afterload. The heart rate response to surgical stimulation appears to be more useful than the blood pressure response in determining the need for additional analgesic medication. Moreover, it would appear that blood pressure and heart rate responses to surgical stimulation are a less useful guide with iv techniques than with volatile anesthetics.

An important problem with the clinical assessment of anesthetic depth is that modern iv anesthesia uses a combination of hypnotics, opioids, muscle relaxants, and adjuvant drugs. The interactions between these drugs can result in additive, supra-additive, infra-additive, or even antagonistic effects. An ideal “depth of anesthesia” indicator would integrate the physiologic information from all aspects of the anesthetic state. In the absence of a global cerebral function monitor, the “depth of anesthesia” device should provide an indication of one or more of the key components of general anesthesia (e.g., hypnosis, analgesia, amnesia, suppression of the stress response, or muscle relaxation). A simple, noninvasive monitor of the depth of anesthesia, which would reliably predict a patient's response to surgical stimulation, would be extremely valuable when utilizing iv anesthetic techniques.

Electromyographic (EMG) activity of the frontalis muscles increases significantly in patients who move in response to a specific surgical stimuli⁴⁹; however, EMG changes occur late and their interpretation can be obscured by muscle relaxant drugs. The EEG changes depend largely on the type of anesthetic drugs used. Although a common EEG pattern can be recognized with increasing depression of CNS function by sedative-hypnotics and opioid analgesics, there is no characteristic EEG pattern associated with unconscious and amnestic states.⁵⁰ Univariate descriptors of EEG activity appear to be of limited clinical utility, and no meaningful correlation could be found between EEG spectral edge frequency and hemodynamic response to surgical stimuli during propofol anesthesia.⁵¹ Although EEG variables (spectral edge frequency, median frequency) appear to be useful indicators of the CNS effects of anesthetic and analgesic drugs in the experimental setting, their usefulness in clinical practice is limited owing to the many confounding factors during the operation (changing drug levels and surgical stimulation). The bispectral index (BIS), a novel approach to the analysis of the spontaneous EEG, may prove to be a useful indicator of anesthetic (hypnotic) depth.⁵² A study showed that the BIS index reliably predicted fast-track eligibility after ambulatory surgery.⁵³

An attractive alternative to the spontaneous EEG is the evoked responses of the EEG to sensory stimuli. The ability to quantitatively assess the response of the body to varying levels of stimulation (sensory or auditory evoked responses) may be the key to assessing depth of anesthesia.⁵⁴ Although all sedative-hypnotic drugs affect the brainstem-evoked potentials, uncertainty still exists regarding the most useful evoked response(s) to measure. In addition, the technical and practical complexity associated with recording evoked responses is much greater than recording the spontaneous EEG. The evoked response is also critically dependent on technical factors (stimulus intensity, stimulus rate, electrode position), body temperature, and the anesthetic drugs. Although most iv anesthetics produce dose-dependent changes in the somatosensory evoked potentials, the correlation between the acute hemodynamic changes to surgical stimuli and the early auditory evoked responses is poor. However, the early cortical (mid-latency) auditory evoked response might be useful in detecting awareness under anesthesia. Furthermore, the auditory evoked potential index (AEPi), a mathematical derivative of the morphology of the auditory evoked potential waveform, may be more discriminatory than BIS in characterizing the transition from wakefulness to unresponsiveness.⁵⁵

As a result of the availability of more rapid and shorter-acting sedative-hypnotics, sophisticated computer technology, and new insights into pharmacokinetic-dynamic interactions, use of TIVA techniques has been increasing. When utilizing constant-rate iv infusions, 4–5 half-lives may be required to achieve a steady-state anesthetic

concentration (Fig. 13-7). To more rapidly achieve a therapeutic blood concentration, it is necessary to administer a loading (priming) dose and to maintain the desired drug concentration using a maintenance infusion. The loading dose (LD) and initial maintenance infusion rate (MIR) can be calculated from previously determined population kinetic values using the following equations:

Figure 13-7. Simulated drug level curves when a constant infusion is administered following a “full” loading dose equal to $C_p \cdot Vd_{ss}$ (curve A), a smaller loading dose equal to $C_p \cdot Vc$ (curve B), or in the absence of a loading (curve C). (Reprinted with permission from White PF: Clinical uses of intravenous anesthetic and analgesic infusions. *Anesth Analg* 68:161, 1989.)

$$LD = C_p(\text{mg} \cdot \text{ml}^{-1}) \cdot Vd(\text{ml} \cdot \text{kg}^{-1})$$

$$MIR = C_p(\text{ml} \cdot \text{kg}^{-1}) \cdot Cl(\text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1})$$

where C_p = plasma drug concentration; Vd = distribution volume; Cl = drug clearance.

The use of the smaller central volume of distribution (Vc) for the Vd component of the LD equation will underestimate the LD, whereas use of the larger steady-state volume of distribution (Vd_{ss}) will result in drug levels that transiently exceed those that are desired. If a smaller LD is administered, a higher initial MIR will be required to compensate for the drug that is removed from the brain by both redistribution and elimination processes. As the redistribution phase assumes less importance, the MIR will decrease because it becomes solely dependent on the drug's elimination and the desired plasma concentration.

An alternative approach is to begin with a rapid loading infusion with a bolus-elimination transfer (BET) scheme that combines three functions as shown in the following equation:

$$\text{Input} = V1 \cdot C_{ss} + Cl \cdot C_{ss} + V1 \cdot C_{ss}(k_{12} \cdot e^{-k_{21}t})$$

where $V1$ = distribution volume of the central compartment; C_{ss} = steady-state plasma concentration; Cl = drug clearance; k_{12} = redistribution constant from the central to the peripheral compartment; k_{21} = redistribution constant from the peripheral to the central compartment. Implementation of the BET infusion scheme requires the use of a microprocessor-controlled pump. If a continuous infusion is to be used in an optimal manner to suppress responses to surgical stimuli, the MIR should be varied according to the individual patient responses (Fig. 13-8). Using an MIR large enough to suppress responses to the most intense surgical stimuli will lead to excessive drug accumulation, postoperative side effects, and delayed recovery. More gradual signs of inadequate or excessive anesthesia can be treated by making 50–100% changes in the MIR. Abrupt increases in autonomic activity can be treated by giving a small bolus dose equal to 10–25% of the initial loading dose and increasing the MIR.

Figure 13-8. The “landscape” of surgical anesthesia. The surgical stimuli are not constant during an operation; therefore, the plasma concentration of an iv anesthetic should be titrated to match the needs of the individual patient. (Reprinted with permission from Glass PSA, Shafer SL, Jacobs JR, Reves JG: Intravenous drug delivery systems. In *Miller's Anesthesia*, 4th ed, p 391. New York, Churchill Livingstone, 1994.)

Automated iv infusion devices are becoming more readily available for clinical practice. Despite the marked pharmacokinetic and pharmacodynamic variability that exists among surgical patients, computer programs have been developed that allow reasonable predictions of concentration–time profiles for iv anesthetics and analgesics. This new technology has led to the concept of target-controlled infusions (TCI), whereby the anesthesiologist chooses a “target” drug concentration and the microprocessor-controlled infusion pump infuses the drug at the rate needed to rapidly achieve and maintain the desired concentration based on population pharmacokinetic data.⁵⁶ It is obvious that the target concentration must be altered depending on the observed pharmacodynamic effect and the anticipated changes in surgical stimulation. Closed-loop control based on plasma drug concentrations is not possible because there is no available methodology to obtain frequent measurements of drug concentrations in real time. A more advanced form of TCI uses a feedback signal generated by simulating a mathematical model of the control process. Clearly, the precision of control achievable with a model-based system is only as accurate as the model. The performance of automated drug delivery devices is defined by the percent performance error (the difference between the measured and predicted drug values divided by the predicted value and multiplied by 100). An example of a model-based drug delivery system is the computer-assisted continuous infusion (CACI) system. An ideal automatic anesthesia delivery device would titrate anesthetic to meet the needs of the individual patient using an acquired feedback signal consisting of a measured value (e.g., evoked responses, EEG parameters) that reflects the adequacy of the anesthetic state. The most successful efforts at feedback control of anesthesia have utilized the BIS and cortical auditory evoked responses to assess the pharmacodynamic end point.^{52,55}

The rapid, short-acting, sedative-hypnotics and opioids are better suited for continuous administration techniques than the more traditional anesthetic and analgesic agents because they can be more precisely titrated to meet the unique and changing needs of the individual patient. Traditionally, the elimination half-life of a particular drug has been used in attempting to predict the duration of drug action and the time to awakening after discontinuation of the anesthetic infusion. Using conceptual modeling techniques, it has been shown that the concept of context-sensitive half-time is more appropriate in choosing drugs for continuous iv administration (Fig. 13-9).⁴ Because none of the currently available iv drugs can provide for a complete anesthetic state without producing prolonged recovery times and undesirable side effects, it is necessary to administer a combination of iv drugs that provide for hypnosis, amnesia, hemodynamic stability, analgesia, and muscle relaxation. Selecting a combination of drugs with similar pharmacokinetics and compatible pharmacodynamic profiles should improve the anesthetic and surgical conditions. Sedative-hypnotics (methohexital, midazolam, propofol, etomidate, ketamine), opioids (fentanyl, alfentanil, sufentanil, remifentanil), and muscle relaxants (*cis*-atracurium, mivacurium, rocuronium, rapacurium) can be successfully administered using continuous infusion TIVA techniques as alternatives to the volatile anesthetics and nitrous oxide.

Figure 13-9. Context-sensitive half-time values as a function of infusion duration for iv anesthetics, including thiopental, midazolam, diazepam, ketamine, etomidate, and propofol. The context-sensitive half-time for thiopental and diazepam is significantly longer compared with etomidate, propofol, and midazolam with an increasing infusion duration increase. (Reprinted with permission from Hughes MA, Jacobs JR, Glass PSA: Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthesia. *Anesthesiology* 76:334, 1992.)

Use of Intravenous Anesthetics for Sedation

The use of sedative-hypnotic drugs as part of a monitored anesthesia care (MAC) technique in combination with local anesthetics is becoming increasingly popular. During local or regional anesthesia, subhypnotic dosages of iv anesthetics can be infused to produce sedation, anxiolysis, and amnesia and enhance patient comfort. The optimum sedation technique achieves the desired clinical end points without producing perioperative side effects (respiratory depression, nausea, and vomiting). In addition, it should provide for ease of titration to the desired level of sedation while providing for a rapid return to a “clear-headed” state upon completion of the surgical procedure. Sedation also constitutes an essential element in the management of patients in the ICU. The ideal sedative agent for critically ill patients would have minimal depressant effects on the respiratory and cardiovascular systems, would not influence biodegradation of other drugs, and would be independent of renal and hepatic function for its elimination. The BIS monitor has been used to monitor the depth of sedation in the ICU. For patients undergoing cardiac surgery, rapid reversibility of the sedative state may result in earlier extubation and lead to a shorter stay in the ICU. Although intermittent bolus injections of sedative-hypnotic drugs (e.g., diazepam 2.5–5 mg, lorazepam 0.5–1 mg, midazolam 1.25–2.5 mg) are often administered, continuous infusion techniques with propofol are becoming increasingly popular for maintaining a stable level of sedation in the OR and ICU settings.

Benzodiazepines, particularly midazolam, are still the most widely used for sedation in the ICU and for relief of acute situational anxiety during local and regional anesthesia. Midazolam has a steeper dose–response curve than diazepam (Fig. 13-3)⁵⁷; therefore, careful titration is necessary to avoid oversedation and respiratory depression. Midazolam infusion, 0.05–5 mg · kg⁻¹ · min⁻¹, can be highly effective in providing sedation for hemodynamically unstable patients in the ICU.⁵⁸ Use of a midazolam infusion has been shown to control agitation and decrease analgesic requirements without producing cardiovascular or respiratory instability. However, marked variability exists for midazolam in the individual patient dose–effect relationships.⁵⁹ In addition, marked tolerance may develop to the CNS effects of midazolam with prolonged administration.

Propofol sedation offers advantages over the other sedative-hypnotics (including midazolam) because of its rapid recovery and favorable side-effect profile.^{31,60} In addition, the degree of sedation is readily changeable from “light” to “deep” levels by varying the MIR. Following a propofol LD of 0.25–0.5 mg · kg⁻¹, a carefully titrated subhypnotic infusion of 25–75 mg · kg⁻¹ · min⁻¹ produces a stable level of sedation with minimal cardiorespiratory depression and a short recovery period. Because even low concentrations of propofol can depress the ventilatory response to hypoxia, supplemental oxygen should always be provided. Sedative infusions of propofol produce less perioperative amnesia than midazolam,⁶⁰ and propofol-induced amnesia appears to be directly related to the infusion rate.

A small dose of midazolam (2 mg iv) administered immediately before a variable-rate infusion of propofol has also been shown to significantly decrease intraoperative anxiety and recall of uncomfortable events without compromising the rapid recovery from propofol sedation.⁶¹ Propofol sedation can also be supplemented with potent opioid and nonopioid analgesics to provide sedation-analgesia.⁶² In comparing propofol and midazolam for patient-controlled sedation,²⁷ midazolam was associated with less intraoperative recall and pain on injection than propofol, while propofol was associated with less residual impairment of cognitive function. Compared with midazolam in the ICU setting, use of propofol sedation allowed for more rapid weaning of critically ill patients from artificial ventilation.⁶³ It has been suggested that the more rapid weaning after propofol sedation may be cost-saving compared with midazolam when only a limited period of sedation (<48 h) is required.⁶⁴ Although a pharmacokinetic study yielded no evidence of a change in receptor sensitivity or drug accumulation over a 4-day study period, preliminary data suggest that tolerance to the CNS effects of propofol may develop with more prolonged administration (>11 week).

Concerns have been raised about elevated lipid plasma levels in patients sedated with propofol for several days, especially when high infusion rates (>16 mg · kg⁻¹ · h⁻¹) are utilized. However, the availability of a 2% concentration of propofol should decrease the risk of this problem. Due to conflicting evidence regarding increased mortality as a result of myocardial failure when propofol was used for sedation in the neonatal ICU,^{65,66} more safety data are needed to define the indications for the use of prolonged propofol infusions, especially in the pediatric population.⁶⁷ Low-dose ketamine infusions (5–25 mg · kg⁻¹ · min⁻¹) can also be used for sedation and analgesia during local or regional anesthetic procedures, as well as in the ICU setting.³⁹ Midazolam, 0.07–0.15 mg · kg⁻¹ infused over 3–5 min, followed by ketamine, 0.25–0.5 mg · kg⁻¹ iv over 1–3 min, produced excellent sedation, amnesia, and analgesia without significant cardiorespiratory depression.

SUMMARY

It is obvious that many of the goals desirable in an ideal iv anesthetic have not been achieved with the currently available drugs. Nevertheless, each of these sedative-hypnotic drugs possesses characteristics that may be useful in specific clinical situations. For example, thiopental remains a widely used iv anesthetic even though it is unstable in solution, produces significant cardiovascular and respiratory depression, and is associated with a high incidence of postoperative drowsiness and sedation. Although recovery from anesthesia with methohexital appears to be more rapid than with thiopental (and thiamylal), it produces more pain on injection and excitatory side effects (e.g., myoclonus, hiccoughing) than the other barbiturates.

Propofol is the iv drug of choice when a rapid and smooth recovery is required (e.g., outpatient anesthesia). Recovery from propofol anesthesia is characterized by the absence of a “hangover effect” and less postoperative nausea and vomiting when used for maintenance anesthesia. The cardiovascular depressant effects produced by propofol appear to be more pronounced than those of thiopental, but can be minimized by careful titration and the use of a variable-rate infusion. Propofol, with its favorable pharmacokinetic-dynamic profile, has greatly facilitated the use of TIVA techniques, especially when combined with remifentanyl (a potent opioid analgesic that has a very short context-sensitive half-life and propofol-sparing activity), because this will provide for an even more rapid emergence from propofol-based anesthesia.

When administered alone for induction of anesthesia, benzodiazepines are associated with a prolonged recovery profile. In the usual induction doses, benzodiazepines are associated with minimal cardiorespiratory depression and the reliable amnesic effects are particularly valuable during iv anesthesia (e.g., for acute sedation prior to induction of anesthesia, in the absence of nitrous oxide as part of a TIVA technique). Recently, midazolam has become an important adjunct during the induction period as part of a co-induction (or co-sedation) technique.

A new benzodiazepine with a favorable pharmacokinetic profile, Ro 48-6791, may find a niche in the future.

Etomidate has minimal cardiovascular and respiratory depressant effects and is therefore an extremely useful induction agent in “high-risk” patients. Unfortunately, pain on injection, excitatory phenomena, adrenocortical suppression, and a high incidence of postoperative nausea and vomiting have limited the use of etomidate to special situations in which it offers significant advantages over other available iv anesthetics. The new lipid formulation, with its fewer side effects, may allow this iv anesthetic to gain wider clinical acceptance.

Ketamine produces a wide spectrum of pharmacologic effects, including sedation, hypnosis, somatic analgesia, bronchodilation, and sympathetic nervous system stimulation. Induction of anesthesia can be rapidly achieved following im injection, making it the drug of choice when iv access is difficult to establish in an emergency situation. Ketamine is also indicated for induction of anesthesia in the presence of hypovolemic shock, acute bronchospastic states, right-to-left intracardiac shunts, and cardiac tamponade. The adverse cardiovascular, cerebrodynamic, and psychomimetic effects of ketamine can be minimized by prior administration of benzodiazepines (e.g., midazolam) and sedative-hypnotic drugs (e.g., thiopental, propofol), making it useful as part of a co-induction technique. The recent introduction of S(+)-ketamine

may increase its use in low-doses (100–250 mg.kg⁻¹) as an adjuvant with anesthetic and analgesic-sparing activity.

In conclusion, iv anesthesia has evolved from being used mainly for induction of anesthesia to providing unconsciousness and amnesia for surgical procedures performed under local, regional, and general anesthesia. New insights into the pharmacokinetics and dynamics of iv anesthetics, as well as the development of computer technology to facilitate iv drug delivery, have greatly enhanced the use of total iv anesthetic techniques. The shorter context-sensitive half-life values of the newer sedative-hypnotic drugs make these compounds more useful as continuous infusions for maintenance of anesthesia or sedation. While the search for the ideal iv anesthetic continues, the challenge for the anesthesiologist is to choose the sedative-hypnotic that most closely matches the needs of the specific clinical situation in the most cost-effective manner.

HISTORY

Opioids have been used in the treatment of pain for thousands of years. The drug opium is obtained from the exudate of seed pods of the poppy *Papaver somniferum*, and the word “opium” is derived from *opos*, the Greek word for juice. The first undisputed reference to poppy juice is found in the third-century (B.C.E.) writings of Theophrastus.¹ Opium contains more than 20 alkaloids. The German pharmacist Sertuener isolated what he called the “soporific principle” in opium in 1806, and in 1817 named it morphine, after the Greek god of dreams, Morpheus.² Isolation of other opium alkaloids followed, and by the mid-1800s, the medical use of pure alkaloids rather than crude opium preparations began to spread.⁴ In 1828, Bally published a memoir dealing with the use of morphine in nearly 800 patients. His observations described oral morphine’s therapeutic indications, side effects, and dosage, as well as the development of tolerance and potential abuse.² Morphine was used widely to treat wounded soldiers during the American Civil War, and in 1869, its use as a premedication was described by Claude Bernard. However, in the absence of muscle relaxants and controlled ventilation, opioids were associated with a significant risk of severe respiratory depression and death. Thus its use in anesthesia was limited at that time.

With the advent of cardiac surgery in the late 1950s came the development of “opioid anesthesia.” A decade later, Lowenstein reported the use of progressively higher doses of morphine (0.5–3 mg · kg⁻¹) without adverse circulatory effects, but two years later described limitations of the technique, including incomplete suppression of the stress response, hypotension, and awareness during anesthesia. Stanley found that much higher doses of morphine were associated with increased fluid and blood requirements.³

Phenoperidine, a derivative of normeperidine, was synthesized in 1957, and fentanyl, a 4-anilinopiperidine derivative, was synthesized in 1960.⁴ These completely synthetic opioids were more potent and had a better safety margin (ratio of median lethal dose to lowest effective dose for surgery) than meperidine. Advances in surgical techniques have created the need for potent opioids with a rapid onset and a brief, predictable duration of action as well as a maximal safety margin for use in clinical anesthesia. Development of sufentanil, alfentanil, and other fentanyl derivatives between 1974 and 1976 was guided by these needs. The newest potent opioid, remifentanil, has an ultrashort duration of action owing to its rapid metabolism by ester hydrolysis. It remains to be seen whether these characteristics provide more safety and flexibility in the clinical setting.

The search for opioid analgesics having no potential for dependence was stimulated by concerns about opioid addiction, and led eventually to the identification of multiple opioid receptor types. In the mid 1960s, nalorphine, a drug known to antagonize the effects of morphine, was also found to have analgesic properties. Two other compounds, pentazocine and cyclazocine, antagonized some of morphine’s effects. Pentazocine also produced analgesia, and both produced some psychotropic effects that morphine did not. These and other observations led Martin to propose the theory of receptor dualism. Intrinsic to this theory were two key concepts: (1) the existence of multiple opioid receptors (originally only two were proposed); (2) the idea of pharmacologic redundancy (*i.e.*, more than one receptor could mediate a physiologic function, such as analgesia).⁵ Thus, a drug could be a strong agonist, a partial agonist, or a competitive antagonist at one or more of the different receptor types. Subsequent research has revealed three distinct families of opioid peptides and multiple categories of opioid receptors. Future research may identify compounds that provide potent analgesia but fewer side effects or propensity for abuse based on receptor selectivity.

TERMINOLOGY

The term *opiate* was originally used to refer to drugs derived from opium, including morphine, its semisynthetic derivatives, and codeine. The more general term *opioid* was introduced to designate all drugs, both natural and synthetic, with morphine-like properties, including endogenous peptides. However, the use of the term “opioid” has expanded to include reference to antagonists and receptors as well. The nonspecific term *narcotic*, which is derived from the Greek *narkotikos* (benumbing or deadening), has been used to refer to morphine and potent morphine-like analgesics. However, because of its use in a legal context, referring to any drug (including nonopioids, such as cocaine) that can produce dependence, the term “narcotic” is not useful in a pharmacologic or clinical context.¹

In its broadest sense, the term “opioid” can refer to agonists, partial agonists, mixed agonist–antagonists, and competitive antagonists. Differentiation of these terms requires understanding of receptor–ligand interactions. Receptor theory states that drugs have two independent characteristics at receptor sites: affinity, the ability to bind a receptor to produce a stable complex; and intrinsic activity or efficacy, which is described by the dose–effect curve resulting from the drug–receptor combination. Efficacy can range from zero (*i.e.*, no effect) to the maximum possible effect, depicted graphically as the plateau of the dose–effect curve (Fig. 14-1). Given a high enough dose, an agonist will produce the maximum possible effect of binding with the receptor, whereas an antagonist produces no direct effect when it binds the receptor. A partial agonist has a dose–effect ceiling that is lower than the maximum possible effect produced by a full agonist, as well as a dose–effect curve that is less steep than that of a full agonist. A mixed agonist–antagonist acts as an agonist (or partial agonist) at one receptor and an antagonist at another. It is important to differentiate the term “potency” from “efficacy.” Whereas efficacy defines the range in magnitude of an effect produced by a drug–receptor combination relative to the maximum possible effect, potency refers to the relative dose required to achieve an effect, and is related to receptor affinity. Thus, at the lower end of the effect range, a partial agonist may be more potent than a full agonist (Fig. 14-1). However, even at very large doses the efficacy, or maximum effect achieved by the partial agonist, will be less than the maximum possible effect of a full agonist.

Figure 14-1. Log dose–effect curves for two agonists (A and B) with equal efficacy but different potency, and a partial agonist (C). Note that the potencies of A and C are similar, but the efficacy is less and the slope of the dose–response curve is shallower for the partial agonist. Note also that at lower doses, the partial agonist C is

more potent than the full agonist B.

ENDOGENOUS OPIOIDS AND OPIOID RECEPTORS

Opioid receptors were discovered in brain tissue before endogenous opioids were isolated. In 1975, Hughes *et al*⁶ identified two pentapeptides with potent opioid activity, and within 10 years, more than 20 opioid peptides had been identified. All of the endogenous opioids are derived from three prohormones—proenkephalin, prodynorphin, and pro-opiomelanocortin (POMC)—and each of these precursors is encoded by a separate gene. The three families of peptides differ in their distribution, receptor selectivity, and neurochemical role,⁷ but they also share some features. For example, endogenous opioids from all three families begin with the pentapeptide sequences of [Leu]- or [Met]-enkephalin. Proenkephalin includes the pentapeptide sequences for [Met]- and [Leu]-enkephalin, and cells that synthesize proenkephalin are widely distributed throughout the brain and spinal cord as well as peripheral sites, particularly the adrenal medulla.⁸ Pro-opiomelanocortin is the common precursor of several peptides, including b-endorphin, adrenocorticotrophic hormone (ACTH), and melanocyte-stimulating hormone (MSH). The term *endorphin* is reserved for peptides of the POMC family. The major site of POMC synthesis is the pituitary, but it is also found in the pancreas and placenta. Prodynorphin was formerly known as proenkephalin B. The dynorphin peptides all begin with the [Leu]-enkephalin sequence. Like the enkephalins, the dynorphins are widely distributed throughout the brain and spinal cord as well as peripheral sites.

Endogenous opioid peptides bind to a number of opioid receptors to produce their effects. Opioid receptor classification is continually being expanded and revised. Martin's initial classification of opioid receptors into the three types was based on binding activity of the exogenous ligands morphine, ketocyclazocine, and SKF10,047 at mu (m), kappa (k), and sigma (s) receptors, respectively. Other opioid receptors identified since that time are delta (d) receptors, bound by enkephalins, and epsilon (e) receptors, bound by endorphin.^{7,8} Of the above receptors, only the m, k, and d receptor classes are firmly established as opioid receptors at this time.⁷ There is also evidence supporting the existence of two m, two d, and three k receptor subtypes.⁸ While it appears that specific opioid receptors are responsible for different opioid effects and that synthetic opioids may be highly selective for a receptor type or subtype, it is important to note that very few endogenous opioids exhibit great selectivity for a single receptor type.⁷ Remember also, that the theory of receptor dualism includes the concept of pharmacologic redundancy of receptor function. Thus, observed opioid effects typically involve complex interactions among the different receptor systems at supraspinal, spinal, and peripheral sites. [Table 14-1](#) summarizes our current understanding of which opioid receptors are responsible for mediating opioid analgesic and side effects. One caveat in interpreting this summary is that species differences in opioid receptor systems exist, so the results of animal studies, from which most of this information is derived, may not always be directly applicable to humans. Most opioids used in clinical anesthesia today (*e.g.*, fentanyl and morphine and their derivatives) are highly selective for m opioid receptors. Naloxone, the most commonly used opioid antagonist, is not selective for opioid receptor type. In fact, current identification of an opioid-receptor-mediated drug effect requires demonstration of naloxone reversibility. Development of selective opioid receptor subtype antagonists is in progress. Such antagonists will be helpful tools in improving our understanding of which receptor subtypes mediate specific opioid effects.

| Receptor | Analgesic | Regulatory | Conductance | Substrate | Other |
|----------|-----------|------------|-------------|---------------|--|
| μ | High | ↓ | ↓ | Morphine | Respiratory depression, constipation, miosis, hypotension, and other effects |
| κ | Low | ↑ | ↓ | Buprenorphine | Respiratory depression, constipation, miosis, hypotension, and other effects |
| δ | Low | ↑ | ↓ | Enkephalins | Respiratory depression, constipation, miosis, hypotension, and other effects |
| σ | High | ↑ | ↓ | Haloperidol | Respiratory depression, constipation, miosis, hypotension, and other effects |
| ε | Low | ↑ | ↓ | Endorphin | Respiratory depression, constipation, miosis, hypotension, and other effects |

Table 14-1. TENTATIVE CLASSIFICATION OF OPIOID RECEPTOR SUBTYPES AND THEIR ACTIONS

At the cellular level, endogenous opioid peptides and exogenous opioids produce their effects by altering patterns of interneuronal communication. Receptor binding initiates a series of physiologic functions resulting in cellular hyperpolarization and inhibition of neurotransmitter release, effects that are mediated by second messengers. All opioid receptors appear to be coupled to G-proteins,⁷ which regulate the activity of adenylate cyclase as well as performing other functions. G-protein interactions, in turn, affect ion channels. There may be different ion conductances involved at different opioid receptor types.⁹ m Opioid receptors are coupled to a potassium conductance; receptor activation increases potassium conductance, which inhibits neurotransmitter release and hyperpolarizes the cell membrane. d Receptor activation increases potassium conductance in a similar manner, but may also affect a voltage-dependent calcium current. k Opioids appear to inhibit calcium entry via voltage-dependent calcium channels.

STRUCTURE–ACTIVITY RELATIONSHIPS

The wide array of different molecules that produce morphine-like analgesia and side effects, including endogenous opioid peptides, all share some common structural characteristics. Horn and Rodgers¹⁰ suggested that the tyrosine moiety at the amino terminal of the enkephalins formed the basis of a significant conformational relationship between the enkephalins and opiates. The structure of the phenanthrene class of opium alkaloids is complex, and consists of five or six fused rings. Morphine, one of three phenanthrenes, has a rigid five-ring structure that conforms to a “T” shape, with a phenylpiperidine ring forming the crossbar and a hydroxylated aromatic ring in the vertical axis ([Fig. 14-2](#)).¹¹ The other phenanthrenes are codeine, a derivative of morphine, and thebaine, a precursor of oxycodone and naloxone. Progressively reducing the number of fused rings from the phenanthrenes yields the morphinans, with four rings; the benzomorphans, with three rings; the phenylpiperidines, with two rings; and finally, the tyramine moiety of the endogenous opioid peptides, with a single hydroxylated ring. All of these distinct classes of drugs possess morphine-like activity. Thorpe¹¹ has proposed an opiate receptor model based on these structural similarities with two aromatic binding sites and one anionic site responsible for binding the positively charged nitrogen. In this model, differences in binding at the aromatic or anionic sites could potentially account for receptor specificity or for agonist *versus* antagonist activity. Structural modifications alter such important properties as opioid receptor affinity, agonist *versus* antagonist activity, resistance to metabolic breakdown, lipid solubility, and pharmacokinetics.¹

Figure 14-2. “T”-shape conformation of opioid molecules. (A) Morphine, one of the phenanthrene alkaloids, has a rigid five-ring structure, with a phenylpiperidine ring forming a crossbar and a hydroxylated aromatic ring in the vertical axis. (B) Reducing the number of fused rings to four yields the morphinan class of opium alkaloids. (C) Benzomorphans have three fused rings. (D) Phenylpiperidines and the 4-anilino-piperidines such as fentanyl have a flexible two-ring structure. (E) Finally, the tyramine moiety, which is the amino terminal peptide of both [Leu]- and [Met]-enkephalin, is shown, with a single aromatic ring. Another key feature is the positively charged basic nitrogen equidistant (4.55 Å) from the aromatic ring. (Adapted with permission from Thorpe DH: Opiate structures and activity: A guide to understanding the receptor. *Anesth Analg* 63:143, 1984.)

PHARMACOKINETICS AND PHARMACODYNAMICS

Basic Considerations

Opioid effects are initiated by the combination of an opioid with one or more receptors at specific tissue sites. The relationship between opioid dose and effects depends on both pharmacokinetic and pharmacodynamic variables. Pharmacokinetics determines the relationship between drug dose and its concentration at the effect site(s). Pharmacodynamic variables relate the concentration of a drug at its site of action, in this case opioid receptors in the brain and other tissues, and the intensity of its effects. It is not generally possible to measure tissue drug concentrations directly, but tissue concentration bears a definable relationship to drug concentration in blood or plasma. Therefore, *pharmacokinetics* generally refers to the study of plasma drug concentration *versus* time because blood is easy to sample and because the blood is the medium by which drugs are distributed throughout the body. Changes in drug concentration over time in the blood, at the effect site and at other sites, are determined by physicochemical properties of the drug as well as a multitude of biologic functions involved in the processes of absorption, redistribution, biotransformation, and elimination.

In clinical anesthesia practice, opioids are typically administered intravenously. After an intravenous bolus dose or brief infusion, with no delay in absorption, peak plasma opioid concentrations occur within minutes. Plasma drug concentrations then fall rapidly as the drug is distributed to extravascular sites, including sites of action, noneliminating tissues, and eliminating organs. Compartmental models describe the time course of change in plasma concentration; typically, opioids used in anesthesia are characterized by two- or three-compartment models (see [Chapter 11](#)). The early rapid decline in plasma concentration after the peak is called the *distribution phase*, and the subsequent slower decline is the *elimination phase*. From a mathematical curve fitted to measured plasma concentration *versus* time data, distribution and elimination half-lives, systemic clearance, compartment volumes, and intercompartmental transfer rate constants can be calculated. [Table 14-2](#) summarizes the estimates of key pharmacokinetic parameters as well as physicochemical characteristics for some of the most commonly used opioids in clinical anesthesia.

| Parameter | Morphine | Hydrocodone | Fentanyl | Sufentanil | Alfentanil | Buprenorphine |
|--|----------|-------------|----------|------------|------------|---------------|
| pK_a | 7.9 | 8.5 | 8.6 | 8.9 | 8.5 | 7.9* |
| V_d (L/kg) | 3.5 | 7 | 4.5 | 3.0 | 3.0 | 3.0* |
| $t_{1/2}$ (min) | 1.4 | 3.0 | 8.0 | 25.7 | 1.0 | 1.0* |
| Protein binding (%) | 35 | 75 | 86 | 95 | 92 | 80-85* |
| Clearance (ml/min) | 1050 | 100 | 100 | 100 | 20 | 400 |
| V_d (L) | 24 | 35 | 35 | 33 | 27 | 30 |
| Rapid distribution half-life ($t_{1/2}$, min) | | | 12-19 | 14 | 10-15 | 10-15 |
| Slow redistribution half-life ($t_{1/2}$, min) | 15-44 | 4-8 | 12-19 | 37 | 15-47 | 10-17 |
| Elimination half-life ($t_{1/2}$, min) | 17-33 | 3-5 | 10-44 | 22-44 | 10-15 | 107-120 |

pK_a = octanol:water partition coefficient, V_d = steady-state volume of distribution.

Table 14-2. PHYSICOCHEMICAL CHARACTERISTICS AND PHARMACOKINETICS OF COMMONLY USED OPIOID AGONISTS IN ADULTS

It is important to note that there is tremendous variability in the values published for opioid pharmacokinetic parameters. This is due, in part, to real population differences (e.g., age, diseases), and in part to differences in study design (e.g., sampling site, duration, concomitant events such as surgery, or other drugs that may affect differential flow to sites of action, metabolism, or elimination). In addition, the distributional and elimination half-lives are of limited use in predicting the onset and duration of opioid action in clinical anesthesia. For drugs with multicompartment characteristics, contributions of distribution processes between compartments vary with time. In an effort to relate pharmacokinetics to the time of onset and duration of action, concepts such as *effect compartment* in pharmacodynamic modeling,¹² and *context-sensitive half-times*¹³ have been developed. The application of these concepts will be considered later in this chapter.

Physicochemical properties of opioids influence both pharmacokinetics and pharmacodynamics. In order to reach its effector sites in the central nervous system (CNS), an opioid must cross biologic membranes from the blood to receptors on neuronal cell membranes. The ability of opioids to cross this blood–brain barrier depends on such properties as molecular size, ionization, lipid solubility, and protein binding (see [Table 14-2](#)). Of these characteristics, lipid solubility and ionization assume major importance in determining the rate of penetration to the CNS. In the laboratory, lipid solubility is measured as an octanol:water or octanol:buffer partition coefficient. Drug ionization is also an important determinant of lipid solubility; nonionized drugs are 1000 to 10,000 times more lipid-soluble than the ionized form.¹⁴ The degree of ionization depends on the pK_a of the opioid and the pH of the environment. An opioid with a pK_a much lower than 7.4 will have a much greater nonionized fraction in plasma than one with a pK_a close to or greater than physiologic pH. While greater lipid solubility correlates with membrane permeability, the relationship is not simply a linear one. Hansch¹⁵ has shown that there is an optimal hydrophobicity for blood–brain barrier penetration, and Bernards¹⁶ has demonstrated a similar biphasic relationship between the octanol:buffer distribution coefficient and spinal meningeal permeability. Plasma protein binding also affects opioid redistribution because only the unbound fraction is free to diffuse across cell membranes. The major plasma proteins to which opioids bind are albumin and α_1 -acid glycoprotein (AAG). Alterations in AAG concentration occur in a variety of conditions and disease states, and result in acute or chronic changes in opioid requirements.

Two main mechanisms are responsible for drug elimination: *biotransformation* and *excretion*. Opioids are biotransformed in the liver by two types of metabolic processes. Phase I reactions include oxidative and reductive reactions, such as those catalyzed by cytochrome P-450 system, and hydrolytic reactions. Phase II reactions involve conjugation of a drug or its metabolite to an endogenous substrate, such as D-glucuronic acid.¹⁴ A new phenylpiperidine, remifentanyl, is metabolized via ester hydrolysis, which is unique for an opioid. With the exceptions of the *N*-deallylated metabolite of meperidine and the 6- and possibly 3-glucuronides of morphine, opioid metabolites are generally inactive. Opioid metabolites and, to a lesser extent, their parent compounds are excreted primarily by the kidneys. The biliary system and gut are other routes of opioid excretion.

Morphine

Morphine produces its major therapeutic as well as adverse effects in the central nervous system (brain and spinal cord) and the gastrointestinal system, but other systems are also affected. CNS effects include analgesia, sedation, changes in affect, respiratory depression, nausea and vomiting, pruritus, and changes in pupil size. Morphine also affects gastric secretions and gut motility, and has endocrine, urinary, and autonomic nervous system effects. Morphine mimics the effects of endogenous opioids by acting as an agonist at m_1 and m_2 opioid receptors throughout the body, and is considered the standard agonist to which other m agonists are compared.

Analgesia

Opioids are administered primarily for their analgesic effect. Morphine analgesia results from complex interactions at a number of discrete sites in the brain, spinal cord, and under certain conditions, peripheral tissues, and involves both m_1 and m_2 opioid effects. Morphine and related opioids act selectively on neurons that transmit and modulate nociception, leaving other sensory modalities as well as motor function intact. At the spinal cord level, morphine acts presynaptically on primary afferent nociceptors to decrease the release of substance P, and also hyperpolarizes post-synaptic neurons in the substantia gelatinosa of the dorsal spinal cord to decrease afferent transmission of nociceptive impulses.¹⁷ Spinal morphine analgesia is mediated by m_2 opioid receptors. Supraspinal opioid analgesia originates in the periaqueductal gray matter (PAG), the locus ceruleus (LC), and nuclei within the medulla, notably the nucleus raphe magnus (NRM), and primarily involves m_1 opioid receptors. Microinjections of morphine into any of these regions activates the respective descending modulatory systems to produce profound analgesia.^{8,17} A more detailed description of the endogenous pain transmission and modulation pathways is given in [Chapter 55](#). Morphine can act at a number of these discrete regions in the CNS to produce synergistic analgesic effects. For example, coadministration at the level of the brain and spinal cord increases morphine's analgesic potency nearly 10-fold,¹⁸ an effect mediated by m_2 opioid receptors.^{8,19} There are also synergistic interactions between supraspinal sites of opioid action (e.g., between the PAG and the NRM).⁸ Recent animal studies as well as preliminary clinical studies in humans²⁰ suggest that morphine can also produce analgesia by peripheral mechanisms, most likely by activating opioid receptors on primary afferent neurons. However, it appears that peripheral opioid analgesia occurs only when inflammation is present.^{20,21}

Although rapidly changing plasma morphine concentrations, such as those that follow bolus dosing, do not correlate well with analgesic effects, constant or very slowly changing (*i.e.*, steady-state) plasma concentrations do correlate with effect intensities. This observation has practical implications for postoperative analgesia. For example, patients using patient-controlled analgesia systems achieve more constant plasma opioid concentrations than those receiving intramuscular injections, and

are able to maintain plasma morphine concentrations within an effective range for analgesia. In these patients, Dahlström measured the minimum effective analgesic concentration (MEAC) of morphine for postoperative pain relief at 10–15 ng · ml⁻¹.²² Cancer patients with severe oropharyngeal mucositis maintained their plasma morphine concentrations at a slightly higher level, 30–50 ng · ml⁻¹, to achieve adequate analgesia.²³

Effect on MAC of Volatile Anesthetics

In awake patients, therapeutic doses of morphine are effective in relieving clinical pain as well as increasing the ability of subjects to tolerate experimentally induced pain. μ Agonists are used extensively in conjunction with nitrous oxide (N₂O) with or without volatile anesthetics to provide “balanced anesthesia.” Roizen *et al*.²⁴ demonstrated that electrical stimulation of the periaqueductal gray (PAG) matter 1 hour prior to surgery reduced the MAC [minimum alveolar concentration] of halothane in 60% N₂O by 70%. One possible mechanism for this effect is the release of endogenous opioids following PAG stimulation. In animals morphine decreases the MAC of volatile anesthetics in a dose-dependent manner,^{25,26} and ²⁷ but there appears to be a ceiling effect to the anesthetic-sparing ability of morphine, with a plateau at 65% MAC.²⁵ Measurement of the maximum effect of very high morphine doses on MAC is limited by undesirable side effects such as hypotension and abdominal wall rigidity. Morphine 1 mg · kg⁻¹ administered with 60% N₂O blocked the adrenergic response to skin incision in 50% of patients.²⁸ Neuraxial morphine may also reduce MAC. Epidural morphine 4 mg given 90 minutes prior to incision reduced halothane MAC by nearly 30%.²⁹ The effect of intrathecal morphine on MAC is unclear. In one study, a relatively large dose of intrathecal morphine (0.750 mg) reduced halothane MAC approximately 40%,³⁰ but an equally large dose (15 mg · kg⁻¹) failed to reduce halothane MAC in another.³¹ The reason for this discrepancy is unclear.

Other CNS Effects

Morphine can produce sedation, as well as cognitive and fine motor impairment, even at plasma concentrations commonly achieved during management of moderate to severe pain.³² Other subjective side effects include euphoria, dysphoria, and sleep disturbances. High doses of morphine and similar opioids produce a slowing of electroencephalogram (EEG) activity associated with a marked shift toward increased voltage and decreased frequency.^{1,33} Morphine can also produce sleep disturbances, including reduction in REM and slow wave sleep,¹ as well as vivid dreams with routine doses used for pain management. In extremely high doses, morphine can produce seizure activity in animals, but this toxic effect is not seen with doses used clinically in humans.

While there are significant species differences in opioid effects on pupil size, morphine produces dose-dependent pupillary constriction (miosis) in humans. This effect is thought to be mediated via the Edinger-Westphal nucleus of the oculomotor nerve.¹ A near maximal degree of miosis is seen with 0.5 mg · kg⁻¹ of morphine.³⁴ In the absence of other drugs, miosis appears to correlate with opioid-induced ventilatory depression. However, hypoxemia from severe opioid-induced respiratory depression will cause pupillary dilation.

Systemic and neuraxial administration of morphine can produce pruritus, although this symptom is more common with spinal administration.¹ Pruritus appears to be a μ receptor-mediated effect which is produced at the level of the medullary dorsal horn (MDH).³⁵ Clinically, antihistamines are often used to treat this side effect, but pruritus induced by morphine microinjection into the MDH is not histamine-mediated.³⁶ Thus, their effectiveness is probably related to nonspecific sedative effects.

Morphine can also affect the release of several pituitary hormones, both directly and indirectly. Inhibition of corticotropin-releasing factor and gonadotropin-releasing hormone decreases circulating concentrations of ACTH, β -endorphin, follicle-stimulating hormone, and luteinizing hormone. Prolactin and growth hormone concentrations may be increased by opioids, and antidiuretic hormone (ADH) release is inhibited by opioids (see [Table 14-1](#)).¹

Respiratory Depression

Morphine and other μ agonists produce dose-dependent ventilatory depression primarily by decreasing the responsiveness of the medullary respiratory center to CO₂.³⁴ Standard therapeutic doses of morphine can produce a shift to the right and a decrease in slope of the ventilatory response to CO₂ curve, as well as abnormal breathing patterns.^{37,38} [Figure 14-3](#) illustrates the prolonged duration of an individual ventilatory response to CO₂ after high dose morphine (2 mg · kg⁻¹). Ventilatory depression, seen as a shift to the right and decrease in slope, was partially reversed by 1 hour after a naloxone loading dose (3.66 mg · kg⁻¹) plus continuous infusion (3.66 mg · kg⁻¹ · h⁻¹). During and after the 10-hour naloxone infusion, end-tidal CO₂ and ventilatory drive gradually returned to control values by 21 hours after the morphine dose.³⁹ The respiratory depressant effects of morphine are similar for young and elderly patients,^{37,38} but normal sleep markedly potentiates the effect of morphine on the ventilatory response to CO₂.⁴⁰ Frequent periods of oxygen desaturation associated with obstructive apnea, paradoxical breathing, and slow respiratory rate have been reported in patients who were receiving morphine infusions for postoperative analgesia. These episodes occurred only when the patients were asleep.⁴¹ Such reports emphasize the need to consider both the expected severity of postoperative pain as well as diurnal variations in pain and opioid sensitivity when including long-acting opioids such as morphine in the anesthetic. With increasing doses, periodic breathing resembling Cheyne-Stokes breathing, decreased hypoxic ventilatory drive, and apnea can occur.⁴² However, even with severe ventilatory depression, patients are usually arousable and will breathe on command.

Figure 14-3 Ventilatory response to CO₂ after morphine 2 mg · kg⁻¹, and antagonism by naloxone in a single subject. The control curve was obtained before morphine, and the prenaloxone curve 6 hours after morphine administration. The naloxone infusion was initiated 6 hours after morphine administration, and was continued at 4 mg · kg⁻¹ · h⁻¹ for 10 hours. The 5-hour postnaloxone curve was obtained 31 hours after the initial morphine dose. (Reprinted with permission from Johnstone RE, Jobes DR, Kennell *et al*: Reversal of morphine anesthesia with naloxone. *Anesthesiology* 41:361, 1974.)

Cough Reflex

Morphine and related opioids depress the cough reflex, at least in part by a direct effect on the medullary cough center. Doses required to attenuate the cough reflex are smaller than the usual analgesic dosage, and receptors mediating this effect appear to be less stereospecific and less sensitive to naloxone than those responsible for analgesia.¹ Dextroisomers of opioids, which do not produce analgesia, are also effective cough suppressants.¹

Muscle Rigidity

Large doses of iv morphine (2 mg · kg⁻¹ infused at 10 mg · min⁻¹) can produce abdominal muscle rigidity and decrease thoracic compliance; this effect reaches a plateau 10 minutes after morphine administration is complete.⁴³ Subjects receiving smaller doses of iv morphine (10–15 mg) also report feelings of muscle tension, most frequently in the neck or legs, but occasionally around the chest (unpublished observations). Muscle rigidity is drastically increased by the addition of 70% N₂O.⁴³ Myoclonus, sometimes resembling seizures, but without EEG evidence of seizure activity, has also been observed with high-dose opioids.⁴⁴ Opioid-induced muscle rigidity appears to be mediated by μ receptors⁴⁵ at supraspinal sites, including the nucleus raphe pontis and sites immediately lateral to it in the hindbrain.⁴⁶ In clinical practice, opioid-induced muscle rigidity and myoclonus are most often observed on induction, but have been observed postoperatively,⁴⁷ and can be severe enough to interfere with manual or mechanical ventilation. These effects are reduced or eliminated by naloxone,⁴⁷ drugs that facilitate GABA agonist activity (such as thiopental⁴³ and diazepam), and muscle relaxants.⁴⁷

Nausea and Vomiting

Nausea and vomiting are among the most distressing side effects of morphine and its derivatives. Increased postoperative vomiting is seen with morphine premedication as well as with the use of intraoperative opioids as part of a balanced anesthesia technique.⁴⁸ The incidence of opioid-induced nausea appears to be similar irrespective of the route of administration, including oral, intravenous, intramuscular, subcutaneous, transmucosal, transdermal, intrathecal, and epidural.⁴⁸ Furthermore, laboratory investigations and clinical postoperative studies comparing the incidence or severity of nausea and vomiting have found no differences among opioids, including morphine, meperidine, fentanyl, sufentanil, and alfentanil.^{32,48,49} Morphine causes dose-dependent nausea and vomiting, but the physiology and neuropharmacology of opioid-induced nausea and vomiting are complex (Fig. 14-4). The vomiting center receives input from the chemotactic trigger zone (CTZ) in the area postrema of the medulla, as well as from the pharynx, gastrointestinal tract, mediastinum, and visual center.^{48,50} The CTZ is rich in opioid, dopamine (D₂), serotonin (5-HT₂), histamine, and (muscarinic) acetylcholine receptors, and also receives input from the vestibular portion of the eighth cranial nerve. Morphine and related opioids induce nausea by direct stimulation of the CTZ, and can also produce increased vestibular sensitivity.¹ Therefore, vestibular stimulation such as ambulation markedly increases the nauseant and emetic effects of morphine. High doses of morphine and other opioids also have naloxone-reversible antiemetic effects at the level of the vomiting center.⁵¹ In volunteer studies, morphine-induced nausea and vomiting increase after a morphine infusion is stopped,⁵² which suggests that antiemetic effects are more short-lived than emetic effects. Another possible explanation for this observation is that the active metabolite morphine-6-glucuronide continues to accumulate and worsens nausea. Prophylaxis and treatment of opioid-induced nausea and vomiting includes the use of drugs that act as antagonists at the various receptor sites (above) in the CTZ as well as others, such as propofol and benzodiazepines, whose antiemetic mechanisms are unknown.⁴⁸

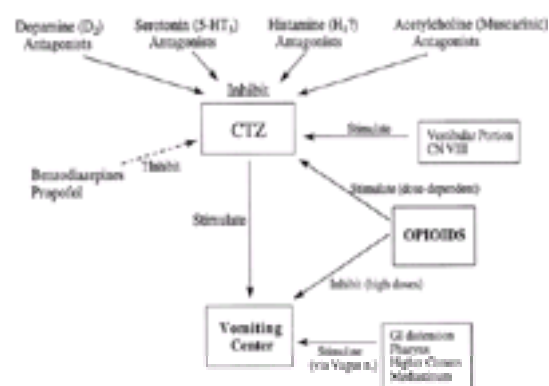

Figure 14-4 Pharmacology of nausea and vomiting. The chemotactic trigger zone (CTZ), located in the area postrema of the brain stem, contains dopamine, serotonin, histamine, and muscarinic acetylcholine as well as opioid receptors. The vomiting center receives input from the CTZ as well as peripheral sites via the vagus nerve. As illustrated, the role of opioids is complex, and they appear to have both emetic and antiemetic effects.

Gastrointestinal Motility and Secretion

Morphine and other opioids also affect gastrointestinal motility and propulsion, as well as gastric and pancreatic secretions via stimulation of opioid receptors in the brain, spinal cord, enteric muscle, and smooth muscle.^{42,53} Selective activation of m, k, and d opioid receptors at different anatomic sites affects each of these gastrointestinal functions differently.^{53,54} In rodents, m agonists inhibit gastric secretion, decrease gastrointestinal motility and propulsion, and suppress diarrhea when administered by intracerebroventricular, intrathecal, and peripheral injection.⁵³ A study in human volunteers demonstrated that methylbuprenorphine, an opioid antagonist that does not cross the blood–brain barrier, attenuated morphine-induced delay in gastric emptying,⁵⁵ suggesting that this effect is mediated primarily by a peripheral opioid mechanism. Morphine decreases lower esophageal sphincter tone and produces symptoms of gastroesophageal reflux in patients as well as normal volunteers,⁴² and diamorphine, a morphine derivative, significantly slows gastric emptying in postoperative patients. This may increase the risk of regurgitation and aspiration of gastric contents in anesthetized or sedated patients. Like other opioid effects, gastrointestinal effects are probably dose-related. In both the small and large bowel tone is increased, but propulsive activity is decreased, leading to constipation. Epidural morphine can also delay gastric emptying. A single epidural dose (4 mg) of morphine slowed gastric emptying, while an intramuscular dose did not.⁵⁶ How the effects of equianalgesic or repeated doses would compare is unknown.

Biliary Tract

Morphine and other opioids increase the tone of the common bile duct and sphincter of Oddi. Symptoms accompanying increases in biliary pressure can vary from epigastric distress to typical biliary colic, and may even mimic angina. While not consistently produced by therapeutic doses of morphine, biliary spasm can produce elevations in plasma amylase and lipase that may persist for up to 24 hours.¹ Morphine and other m agonists such as fentanyl have been used in provocative tests to evaluate sphincter of Oddi dysfunction and biliary-type pain.⁵⁷ In volunteers, morphine caused a greater delay in gallbladder emptying⁵⁸ and an increase in contractions of the sphincter of Oddi⁵⁹ than meperidine. Nitroglycerine, atropine, and naloxone can reverse opioid-induced increases in biliary pressure.¹ It has been suggested that morphine causes biliary tract contraction via histamine release. Antagonism of morphine's biliary effects by diphenhydramine supports this hypothesis.⁶⁰

Genitourinary Effects

Urinary retention, seen after both systemic and spinal morphine administration, is due to complex effects on central and peripheral neurogenic mechanisms. It results in dyssynergia between the bladder detrusor muscle and the urethral sphincter, due to a failure of sphincter relaxation.^{1,61} Estimates of the incidence of this bothersome side effect vary widely, and are confounded by the effects of anesthesia and surgery on urinary retention, but it is probably more common after spinal administration. Spinal morphine appears to cause naloxone-reversible urinary retention via m and/or d, but not k opioid receptors.⁶¹ The dopamine agonist apomorphine was also effective in treatment of spinal morphine-induced urinary retention in an animal model,⁶² but this treatment is not recommended for clinical practice because of the potent emetic effects of apomorphine. In the same study cholinomimetic agents and α -adrenergic agonists aggravated high intravesical pressures, and therefore may be harmful agents to use for treatment of morphine-induced urinary retention.

Histamine Release

Opioids stimulate the release of histamine from circulating basophils as well as from tissue mast cells in skin and lung in a heterogeneous manner.^{63,64} Morphine causes dose-dependent histamine release; intradermal injection of morphine in a concentration of 1 mg · ml⁻¹ induces an urticarial wheal and flare.⁶⁴ In human basophil and mast cell preparations, this effect appears to be selective for mast cells,^{63,64} particularly skin mast cells.⁶³ However, in an isolated perfused lung model, morphine increased pulmonary vascular resistance, which was reversed by histamine H₁-receptor antagonism.⁶⁵ Morphine-induced histamine release is not prevented by pretreatment with naloxone,⁶⁴ suggesting that histamine release is not mediated by opioid receptors. Morphine-induced histamine release has clinical relevance. The decrease in peripheral vascular resistance seen with high-dose morphine (1 mg · kg⁻¹) correlates well with elevated plasma histamine concentration.⁶⁶ Furthermore, differences in the release of histamine could account for most of the hemodynamic differences between morphine and fentanyl (Fig. 14-5).⁶⁶ Histamine release may also be responsible for increased pulmonary vascular resistance and acute pulmonary edema associated with intravenous opioid abuse.⁶⁵

Figure 14-5 Mean arterial pressure (BP), systemic vascular resistance (SVR), and plasma histamine concentration (mean \pm SE) before and after morphine 1 mg \cdot kg⁻¹ and fentanyl 50 mg \cdot kg⁻¹ (both infused over 10 minutes). Morphine, but not fentanyl, causes significant decrements in BP and SVR, which parallel the increase in plasma histamine concentration. (Reprinted with permission from Rosow CE, Moss J, Philbin DM *et al*: Histamine release during morphine and fentanyl anesthesia. *Anesthesiology* 56:93, 1982.)

Cardiovascular Effects

Opioids are popular in clinical anesthesia because they reliably produce analgesia and stable hemodynamics. In doses typically used for pain management or as part of balanced anesthesia, morphine has little effect on blood pressure or heart rate and rhythm in the supine, normovolemic patient. However, therapeutic doses of morphine can produce arteriolar and venous dilation, decreased peripheral resistance, and inhibition of baroreceptor reflexes,¹ which can lead to postural hypotension. Peripheral vasodilation is thought to be mediated by central sympatholytic activity. Thus, morphine's effect on vascular resistance is greater under conditions of high sympathetic tone.⁶⁷ The clinical implications of this finding are important. Patients who are critically ill (*e.g.*, patients with severe trauma or cardiac disease) can be expected to have high sympathetic tone, and thus may experience hypotension in response to doses of morphine which would not normally produce hemodynamic instability. Morphine may also have some direct action on vascular smooth muscle,⁶⁷ but the primary mechanism for morphine-mediated vasodilation appears to be histamine release, as discussed earlier. At clinically relevant doses, morphine does not suppress myocardial contractility.^{1,68} However, opioids do produce dose-dependent bradycardia, probably by both sympatholytic and parasympathomimetic mechanisms.⁶⁹ In clinical anesthesia practice, opioids are often used to prevent tachycardia and reduce myocardial oxygen demand. Patients undergoing cardiovascular surgery who received morphine 1–2 mg \cdot kg⁻¹ experienced minimal changes in heart rate, mean arterial pressure, cardiac index, and systemic vascular resistance. However, outcome was no different from that achieved with carefully administered inhalation-based anesthesia.⁶⁹

Morphine does not directly affect cerebral circulation. However, with morphine-induced respiratory depression, CO₂ retention causes cerebral vasodilation and an elevation in cerebrospinal fluid pressure. This effect is not seen when mechanical ventilation is used to prevent hypercarbia.¹ Thus, morphine and other potent opioids must be used with caution in spontaneously breathing patients with head injury or other conditions associated with elevated intracranial pressure.

Disposition Kinetics

Morphine is rapidly absorbed after intramuscular, subcutaneous, and oral administration. Following intramuscular administration, peak plasma concentration is seen at 20 minutes and absorption half-life is estimated at 7.7 minutes (range 2–15 min).⁷⁰ After intravenous administration morphine undergoes rapid redistribution, with a mean redistribution half-time between 1.5 and 4.4 minutes in awake and anesthetized adults.^{70,71} and ⁷² Morphine has a terminal elimination half-life between 1.7 and 3.3 hours.^{71,72} and ⁷³ Age affects morphine pharmacokinetics. The average elimination half-life of morphine is 7–8 hours in neonates less than 1 week of age, and 3–5 hours in older infants.⁷⁴ Patients between 61 and 80 years were found to have a terminal elimination half-life of 4.5 hours compared to 2.9 hours in younger patients.⁷⁰

Morphine is about 35% protein-bound, mostly to albumin.¹⁴ Its steady-state volume of distribution is large, with estimates in the range of 3–4 l \cdot kg⁻¹ in normal adults.^{70,71} and ⁷² Morphine's major metabolic pathway is phase II conjugation. In the liver, morphine undergoes extensive conjugation to form morphine-3-glucuronide (M3G) and morphine-6b-glucuronide (M6G). 3-Glucuronidation is the predominant pathway, and following a single intravenous morphine dose, 40% and 10% of the dose are excreted in the urine as M3G and M6G, respectively.⁷⁵ Unchanged morphine in the urine accounts for only about 10% of the dose. Other minor metabolites in urine are morphine-3, 6-diglucuronide, morphine-3-etheral sulfate, normorphine, and its 3- and 6-glucuronides. The rate of hepatic clearance of morphine is high, with a hepatic extraction ratio of 0.7.⁷⁰ Thus, morphine elimination may be slowed by processes that decrease hepatic blood flow.⁷² Extrahepatic sites, such as kidney, intestine, and lung, have been suggested for morphine glucuronidation, but their importance in humans is unknown.

Active Metabolites

M6G possesses significant m receptor affinity and potent antinociceptive activity.⁷⁶ Appreciable plasma concentrations of M6G and M3G have been measured in cancer patients receiving high doses of oral morphine. During chronic oral morphine therapy, plasma M6G concentrations can be higher than those of the parent morphine compound.⁷⁷ Because morphine glucuronides are eliminated by the kidney, it is not surprising that very high M6G:morphine ratios have been reported in patients with renal dysfunction. This accumulation of the active metabolite is thought to be responsible for the unusual sensitivity of renal failure patients to morphine. While common wisdom suggests that glucuronide conjugates do not penetrate the blood–brain barrier, M6G concentration in cerebrospinal fluid (CSF) is 20–80% that of morphine.⁷⁸ Despite a mounting volume of animal literature demonstrating the analgesic potency of M6G, there is little information in humans concerning the magnitude of analgesia and side effects of M6G relative to morphine. Portenoy *et al*⁷⁹ demonstrated that in cancer patients on chronic morphine therapy, pain relief correlated positively with the M6G:morphine ratio, suggesting a contributing role of M6G to overall morphine analgesia. In a study of cancer patients with severe pain who received synthetic M6G (up to 60 mg \cdot kg⁻¹), 17 of 19 patients experienced effective analgesia, with no changes in blood pressure or minute ventilation, and no nausea.⁷⁹ However, side effects such as dizziness, nausea, sedation, muscle aches, and respiratory depression have been reported in volunteers who received M6G.⁷⁷ While the contribution of M6G to morphine-induced analgesia and side effects remains to be determined, morphine should probably be administered cautiously to patients with renal failure.

Dosage and Administration of Morphine

In clinical practice morphine is used as a premedicant, a component of balanced anesthesia, in high-dose opioid anesthesia, and for postoperative analgesia. Intravenous analgesic doses of morphine for adults typically range from 0.01 to 0.20 mg \cdot kg⁻¹. When used in a balanced anesthetic technique with N₂O, morphine can be given in total doses of up to 3 mg \cdot kg⁻¹ with remarkable hemodynamic stability. However, with the use of morphine 3 mg \cdot kg⁻¹ as the sole “anesthetic” agent, awareness (but not pain) has been reported.³ When used in conjunction with other inhalation agents, it is unlikely that more than 1–2 mg \cdot kg⁻¹ of morphine is necessary. Because of its hydrophilicity, morphine crosses the blood–brain barrier relatively slowly; and while its onset can be observed within 5 minutes, peak effects may be delayed for 10 minutes or longer. Because of its delay in action, morphine can be more difficult to titrate as an anesthetic supplement than the more rapidly acting opioids. Patients may experience prolonged analgesia and adverse side effects such as respiratory depression even when plasma morphine concentration is low. However, Gross and Alexander⁸⁰ reported that a single dose of morphine 0.1 mg \cdot kg⁻¹ given 80 minutes prior to the end of surgery did not affect the time to awakening or the awakening concentration of isoflurane.

Meperidine

Meperidine, a phenylpiperidine derivative (Fig. 14-6), was the first totally synthetic opioid, described in 1939 by Eisleb and Schaumann. It was initially studied as an anticholinergic agent, but was found to have significant analgesic activity.¹

Figure 14-6 Chemical structures of phenylpiperidine, meperidine, and the 4-anilinopiperidine derivatives fentanyl, sufentanil, alfentanil, and remifentanil.

Analgesia and Effect on MAC of Volatile Anesthetics

Meperidine's analgesic potency is about one tenth that of morphine's and is most likely mediated by m opioid receptor activation. However, meperidine also has moderate affinity for k and d opioid receptors.^{1,81} Unlike morphine, meperidine plasma concentrations correlate reasonably well with analgesic effects.^{82,83} While there is considerable interpatient variability, the minimum effective analgesia concentration of meperidine is approximately $200 \text{ ng} \cdot \text{mL}^{-1}$. There is very little information available on the effect of meperidine on MAC of inhaled anesthetics, but a study in dogs demonstrated a dose-dependent reduction in the MAC of halothane.⁸⁴

Meperidine also has well recognized weak local anesthetic properties. Compared to morphine, fentanyl, and buprenorphine injected perineurally, only meperidine alters nerve conduction and produces analgesia.^{85,86} This has led to its increasing popularity for epidural and subarachnoid administration, particularly in obstetric anesthesia. But because of its local anesthetic effects, spinal meperidine may also produce sensory and motor blockade as well as sympatholytic effects that are not seen with other opioids.

Side Effects

Like morphine, therapeutic doses of meperidine can produce sedation, pupillary constriction, and euphoria. Very high doses of meperidine are associated with CNS excitement and seizures (see below). In equianalgesic doses, meperidine produces respiratory depression equal to that of morphine, as well as nausea, vomiting, and dizziness, particularly in ambulatory patients.¹

Like other opioids, meperidine causes significant delay in gastric emptying. While meperidine does increase common bile duct pressure and delay gall bladder emptying, this occurs to a lesser extent than with equianalgesic doses of morphine and fentanyl (Fig. 14-7).^{58,89}

Figure 14-7 The effect of several opioids on common bile duct pressures in patients anesthetized with enflurane and $\text{N}_2\text{O}-\text{O}_2$. Patients received either fentanyl $100 \text{ mg} \cdot 70 \text{ kg}^{-1}$, morphine $10 \text{ mg} \cdot 70 \text{ kg}^{-1}$, meperidine $75 \text{ mg} \cdot 70 \text{ kg}^{-1}$, or butorphanol $2 \text{ mg} \cdot 70 \text{ kg}^{-1}$. After 20 minutes, the effects were reversed with naloxone. (Reprinted with permission from Radnay PA, Duncalf D, Novakovic M, Lesser ML: Common bile duct pressure changes after fentanyl, morphine, meperidine, butorphanol, and naloxone. *Anesth Analg* 63:441, 1984.)

Analgesic doses of meperidine in awake patients are not associated with hemodynamic instability. However, patients with cardiac disease who received $1 \text{ mg} \cdot \text{kg}^{-1}$ of meperidine experienced decreases in heart rate, cardiac index, and rate-pressure product.⁹⁰ In an isolated papillary muscle preparation, high concentrations of meperidine depressed contractility. This effect was not naloxone-reversible and is consistent with a nonspecific, local anesthetic effect.⁹¹ In higher doses, meperidine causes significantly more hemodynamic instability than morphine or fentanyl and its derivatives.⁹² This may be at least partially related to histamine release. In a comparison of opioids administered as part of balanced anesthesia, Flacke *et al*⁹² found that 4 of 16 patients in the meperidine group did not receive the total planned induction dose ($5 \text{ mg} \cdot \text{kg}^{-1}$) because of hypotension. Five patients developed tachycardia, three of these with marked flushing. These five patients were found to have abnormally elevated plasma histamine concentrations. Interestingly, only one patient in the morphine group ($0.6 \text{ mg} \cdot \text{kg}^{-1}$ morphine given) had a similar histamine plasma concentration. Thus, meperidine is not recommended in high doses for clinical anesthesia.

Shivering

Meperidine is effective in reducing shivering from diverse causes, including general and epidural anesthesia, fever, experimentally induced cold, transfusion reactions, and administration of amphotericin B. Intravenous doses of 25–50 mg reduce or eliminate visible shivering as well as the accompanying increase in oxygen consumption^{93,94} following general and epidural anesthesia. Equianalgesic doses of fentanyl (25 mg) and morphine (2.5 mg) did not reduce postoperative shivering,⁹⁵ suggesting that the antishivering effect of meperidine is not mediated by m-opioid receptors. Several observations suggest that this effect may be mediated by k-opioid receptors. Butorphanol, a drug with significant k agonist activity, effectively reduces postoperative shivering in a dose of 1 mg.⁹⁶ Furthermore, low doses of naloxone, sufficient to block m receptor-mediated miosis, did not reverse meperidine's antishivering effect, but high-dose naloxone, designed to block both m and k receptors, did reverse the antishivering effect.⁸¹ However, infusion of alfentanil, a pure m agonist, has been shown to impair thermoregulation, including reducing the shivering threshold and raising the sweating threshold.⁹⁷ The plasma alfentanil concentrations measured in this study were typical of those used during alfentanil anesthesia. Whether a smaller dose of alfentanil can eliminate postoperative shivering has not been evaluated. The observation that other types of drugs, such as α_1 -adrenergic agonists and serotonin (5-HT_2) antagonists⁹⁸ as well as propofol,⁹⁹ can also reduce postoperative shivering suggests that a nonopioid mechanism may be involved. Physostigmine can also prevent postoperative shivering, suggesting a role for the cholinergic system. Horn¹⁰⁰ and others⁹⁷ suggest that a central inhibition of thermoregulatory control is the mechanism by which many classes of drugs reduce or prevent shivering. Perhaps meperidine's greater antishivering effect, relative to other opioids, is due to additive thermoregulatory impairment by more than one mechanism.

Disposition Kinetics

Following intravenous administration, meperidine plasma concentration falls rapidly, and has been described by both two- and three-compartment models. Meperidine's redistribution phase is rapid, with a half-life of 4–16 minutes,^{101,102} and its terminal elimination half-life is between 3 and 5 hours.^{101,102} and ¹⁰³ The elimination half-life is not prolonged in patients 60–80 years old. However, in neonates and infants, a median elimination half-life, 8–10 hours, with greater individual variability (3–5-fold) compared to adults, has been reported. Absorption after intramuscular administration was complete in normal volunteers, with peak plasma concentration at 5–15 minutes after injection; but in postoperative patients, intramuscular meperidine absorption can be more variable, with time to reach peak concentration between 5 and 110 minutes.⁸²

Meperidine is moderately lipid-soluble, and is about 40–70% protein-bound, mostly to albumin and α_1 -acid glycoprotein (Table 14-2).¹⁰⁴ Meperidine has a large steady-state volume of distribution, with estimates in the range of $3.5\text{--}51 \cdot \text{kg}^{-1}$ in adults.^{101,102} The high clearance rate ($10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) reflects a high hepatic extraction ratio. Meperidine is metabolized mainly in the liver by *N*-demethylation to form normeperidine, the principal metabolite, and by hydrolysis to form meperidinic acid. Both of these metabolites may then be conjugated¹ and excreted renally. Normeperidine is pharmacologically active and potentially toxic (see below).

Active Metabolites

Normeperidine has appreciable pharmacologic activity, and can produce signs of central nervous system excitation. In humans, mood alterations such as apprehension and restlessness, as well as neurotoxic effects such as tremors, myoclonus, and seizures, have been reported.¹⁰⁵ The elimination half-life of the metabolite normeperidine (14–21 hours) is considerably longer than the parent compound, and therefore is likely to accumulate with repeated or prolonged administration, particularly in patients with renal dysfunction.¹⁰⁵ Myoclonus and seizures have been reported in patients receiving meperidine for postoperative or chronic pain. Patients who developed seizures had a mean plasma normeperidine concentration of $0.81 \text{ mg} \cdot \text{mL}^{-1}$,¹⁰⁵ and it appears that a total daily dosage of 1000 mg is associated with an increased risk of seizures.

Dosage and Administration of Meperidine

A single dose of meperidine is approximately one tenth as potent as morphine when given parenterally, but has a shorter duration of action. Intravenous analgesic doses of meperidine for adults typically range from 0.1 to 1 mg · kg⁻¹. Doses of 25–50 mg are generally effective in reducing postoperative shivering, but doses as low as 12.5 mg may be effective in some individuals. As discussed above, high doses of meperidine for intraoperative use are not recommended due to hemodynamic instability. In addition very high single doses or prolonged administration may produce seizures due to the metabolite normeperidine; thus the total daily dose should not exceed 1000 mg/24 hours.

Methadone

Methadone, a synthetic opioid introduced in the 1940s, is primarily a μ agonist with pharmacologic properties that are similar to morphine. While its chemical structure is very different from that of morphine, steric factors force the molecule to simulate the pseudopiperidine ring conformation that appears to be required for opioid activity.¹ Because of its long elimination half-life, methadone is most often used for long-term pain management and in treatment of opioid abstinence syndromes.

Analgesia and Use in Anesthesia

Following parenteral administration, the onset of analgesia is rapid, within 10–20 minutes. After single doses of up to 10 mg, the duration of analgesia is similar to morphine,¹ but with large or repeated parenteral doses, prolonged analgesia can be obtained. Several investigators have administered methadone intra- and postoperatively with the aim of providing prolonged postoperative analgesia.^{106,107} and ¹⁰⁸ Patients who received 20 mg methadone intraoperatively and up to 20 mg additional methadone in the immediate postoperative period had a median duration of postoperative analgesia of over 20 hours.^{106,107} Gourlay *et al*¹⁰⁷ found that for relief of postoperative pain, the minimum effective concentration of methadone in blood is 58 ng · ml⁻¹ (range 34–80 ng · ml⁻¹). The effect of methadone on the MAC of volatile anesthetics has not been reported.

Side Effects

Side effects of methadone are similar in magnitude and frequency to those of morphine.^{1,106} Patients who received 20 mg methadone at the beginning of surgery were sedated in the immediate postoperative period, but did not appear to have clinically significant respiratory depression. About 50% experienced nausea or vomiting, which was easily treated with standard antiemetic therapy.¹⁰⁶ Methadone produces typical opioid effects on smooth muscle. Like morphine, it markedly decreases intestinal propulsive activity, and can cause constipation as well as biliary spasm.¹

Disposition Kinetics

Following an intravenous dose, the plasma concentration-time data for methadone are described by a biexponential equation. The mean redistribution half-time is 6 minutes (range 1–24 min), and the mean terminal elimination half-time is 34 hours (range 9–87 h).¹⁰⁷ Methadone is well absorbed after an oral dose, with bioavailability approximately 90%, and reaches peak plasma concentration at 4 hours after oral administration.¹ It is nearly 90% plasma protein-bound, and undergoes extensive metabolism in the liver, mostly *N*-demethylation and cyclization to form pyrrolidines and pyrroline.¹

Dosage and Administration of Methadone

The use of methadone in clinical anesthesia has focused on attempts to achieve prolonged postoperative analgesia, providing that an adequate initial dose is administered. Because adverse effects can also be prolonged, careful titration of the dose is necessary. In general, an initial single dose of 20 mg can provide analgesia without significant postoperative respiratory depression.¹⁰⁶ Wangler¹⁰⁸ described a technique to avoid respiratory depression in which 8–12 mg methadone is administered to the awake patient until the threshold of respiratory depression (respiratory rate of 6–8 min⁻¹) is reached. Immediately prior to incision, an additional dose equal to half the initial dose is given. For patients who need supplemental analgesic doses in the immediate postoperative period, Gourlay *et al*¹⁰⁹ have suggested that to avoid respiratory depression, the patients must meet the following criteria prior to each supplementary dose of methadone 5 mg:

1. The patient complains of significant postoperative pain
2. The respiratory rate is >10 breaths per minute
3. No marked depression of the level of consciousness is observed

They also recommend that 30–40 minutes (5–6 times the mean distribution half-life) should elapse between supplementary doses to allow full assessment of the effects of the previous dose.

Fentanyl

Fentanyl and its analogs sufentanil and alfentanil are the most frequently used opioids in clinical anesthesia today. Fentanyl, first synthesized in 1960, is structurally related to the phenylpiperidine (see Fig. 14-6), and has a clinical potency ratio 50–100 times that of morphine. Clear plasma concentration–effect relationships have been demonstrated for fentanyl (Table 14-3). Scott *et al*¹¹⁰ demonstrated progressive EEG changes with increasing serum fentanyl concentration (Fig. 14-8). During a 5-minute fentanyl infusion, the time lag between increasing serum fentanyl concentration and EEG slowing was 3–5 minutes. After the infusion was stopped, the resolution of EEG changes lagged behind decreasing serum fentanyl concentration by 10–20 minutes.

| Effect | Morphine | Meperidine | Fentanyl | Sufentanil | Alfentanil | Remifentanyl |
|---|----------|--------------|----------|------------|------------|--------------|
| MEAC | 10–15 | 20 | 6.1 | 0.5 | 5 | |
| Moderate to strong analgesia | 20–50 | 40–60 | 15–1 | 0.5–1.0 | 4–6 | |
| 5% MAC reduction | NA | >90 | 0.5–1 | 0.16 | 20 | 13 |
| Surgical analgesia with ~70% N ₂ O | NA | NA | 15–25 | NA | 30–50 | |
| Respiratory depression threshold | 25 | 20 | 1 | 0.02–0.04 | 50–100 | |
| 5% ↓ ventilatory response to CO ₂ | 30 | NA | 1.5–1 | 0.04 | 25–50 | 1.07–2.07 |
| Apnea | NA | NA | 7–2 | NA | 30–60 | |
| Unconsciousness (not reliably achieved with opioid alone) | | (Sufentanil) | 15–20 | NA | 30–50 | |

Effects were generally achieved during continuous infusions or patient-controlled analgesia systems. Note that plasma concentrations associated with noticeable depression of ventilatory drive are similar to those associated with analgesia for all opioids.
MEAC = minimum effective analgesic concentration, defined in most studies as the plasma opioid concentration associated with just perceptible analgesia. NA = information not available.

Table 14-3. PLASMA CONCENTRATION RANGES (ng · ml⁻¹) FOR VARIOUS THERAPEUTIC AND NONTHERAPEUTIC OPIOID EFFECTS

Figure 14-8 The time course of EEG spectral edge and serum concentrations of fentanyl (A) and alfentanil (B). Infusion rates were 150 mg · min⁻¹ fentanyl and 1500 mg · min⁻¹ alfentanil. Increasing opioid effect is seen as a decrease in spectral edge. Changes in spectral edge follow serum concentrations more closely with alfentanil

than with fentanyl. (Reprinted with permission from Scott JC, Ponganis KV, Stanski DR: EEG quantitation of narcotic effect: The comparative pharmacodynamics of fentanyl and alfentanil. *Anesthesiology* 62:234, 1985.)

Analgesia

Fentanyl is a μ -opioid receptor agonist that produces profound dose-dependent analgesia, ventilatory depression, sedation, and at high doses can produce unconsciousness. In postoperative patients receiving fentanyl by a patient-controlled analgesia system, the mean fentanyl dose requirement was $55.8 \text{ mg} \cdot \text{h}^{-1}$, and mean minimum effective analgesic concentration (MEAC) in blood was $0.63 \text{ ng} \cdot \text{mL}^{-1}$.¹¹¹ A large interpatient variability in MEAC ($0.23\text{--}1.18 \text{ ng} \cdot \text{mL}^{-1}$) typical of opioids was observed, but over the 2-day study period, the MEAC for any individual patient remained relatively constant. In a volunteer study, a mean plasma fentanyl concentration of $1.3 \text{ ng} \cdot \text{mL}^{-1}$ reduced experimental pain intensity ratings by 50%.⁴⁹ This is consistent with other estimates of plasma fentanyl concentrations associated with mild to moderate analgesia.¹¹²

Effect on MAC of Volatile Anesthetics and Use in Anesthesia

Fentanyl reduces the MAC of volatile anesthetics in a concentration- or dose-dependent fashion. A single intravenous bolus dose of fentanyl $3 \text{ mg} \cdot \text{kg}^{-1}$, given 25–30 minutes prior to incision, reduced both isoflurane and desflurane MAC by approximately 50%.¹¹³ Fentanyl $1.5 \text{ mg} \cdot \text{kg}^{-1}$ administered 5 minutes prior to skin incision reduces the minimum alveolar concentration which blocks adrenergic responses to stimuli (MAC-BAR) of isoflurane or desflurane in 60% N_2O by 60–70%.¹¹⁴ No further drop is seen with an increase in fentanyl dose to $3 \text{ mg} \cdot \text{kg}^{-1}$. Utilizing a computer-assisted continuous infusion (CACI) designed to provide constant fentanyl concentrations, a 50% reduction of isoflurane MAC was associated with plasma fentanyl concentrations of $0.5\text{--}1.7 \text{ ng} \cdot \text{mL}^{-1}$.^{115,116} Fentanyl produces a steep concentration-related reduction in sevoflurane MAC.¹¹⁷ Fentanyl $3 \text{ ng} \cdot \text{mL}^{-1}$ provides a 59% reduction. Further increases in fentanyl concentration produce a ceiling effect, such that a 3-fold increase to $10 \text{ ng} \cdot \text{mL}^{-1}$ reduced MAC by only an additional 17%.

Epidural fentanyl reduces halothane MAC in patients undergoing hysterectomy.¹¹⁸ Epidural fentanyl 1, 2, and $4 \text{ mg} \cdot \text{kg}^{-1}$ reduced halothane MAC by 45, 58, and 71%, respectively, while the same doses of fentanyl given iv reduced halothane MAC by 8, 40, and 49%, respectively.

Combining opioids with propofol rather than an inhalation agent is another common technique for providing general anesthesia, and is often referred to as “total intravenous anesthesia” or TIVA. For an intravenous anesthetic, the potency index is described as the plasma concentration required to prevent a response in 50% (CP_{50}) or 95% (CP_{95}) of patients to various surgical stimuli. Plasma concentrations of fentanyl and propofol that reduce hemodynamic or somatic responses to various surgical stimuli in 50% of patients have been determined using computer-assisted continuous infusion.¹¹⁹ Fentanyl plasma concentrations of 1.2, 1.8, and $2.8 \text{ ng} \cdot \text{mL}^{-1}$ were required for 50% reductions in propofol's CP_{50} s for skin incision, peritoneal incision, and abdominal retraction, respectively. Greater fentanyl concentrations were required to suppress hemodynamic responses to these same stimuli. Thus, fentanyl reduces requirements for both volatile agents and propofol by a similar proportion.

Several other investigators have also used computer-assisted continuous infusion to administer fentanyl as a component of a balanced anesthetic technique.^{120,121} and ¹²² In combination with 50% N_2O in oxygen, loss of consciousness is achieved at a plasma fentanyl concentration between 15 and $25 \text{ ng} \cdot \text{mL}^{-1}$. Patients whose plasma fentanyl concentrations are maintained greater than $3.7 \text{ ng} \cdot \text{mL}^{-1}$ did not respond to skin incision, and concentration requirements during the course of surgery varied between 1 and $9 \text{ ng} \cdot \text{mL}^{-1}$. Finally, spontaneous ventilation upon emergence from anesthesia was seen when the fentanyl concentration dropped to $1.5\text{--}2 \text{ ng} \cdot \text{mL}^{-1}$.^{120,121} Given with 70% N_2O , similar plasma fentanyl concentrations were required to prevent movement and hemodynamic response to skin incision in 50% of patients.¹²²

Fentanyl has also been used as the sole agent for anesthesia, a technique that requires a large initial dose of $50\text{--}150 \text{ mg} \cdot \text{kg}^{-1}$ or stable plasma fentanyl concentrations in the range of $20\text{--}30 \text{ ng} \cdot \text{mL}^{-1}$.¹¹² The major advantage of this technique, particularly in patients with coronary disease, is in the reliable hemodynamic stability that is achieved. High doses of fentanyl significantly blunt the “stress response”—*i.e.*, hemodynamic and hormonal responses to surgical stimuli—while producing only minimal cardiovascular depression. Thus, the technique is sometimes referred to as “stress-free anesthesia.” There are also disadvantages to using high-dose fentanyl as the sole anesthetic agent. It appears that no dose of fentanyl will completely block hemodynamic or hormonal responses in all patients.¹²³ Furthermore, although high doses generally result in unconsciousness, there have been reports of intraoperative awareness and recall in patients who received 5000 mg of fentanyl.¹²⁴ Because opioids do not produce muscle relaxation, and high-dose fentanyl can produce muscle rigidity, a muscle relaxant is generally required to achieve adequate surgical conditions. This can potentially increase the difficulty in detecting signs of intraoperative awareness. EEG monitoring has been used to assess the depth of anesthesia achieved with high-dose opioids, and high-dose fentanyl produces typical opioid effects on the EEG. That is, a marked shift to the left in frequency and amplitude, including an increased low-frequency amplitude (d waves) and a decrease in higher frequency amplitudes (a and b).³³

Other CNS Effects

The effects of fentanyl on cerebral blood flow (CBF) and intracranial pressure (ICP) have been studied in normal patients as well as in those with neurologic disease. An induction dose of $16 \text{ mg} \cdot \text{kg}^{-1}$ increased middle cerebral artery flow by 25% in normal patients having noncranial neurosurgery.¹²⁵ A smaller dose ($3 \text{ mg} \cdot \text{kg}^{-1}$) resulted in an elevation in ICP in ventilated patients with head trauma.¹²⁶ However, in brain tumor patients anesthetized with $\text{N}_2\text{O}\text{--O}_2$, a dose of $5 \text{ mg} \cdot \text{kg}^{-1}$ of fentanyl did not result in elevated ICP.¹²⁷ In all cases of elevation in ICP and CBF, there were decreases in mean arterial pressure, which may have contributed to these changes.

Muscle rigidity is often seen on induction with high-dose fentanyl and its derivatives. When rigidity is intense, it may be difficult or impossible to ventilate the patient. In a study in normal volunteers, 1500 mg fentanyl infused over 10 minutes produced rigidity in 50% of subjects.¹²⁸ A similar incidence, 35%, was seen in patients receiving $750\text{--}1000 \text{ mg}$ fentanyl during induction of general anesthesia,⁴⁵ and up to 80% of patients receiving $30 \text{ mg} \cdot \text{kg}^{-1}$ developed moderate to severe rigidity.¹²⁹ Muscle rigidity seen with high doses of fentanyl increases with age,¹²⁹ and is accompanied by unconsciousness and apnea^{128,129}; but lower doses, $7\text{--}8 \text{ mg} \cdot \text{kg}^{-1}$, have produced chest wall rigidity without unconsciousness or apnea. Streisand *et al.*¹²⁸ hypothesized that hypercarbia from fentanyl-induced respiratory depression may have influenced fentanyl ionization and cerebral blood flow, and hence the delivery of fentanyl to brain tissue. It would follow that patients instructed to deep-breathe during fentanyl induction may experience less rigidity during induction of anesthesia. This is consistent with observations by Lunn *et al.*¹³⁰ During high-dose fentanyl induction ($75 \text{ mg} \cdot \text{kg}^{-1}$), PaCO_2 was maintained at 35–40 torr by assisting and then controlling respirations at 10–15 breaths/minute. Chest wall compliance was reduced in 4 of 18 patients, but no patient developed rigidity sufficient to impair ventilation.

Fentanyl has also been associated with seizure-like movements during anesthetic induction. However, this activity is not associated with seizure activity on the EEG.¹³¹ Whereas fentanyl can induce seizures in other animals, the doses required to produce EEG-documented seizures is generally higher than that used in humans. Such activity may represent myoclonus, due to opioid-mediated blockade of inhibitory motor pathways of cortical origin, or may represent exaggerations of opioid-induced muscle rigidity.¹³¹ Manninen demonstrated that both fentanyl and alfentanil activate epileptiform EEG activity in patients having surgery under general anesthesia for intractable temporal lobe epilepsy.¹³²

Fentanyl-induced pruritus often presents as facial itching, but can be generalized. A comparison of iv fentanyl with morphine and alfentanil demonstrated that the intensity of pruritus was equivalent among all three opioids at equianalgesic plasma concentrations.⁴⁹ Fentanyl has also been reported to have a tussive effect. Twenty-eight percent of patients coughed within 1 minute after receiving a bolus dose of fentanyl ($1.5 \text{ mg} \cdot \text{kg}^{-1}$). While the mechanism of this tussive effect is unclear, it was attenuated by pretreatment with morphine but not by atropine or midazolam.¹³³

Respiratory Depression

Fentanyl produces approximately the same degree of ventilatory depression as equianalgesic doses of morphine.⁴⁹ Respiratory depression—expressed as an elevation in end-tidal CO_2 , a decrease in the slope of the CO_2 response curve, or the minute ventilation at an end-tidal CO_2 of 50 mm Hg (V_{E50})—develops rapidly, reaching a peak in ~5 minutes,^{110,134,135} and the time course closely follows plasma fentanyl concentration,^{134,136} as illustrated in Figure 14-9. Even at plasma concentrations associated with mild analgesia, ventilatory depression can be detected, and the magnitude of respiratory depression is linearly related to intensity of analgesia (Table 14-3).^{49,137} In postoperative patients, plasma fentanyl concentrations of $1.5\text{--}3.0 \text{ ng} \cdot \text{mL}^{-1}$ were associated with a 50% reduction in CO_2 responsiveness.¹³⁸

Figure 14-9 Comparison of the decline in plasma fentanyl concentration in 5 subjects given fentanyl $6.4 \text{ mg} \cdot \text{kg}^{-1}$ with 10 different subjects who received fentanyl $6 \text{ mg} \cdot \text{kg}^{-1}$ intravenously. A close correlation is seen between changes in plasma fentanyl concentration and ventilatory depression. (Reprinted with permission from McClain DA, Hug CC Jr: Intravenous fentanyl kinetics. Clin Pharmacol Ther 28:106, 1980.)

The magnitude of respiratory depression can be greatly increased when fentanyl is given in combination with another respiratory depressant such as midazolam. Bailey *et al*¹³⁵ determined that midazolam alone ($0.05 \text{ mg} \cdot \text{kg}^{-1}$) did not depress ventilation or cause hypoxemia. Fentanyl alone ($2 \text{ mg} \cdot \text{kg}^{-1}$) reduced the slope of the CO_2 response curve and the V_{E50} by 50%, and 6 of 12 subjects became hypoxemic. Fentanyl and midazolam produced no greater depression of the ventilatory response to CO_2 than fentanyl alone, but 11 of 12 subjects became hypoxemic and 6 of 12 became apneic within 5 minutes. These observations suggest that this frequently used combination blunts the hypoxic ventilatory drive to a greater extent than the hypercarbic ventilatory drive. Precautions such as supplemental oxygen and pulse oximetry monitoring are recommended when such drug combinations are used.

Airway Reflexes

Although obtundation of airway reflexes by general inhalation anesthetics is well described, little is known about the direct effects of opioids on these protective reflexes. Tagaito *et al* examined the dose-related effects of fentanyl on airway responses to laryngeal irritation during propofol anesthesia in humans.¹³⁹ All patients had laryngeal mask airways; half breathed spontaneously, and half had ventilation controlled to maintain an end-tidal CO_2 of 38 mm Hg. In both groups, stimulation of the larynx (application of water to mucosa) elicited a forced expiration, followed by spasmodic panting mingled with cough reflexes and brief laryngospasm. With three cumulative fentanyl doses (50, 50, and 100 mg), expiration, panting, and coughing decreased in a dose-dependent fashion. After the first dose of fentanyl, apnea with laryngospasm replaced the other reflexes, and with cumulative fentanyl dosing, the duration of laryngospasm shortened. These investigators also described specific characteristic laryngeal behaviors, which were observed endoscopically during laryngeal stimulation. Cough was the airway reflex most vulnerable to depression by fentanyl. While attenuation of airway reflexes is desirable during general anesthesia, it is equally desirable that these protective reflexes should return to baseline rapidly after emergence. Doses required to suppress cough and other reflexes in awake or sedated individuals have not been characterized.

Cardiovascular and Endocrine Effects

Isolated heart muscle models have shown concentration-dependent negative inotropic effects of opioids, including morphine, meperidine, and fentanyl.⁶⁹ Fentanyl concentrations up to $1 \text{ mg} \cdot \text{ml}^{-1}$ had no significant effects on papillary muscle mechanics, while $10 \text{ mg} \cdot \text{ml}^{-1}$ reduced contractility by 50%. In clinical practice, high-dose fentanyl administration (up to $75 \text{ mg} \cdot \text{kg}^{-1}$) produces much lower plasma concentrations, *i.e.*, in the range of $50 \text{ ng} \cdot \text{ml}^{-1}$,¹³⁰ and is associated with remarkable hemodynamic stability. Patients who received $7 \text{ mg} \cdot \text{kg}^{-1}$ fentanyl at induction of anesthesia had a slight decrease in heart rate, but no change in mean arterial pressure compared to control.⁹² Fentanyl-induced bradycardia is more marked in anesthetized than conscious subjects, but atropine is usually effective in treating opioid-induced bradycardia. Fentanyl doses in the range of $20\text{--}25 \text{ mg} \cdot \text{kg}^{-1}$ can decrease heart rate, mean arterial pressure, systemic and pulmonary vascular resistance, and pulmonary capillary wedge pressure by approximately 15% in patients with coronary artery disease.^{130,140} Higher doses, up to $75 \text{ mg} \cdot \text{kg}^{-1}$ produced no further hemodynamic changes. All of these patients had been premedicated with a valium or pentobarbital and scopolamine or atropine. In unpremedicated patients undergoing noncardiac surgery, induction with fentanyl $30 \text{ mg} \cdot \text{kg}^{-1}$ produced no changes in heart rate or systolic blood pressure.¹²⁹ Hypertension in response to sternotomy is the most common hemodynamic disturbance during high-dose fentanyl anesthesia. The incidence varies widely, and is reported to be between 40 and 100% in patients receiving $50\text{--}100 \text{ mg} \cdot \text{kg}^{-1}$.¹⁴¹ Unlike morphine and meperidine, which induce hypotension, at least in part due to histamine release,^{67,142} high-dose fentanyl ($50 \text{ mg} \cdot \text{kg}^{-1}$) is not associated with significant histamine release (see Fig. 14-5).

While high doses of fentanyl are associated with minimal cardiovascular changes, combining fentanyl with other drugs can compromise hemodynamic stability. The combination of fentanyl and diazepam produces significant cardiovascular depression.^{129,140} Diazepam 10 mg given after $20\text{--}50 \text{ mg} \cdot \text{kg}^{-1}$ of fentanyl decreased stroke volume, cardiac output, systemic vascular resistance, and mean arterial pressure, and increased central venous pressure significantly.¹⁴⁰ In an animal model, these negative inotropic effects were shown to be simply additive.¹⁴³ The addition of 60% N_2O to high-dose fentanyl produced a significant decrease in cardiac output as well as increases in systemic and pulmonary vascular resistance.¹³⁰

High-dose fentanyl ($100 \text{ mg} \cdot \text{kg}^{-1}$) prevented increases in plasma epinephrine, cortisol, glucose, free fatty acids, and growth hormone (the “stress response”) during surgery. Lower dose fentanyl ($5 \text{ mg} \cdot \text{kg}^{-1}$ followed by an infusion of $3 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) failed to block increases in plasma epinephrine and cortisol.¹⁴⁴

Smooth Muscle and Gastrointestinal Effects

Fentanyl, like morphine and meperidine, significantly increases common bile duct pressure (see Fig. 14-7).⁸⁹ Like other opioids, fentanyl can cause nausea and vomiting, particularly in ambulatory patients, and can delay gastric emptying and intestinal transit.

Disposition Kinetics

Fentanyl's extreme lipid solubility (see Table 14-2) allows it to cross biologic membranes quickly and to be taken up rapidly by the highly perfused tissue groups, including the brain, heart, and lung. Thus, after a single bolus dose, the onset of effects is rapid and the duration brief. Hug and Murphy¹⁴⁵ determined the relationships between fentanyl effects and its concentration over time in plasma and various tissues in rats given fentanyl $50 \text{ mg} \cdot \text{kg}^{-1}$ (Fig. 14-10). The onset of opioid effects occurred within 10 seconds, and correlated with a rapid increase in brain tissue fentanyl concentration, which equilibrated with plasma by 1.5 minutes. Recovery from fentanyl effects started within 5 minutes and was complete by 60 minutes. Elimination from the “central tissues” (brain, heart, and lung) was also rapid, as fentanyl was redistributed to other tissues, particularly muscle and fat. Peak muscle concentration was seen at 5 minutes, while fat concentration reached a maximum approximately 30 minutes after the dose. The delay in fat uptake despite fentanyl's high lipid solubility is due to the limited blood supply to that tissue. Thus, redistribution to muscle and fat limits the duration of a bolus dose of fentanyl, and accumulation in peripheral tissue compartments can be extensive because of the large mass of muscle and high affinity of fentanyl for fat. With prolonged administration of fentanyl, fat can act as a reservoir of drug.

Figure 14-10 Fentanyl uptake and elimination in various tissues of the rat following intravenous injection. Unchanged fentanyl tissue concentrations (means for 6 rats)

are expressed as percentage of dose. "Central" represents the combined content of brain, heart, and lung tissues. The large mass of muscle (50% body weight of the rat) and high affinity of fat for fentanyl (despite slow equilibration) serve as a drain on the central compartment. (Reprinted with permission from Hug CC, Murphy MR: Tissue redistribution of fentanyl in terms of its effects in rats. *Anesthesiology* 55:369, 1981.)

Fentanyl pharmacokinetics have been studied in normal volunteers as well as patients under general anesthesia. After an iv dose, plasma fentanyl concentration falls rapidly, and the concentration–time curve has been described by both two- and three-compartment models.¹⁴⁶ McClain and Hug¹³⁴ administered a 3.2 or 6.4 mg · kg⁻¹ dose of fentanyl to healthy male volunteers and found that nearly 99% of the dose was eliminated from plasma by 60 minutes. These investigators found both rapid and slower distribution phases, with half-times of 1.2–1.9 minutes and 9.2–19 minutes, respectively. The terminal elimination half-time ranged from 3.1 to 6.6 hours, which is somewhat longer than that for morphine. Similar values were noted in surgical patients less than 50 years old,^{146,147} including morbidly obese patients.¹⁴⁶ Reports of age effects on fentanyl kinetics are conflicting. Scott and Stanski¹⁴⁸ found a decrease in fentanyl requirement with increasing age (20–89 years), but they did not observe differences in pharmacokinetic parameters. In contrast, Bentley *et al*¹⁴⁷ observed a marked decrease in clearance and an increase in terminal elimination half-time to approximately 15 hours in patients over 60 years old compared to 4.4 hours in patients less than 50 years old. However, another comparison between older (>70 years old) and younger (<42 years old) patients anesthetized in a manner similar to that used in Bailey's study failed to show any differences in plasma clearance and elimination half-times between the two groups.¹⁴⁹

Unlike its derivatives, fentanyl is significantly bound to red blood cells, approximately 40%, and has a blood:plasma partition coefficient of approximately 1.¹⁴⁶ Plasma fentanyl is highly protein-bound, with estimates in the range of 79–87%. It binds avidly to α_1 -acid glycoprotein, but also binds to albumin.^{146,150} Fentanyl protein binding is pH-dependent, such that a decrease in pH will increase the proportion of fentanyl that is unbound.¹⁴⁶ Mean values for unbound fractions of fentanyl in plasma have been estimated between 13 and 21%.¹⁴⁶

Clearance of fentanyl is primarily by metabolism, which occurs rapidly and extensively in the liver. Clearance estimates^{134,148} of 8–21 ml · kg⁻¹ · min⁻¹ approach liver blood flow, and indicate a high hepatic extraction ratio. Thus, hepatic metabolism of fentanyl is expected to be dependent on liver blood flow. Metabolism is primarily by *N*-dealkylation to norfentanyl, and by hydroxylation of both the parent and norfentanyl to hydroxypropionylfentanyl and hydroxypropionylnorfentanyl.¹⁴⁶ Only about 6% of the dose of fentanyl is excreted unchanged in the urine.¹³⁴

Dosage and Administration of Fentanyl

From administration as a single bolus dose, fentanyl developed an early reputation as a short-acting opioid. Experience with very large doses and multiple doses revealed that prolonged respiratory depression and delayed recovery could occur. These observations demonstrate that fentanyl's clinical duration is limited by redistribution, and that with prolonged administration, accumulation can occur.

Fentanyl can be useful as a sedative/analgesic premedication when given a short time prior to induction. For this use incremental doses of 25–50 mg can be used and titrated until the desired effect is achieved. It is important to note that although the onset of fentanyl's effects is rapid, peak effect lags behind peak plasma concentration by up to 5 minutes.¹¹⁰ A transmucosal delivery system for fentanyl is also available, and has been shown to be an effective premedicant for pediatric as well as adult patients. In children, doses of 10–20 mg · kg⁻¹, and in adults, 400–800 mg, administered 30 minutes prior to induction or a painful procedure are safe and effective.^{151,152} However, dose-dependent side effects typical of opioids are reported, including sedation, respiratory depression, nausea, and pruritus.^{151,152} and ¹⁵³ Because respiratory depression and hypoxemia can occur, transmucosal fentanyl should be administered in a monitored environment.

Fentanyl is also used frequently as an adjunct to induction agents such as thiopental to blunt the hemodynamic response to laryngoscopy and tracheal intubation, which can be particularly severe in patients with hypertension or cardiovascular disease. In patients undergoing major vascular surgery, induction with 3 mg · kg⁻¹ thiopental and pancuronium was followed by fentanyl 8 mg · kg⁻¹, administered over 2 minutes. Patients who received this combination experienced no significant increase in heart rate or blood pressure compared to baseline, preinduction values compared to those who received 6 mg · kg⁻¹ thiopental.¹⁵⁴ Patients in both groups experienced a 20% drop in mean arterial pressure after induction but prior to laryngoscopy. Common clinical practice involves titration of fentanyl in doses of 1.5–5 mg · kg⁻¹ prior to administration of a barbiturate or other induction agent. Because fentanyl's peak effect lags behind peak plasma concentration by 3–5 minutes, fentanyl titration should be complete approximately 3 minutes prior to laryngoscopy in order to maximally blunt hemodynamic responses to tracheal intubation. When fentanyl was administered with 50% N₂O in oxygen for induction, the effective dose for loss of consciousness was 8–23 mg · kg⁻¹.¹²¹ Recall, however, that the combination of N₂O and a moderate to high dose of opioid may cause significant muscle rigidity, which can be attenuated by a variety of adjuvants, including benzodiazepines, barbiturates, and muscle relaxants.

Perhaps the most common clinical use of fentanyl and its derivatives is as an analgesic component of balanced general anesthesia. With this technique, incremental doses of fentanyl 0.5–2.5 mg · kg⁻¹ are administered intermittently as dictated by the intensity of the surgical stimulus, and may be repeated approximately every 30 minutes. Generally, administration of up to 3–5 mg · kg⁻¹ · h⁻¹ will allow recovery of spontaneous ventilation at the end of surgery. As an alternative to intermittent dosing, a loading dose of 5–10 mg · kg⁻¹ and continuous fentanyl infusion at a rate between 2 and 10 mg · kg⁻¹ · h⁻¹ are recommended.¹²¹ It is important to remember, however, that anesthetic requirements vary with age, concurrent diseases, and the surgical procedure. For example, fentanyl requirements decrease by 50% as age increases from 20 to 89 years.¹⁴⁸ Fentanyl requirements can also be expected to decrease with the duration of infusion (see discussion of context-specific half-times at the end of this chapter).

Fentanyl can also be used in combination with droperidol, a butyrophenone, and nitrous oxide, in a technique called neuroleptanesthesia.¹⁵⁵ This technique entails premedication with intramuscular (im) diphenhydramine (50–100 mg), scopolamine (0.3–0.4 mg), and an opioid such as meperidine (25–75 mg) in order to minimize the side effects of high-dose droperidol, which include dysphoria and extrapyramidal motor effects. Induction consists of infusion of 0.15 mg · kg⁻¹ droperidol followed by a small dose (20–60 mg) of fentanyl. Nitrous oxide 60–70% is added to induce sleep, and then fentanyl is further titrated in small increments. The total loading dose of fentanyl is in the range of 2–2.5 mg · kg⁻¹, and the average total fentanyl dose is approximately 2 mg · kg⁻¹ · h⁻¹. Because this technique does not provide muscle relaxation, neuromuscular blockers are generally required.

High dose (e.g., 50–150 mg · kg⁻¹) fentanyl "anesthesia" has been used extensively for cardiac surgery. With this technique, a mean plasma fentanyl concentration of 15 ng · ml⁻¹, which prevents hemodynamic changes in response to noxious stimuli,¹⁵⁶ can be achieved with a loading dose of 50 mg · kg⁻¹, followed by a continuous infusion of 30 mg · kg⁻¹ · h⁻¹. With high-dose fentanyl, muscle relaxants and mechanical ventilation are required. Whether opioids alone are suitable as the sole "anesthetic" agent continues to be debated.

Finally, fentanyl has been used as an analgesic in management of postoperative as well as cancer pain. For acute pain, fentanyl is administered as a continuous iv infusion, or via an on-demand system, such as a patient-controlled analgesia (PCA) pump. Effective continuous infusion rates for nontolerant individuals are generally in the range of 50–100 mg · h⁻¹. A reasonable starting dose regimen for PCA includes a background continuous infusion of 20–50 mg · h⁻¹ plus a bolus "demand" dose of 10–25 mg, and a lockout period of 5 minutes. Transdermal fentanyl has also been used for postoperative analgesia; a nominal delivery rate of 100 mg · h⁻¹ produces a serum fentanyl concentration of 2 ng · ml⁻¹. However, the slow increase to a stable serum concentration (approximately 15 hours) and the long apparent elimination half-life (21 hours) make this a reasonable choice for long-term pain relief. Thus transdermal delivery is an impractical method to use when drug titration is necessary and fairly rapid (e.g., over hours to days) changes in opioid dose and plasma concentrations are required. Both transdermal and transmucosal fentanyl delivery systems have proved effective for cancer pain relief. The transmucosal system is particularly useful for therapy of acute pain exacerbation episodes, or "breakthrough" pain.

Sufentanil

Sufentanil, a thienyl derivative of fentanyl (see Fig. 14-6) first described in the mid 1970s, has a clinical potency ratio 2000–4000 times that of morphine and 10–15 times that of fentanyl.^{157,158} Like fentanyl, sufentanil equilibrates rapidly between blood and brain, and demonstrates clear plasma concentration-effect relationships. In a study comparing sufentanil and fentanyl pharmacodynamics, using EEG changes as a measure of opioid effects, Scott *et al*¹⁵⁸ noted similar profiles. During a 4-minute sufentanil infusion, the change in spectral edge lagged behind rising sufentanil concentration by approximately 2–3 minutes, while resolution of the EEG changes lagged behind plasma concentration changes by 20–30 minutes.

Analgesia

Sufentanil is a highly selective μ opioid receptor agonist, and exerts potent analgesic effects in animals when given by either systemic or spinal routes.¹⁵⁹ While the

literature describing clinical experience with sufentanil as a component of general anesthesia is extensive, available information regarding the analgesic potency of systemically administered sufentanil in humans is limited. Geller *et al*¹⁶⁰ titrated an iv infusion rate to adequate postoperative analgesia, and noted that a mean rate of 8–17 mg · h⁻¹ was required during the first 48 hours. This was associated with a 5-fold range in plasma sufentanil concentrations, between 0.02 and 0.1 ng · ml⁻¹. Lehmann *et al*¹⁶¹ found similar sufentanil requirements (including a wide interpatient variability) in postoperative patients, and estimated that the minimum effective analgesic concentration of sufentanil is near 0.03 ng · ml⁻¹. A laboratory study using normal volunteers found that a steady-state plasma sufentanil concentration of 0.05 ng · ml⁻¹ was associated with a 50% pain reduction.¹⁶²

Effect on MAC of Volatile Anesthetics and Use in Anesthesia

Animal studies have shown that sufentanil decreases the MAC of volatile anesthetics in a dose-dependent manner.^{163,164} The maximum reduction of enflurane or halothane MAC by sufentanil in animals is between 70 and 90%. A study in humans found that a plasma sufentanil concentration of 0.145 ng · ml⁻¹ was associated with a 50% reduction in isoflurane MAC¹⁶⁵. Increasing the plasma sufentanil concentration to 0.5 ng · ml⁻¹ reduced isoflurane MAC by 78%, and a ceiling effect was approached with greater plasma sufentanil concentrations. The maximum MAC reduction seen in humans was 89%, at a sufentanil concentration of 1.4 ng · ml⁻¹.

In clinical anesthesia practice, sufentanil is used as a component of balanced anesthesia, and has been employed extensively in high doses (10–30 mg · kg⁻¹) with oxygen and muscle relaxants for cardiac surgery. In this dose range, sufentanil is at least as effective as fentanyl in its ability to produce and maintain hypnosis. In addition, hemodynamic stability appears to be as good as or better than that achieved with fentanyl.^{92,157} Bailey *et al*¹⁶⁶ used a computer-assisted continuous infusion system to determine sufentanil plasma concentration–response to various noxious stimuli during high-dose sufentanil anesthesia for cardiac surgery. They estimated the plasma concentration associated with a 50% probability of no response (movement, hemodynamic, or sympathetic) to intubation, incision, sternotomy, and mediastinal dissection (CP₅₀). The CP₅₀ for intubation, incision, and sternotomy (pooled data) was 7.06 ng · ml⁻¹, and for mediastinal dissection CP₅₀ was 12.1 ng · ml⁻¹. As is typical of opioids, a wide intersubject variability was noted in sufentanil concentration requirements (3–10-fold) to suppress responses to these stimuli. However, even at high doses, when used as the sole anesthetic agent, sufentanil may not completely block the hemodynamic responses to noxious stimuli.¹²³

Other CNS Effects

Equianalgesic doses of sufentanil and fentanyl produce similar changes in the EEG.^{157,158} In cardiac patients who received sufentanil 15 mg · kg⁻¹, a activity became prominent within a few seconds, and within 3 minutes, the EEG consisted almost entirely of slow d activity.¹⁵⁷ Rigidity and myoclonic activity have been reported during induction of, and on emergence from, anesthesia with sufentanil in doses of approximately 1–2 mg · kg⁻¹.^{44,47,167} While the observed myoclonic activity resembles seizures, it has not been associated with EEG evidence of seizures.^{44,167}

There has been considerable investigation of the effects of sufentanil on cerebral hemodynamics and intracranial pressure. In patients with intracranial tumors, sufentanil 1 mg · kg⁻¹ was associated with an elevation in spinal cerebrospinal pressure, and a decrease in cerebral perfusion pressure.¹⁶⁸ As in patients with elevated intracranial pressure and cerebral blood flow after fentanyl, mean arterial pressure had dropped significantly in these patients. In normal volunteers, a smaller dose of sufentanil (0.5 mg · kg⁻¹) was not associated with changes in cerebral blood flow.¹⁶⁹ In dogs that received very large doses of sufentanil (20 mg · kg⁻¹) cerebral blood flow decreased in proportion to a decrease in cerebral metabolism, and intracranial pressure did not change.¹⁷⁰

Respiratory Depression

Like other m opioid agonists, sufentanil causes respiratory depression in doses associated with clinical analgesia.^{136,137} Respiratory depression can be especially marked in the presence of inhalation anesthetics. In spontaneously breathing patients anesthetized with 1.5% halothane in N₂O and 33% oxygen, a small dose of sufentanil (approximately 2.5 mg) reduced mean minute ventilation by 50%, and 4 mg reduced mean respiratory rate by 50%.¹⁷¹ Postoperative respiratory depression after apparent recovery from anesthesia has been reported for both sufentanil and fentanyl.¹⁷² The occurrence of secondary peaks in plasma drug concentration has been suggested as a mechanism, but a lack of exogenous stimulation in the early postoperative period may be just as important a factor.

Results of one study in normal volunteers who received bolus doses of fentanyl and sufentanil suggest that sufentanil may cause less respiratory depression than fentanyl.¹³⁶ The magnitude and time course of change in end-tidal CO₂ were the same for fentanyl and sufentanil, but the slope of the ventilatory response to CO₂ was depressed to a greater extent by fentanyl. In another study with normal volunteers, equianalgesic steady plasma concentrations of morphine (25, 50, and 100 ng · ml⁻¹) and sufentanil (0.02, 0.04, and 0.08 ng · ml⁻¹) produced equivalent respiratory depression, measured as increased end tidal CO₂ and a decreased ventilatory response to CO₂.¹⁶²

Cardiovascular and Endocrine Effects

In animal studies, sufentanil has been shown to cause vasodilation by a sympatholytic mechanism, but may also have a direct smooth muscle effect.¹⁶³ Clinically, a prominent feature of many clinical trials involving sufentanil is the remarkable hemodynamic stability achieved during balanced and high dose (up to 30 mg · kg⁻¹) opioid anesthesia. In general, only a modest decrease in mean arterial pressure is observed when sufentanil (approximately 15 mg · kg⁻¹) is used for induction of anesthesia.^{92,173} Intraoperatively, sufentanil in moderate or high doses does not completely abolish the hypertensive response to sternotomy or other noxious stimuli.^{123,173,174} and ¹⁷⁵ In general, sufentanil and fentanyl have been found to be equivalent for use in balanced and high-dose opioid anesthesia,^{123,173,175} but two clinical comparisons between fentanyl and sufentanil suggest that sufentanil may be associated with less respiratory depression¹⁷⁶ and better analgesia^{176,177} in the immediate postoperative period.

The choice of premedication and muscle relaxant may significantly affect hemodynamics during induction and maintenance of anesthesia with sufentanil. Combining vecuronium and sufentanil can cause a decrease of 10–15 torr in mean arterial pressure during induction,¹⁷⁸ and significant bradycardia and sinus arrest¹⁷⁹ have been reported. Bradycardia is not seen when pancuronium is used during anesthesia with sufentanil.¹⁸⁰

Sufentanil, like fentanyl, reduces the endocrine and metabolic responses to surgery.¹⁵⁷ However, even a large induction dose (20 mg · kg⁻¹) did not prevent increases in cortisol, catecholamines, glucose, and free fatty acids during and after cardiopulmonary bypass.¹⁸¹

Disposition Kinetics

Sufentanil is an extremely lipophilic opioid, and has pharmacokinetic properties similar to that of fentanyl. Because of a higher degree of ionization at physiologic pH and higher degree of plasma protein binding, its volume of distribution is somewhat smaller and its elimination half-life shorter than that of fentanyl (see Table 14-2). Sufentanil pharmacokinetics have been studied in patients under general anesthesia who had received methohexital for anesthetic induction, followed by the sufentanil dose of 5 mg · kg⁻¹, and N₂O in oxygen 33%.¹⁸² After an iv bolus dose, plasma sufentanil concentration drops very rapidly, and 98% of the drug is cleared from plasma within 30 minutes. Plasma concentration–time data in this study were best fitted to a three-compartment model. The rapid and slower distribution half-times were 1.4 and 17.7 minutes, respectively, and the elimination half-life was 2.7 hours. In other pharmacokinetic studies involving anesthetized patients, mean elimination half-lives were in the range of 2.2–4.6 hours.^{183,184} and ¹⁸⁵ In contrast, Hudson¹⁸⁶ reported a much longer elimination half-life (12.2 hours). In this study, patients undergoing aortic surgery received larger sufentanil doses (12.5 mg · kg⁻¹) during abdominal aortic surgery, and a significant correlation between increasing age and elimination half-life was noted. Obese patients were found to have a larger total volume of distribution and a longer elimination half-life (3.5 vs. 2.2 hours) compared to nonobese patients.¹⁸³

Sufentanil is less red cell-bound than fentanyl (22% compared to 40%), and has a whole blood:plasma concentration ratio of 0.741.¹⁴⁶ Plasma sufentanil is approximately 92% protein-bound at pH 7.4, mostly to α₁-acid glycoprotein. Clearance of sufentanil is rapid, and like fentanyl, sufentanil has a high hepatic extraction ratio.¹⁴⁶ Metabolism in the liver is by *N*-dealkylation and *O*-demethylation. However, sufentanil clearance in patients with cirrhosis was similar to controls, as was the elimination half-life.¹⁸⁴

Dosage and Administration of Sufentanil

Like fentanyl, sufentanil is most often used as a component of balanced anesthesia, or as a single agent in high doses, particularly for cardiac surgery. Several investigations have found similar sufentanil dose requirements for induction of anesthesia.^{92,166,187} When sufentanil is titrated during induction, loss of consciousness is seen with total doses between 1.3–2.8 mg · kg⁻¹. Doses in the range of 0.3–1.0 mg · kg⁻¹ given 1–3 minutes prior to laryngoscopy can be expected to blunt

hemodynamic responses to intubation. Muscle rigidity can occur, particularly in the elderly, even at these lower doses.

For maintenance of balanced anesthesia, intermittent bolus doses or a continuous infusion can be used. With bolus doses in the range of 0.1–0.5 mg · kg⁻¹, mean maintenance requirements of 0.35 mg · kg⁻¹ · h⁻¹ have been reported.⁹² Cork *et al*¹⁸⁵ administered an initial bolus of 0.5 mg · kg⁻¹ followed by an infusion of 0.5 mg · kg⁻¹ · h⁻¹, which was varied according to patient need. This regimen of sufentanil in combination with N₂O 70% in oxygen provided satisfactory anesthesia with good hemodynamic stability, and stable plasma sufentanil concentrations of approximately 0.15–0.25 ng · ml⁻¹. Thus, for balanced anesthesia, sufentanil can be administered as repeated bolus doses or continuous infusion, with an expected dose requirement in the range of 0.3–1 mg · kg⁻¹ · h⁻¹. Much higher bolus doses and/or infusion rates are required to achieve the plasma sufentanil concentration range of 6–60 ng · ml⁻¹ required during cardiac anesthesia using sufentanil as the sole agent. For “complete anesthesia” total sufentanil doses in the range of 8–50 mg · kg⁻¹ are required.¹⁶⁶

Alfentanil

Alfentanil, a tetrazole derivative of fentanyl (see Fig. 14-6), was synthesized two years after sufentanil and introduced into clinical practice in the early 1980s. On a milligram basis, its clinical potency is approximately ten times that of morphine and one fourth to one tenth that of fentanyl when given in single doses. Alfentanil differs from fentanyl in its pharmacokinetics as well as in its speed of equilibration between plasma and effect site in the brain. In a comparison using EEG spectral edge effects to quantify fentanyl and alfentanil pharmacodynamics, Scott *et al*¹¹⁰ demonstrated that alfentanil's effect followed serum drug concentration more closely than fentanyl (see Fig. 14-8). Peak effect lagged behind peak plasma concentration by less than 1 minute, and resolution of effect followed decreasing serum alfentanil concentration by no more than 10 minutes. Alfentanil is a m-opioid receptor agonist, and produces typical naloxone-reversible analgesia and side effects such as sedation, nausea, and respiratory depression.

Analgesia

Alfentanil has been administered intravenously for treatment of postoperative and cancer-related pain, as well as in laboratory pain models with normal volunteers. Clear concentration and dose-related analgesic effects have been demonstrated for alfentanil, but individual requirements in terms of dosage or plasma concentrations vary widely. For postoperative analgesia, the MEAC is approximately 10 ng · ml⁻¹, with a range of 2 to >40 ng · ml⁻¹.¹⁸⁸ In a laboratory investigation, pain intensity ratings decreased in a plasma concentration-dependent fashion, and 80 ng · ml⁻¹ was associated with a 50% reduction in pain intensity.⁴⁹ Clinical studies have shown that in patients receiving continuous iv infusion of alfentanil, mean plasma concentrations required for relief of moderate to severe pain are approximately 40–80 ng · ml⁻¹ (see Table 14-3).^{189,190} Following an adequate loading dose, average alfentanil requirements for postoperative analgesia are approximately 10–20 mg · kg⁻¹ · h⁻¹.^{189,191,192}

Effect on MAC of Volatile Anesthetics and Use in Anesthesia

Like other opioids, alfentanil decreases the MAC of enflurane in a curvilinear fashion up to a plateau in dogs.^{26,193} An infusion rate of 8 mg · kg⁻¹ · min⁻¹ achieved a plasma concentration of 223 ng · ml⁻¹ and reduced enflurane MAC by 69%. Increasing the infusion rate 4-fold did not reduce enflurane MAC further.¹⁹³ In rats, an infusion of 15 mg · kg⁻¹ · min⁻¹ reduced the MAC of halothane by 48%, but evaluation of higher doses was precluded by the development of muscle rigidity.²⁶

In humans, alfentanil plasma concentrations required to supplement nitrous oxide anesthesia for various noxious stimuli have been determined.¹⁹⁴ Patients received a loading dose of 150 mg · kg⁻¹, followed by an infusion that was titrated between 25 and 150 mg · kg⁻¹ · h⁻¹ according to the patients' responses to surgical stimuli, and steep concentration–effect curves were demonstrated. Plasma concentrations required along with 66% N₂O to obtund somatic, autonomic, and hemodynamic responses to stimuli in 50% of patients were 475, 279, and 150 ng · ml⁻¹ for tracheal intubation, skin incision, and skin closure, respectively. The plasma alfentanil concentration associated with spontaneous ventilation after discontinuation of N₂O was 223 ng · ml⁻¹. Nearly identical results were obtained in a similar study using computer-controlled infusions to deliver alfentanil (Fig. 14-11).¹⁹⁵ Plasma alfentanil concentrations required in combination with propofol to obtund responses to intubation and surgical stimuli have also been determined. Vuyk *et al*¹⁹⁶ found alfentanil requirements with 66% N₂O that were nearly identical to those of Ausems.^{194,195} In contrast, much lower alfentanil plasma concentrations, 55–92 ng · ml⁻¹, were required to prevent responses in 50% of patients when alfentanil was combined with propofol at a plasma concentration of 3 mg · ml⁻¹ (Fig. 14-12).

Figure 14-11 The relationship between alfentanil plasma concentration (with 66% N₂O) and the probability of no response for intubation, skin incision, and skin closure; and the relationship of plasma alfentanil concentration (without N₂O) and the recovery of adequate spontaneous ventilation. (Reprinted with permission from Ausems ME, Vuyk J, Hug CC *et al*: Comparison of a computer-assisted infusion versus intermittent bolus administration of alfentanil as a supplement to nitrous oxide for lower abdominal surgery. *Anesthesiology* 68:851, 1988.)

Figure 14-12 The alfentanil plasma concentration–effect relationships for intubation, skin incision, and the opening of the peritoneum when given as a supplement to propofol. (Reprinted with permission from Vuyk J, Lim T, Engbers FHM, *et al*: Pharmacodynamics of alfentanil as a supplement to propofol or nitrous oxide for lower abdominal surgery in female patients. *Anesthesiology* 78:1036, 1993.)

High-dose alfentanil has been used as an induction agent for patients with and without cardiac disease,¹⁹⁷ and for induction and maintenance of cardiac anesthesia.^{141,198,199} Patients with cardiac (valvular or coronary artery) disease required half as much alfentanil to induce unconsciousness.¹⁹⁷ When used as the sole anesthetic agent, mean plasma alfentanil concentrations required to significantly blunt hemodynamic responses to intubation and sternotomy were 700–830 ng · ml⁻¹ and 1200–1800 ng · ml⁻¹, respectively.^{198,200} These values are approximately twice those reported for alfentanil in combination with 66% nitrous oxide.^{194,195} However, even doses that produced very high plasma alfentanil concentrations (1200 to >2000 ng · ml⁻¹) did not eliminate responses to intubation and intraoperative stimuli in all patients.¹⁹⁹ In contrast to fentanyl and sufentanil, the duration of even very large doses of alfentanil is short. Thus, for cardiac anesthesia, repeated doses or a

continuous infusion of alfentanil is required.

Other CNS Effects

Alfentanil produces the typical generalized slowing of the EEG^{110,201}; a plasma concentration of approximately 1400 ng · ml⁻¹ is associated with the onset of d-wave activity. Unlike fentanyl and sufentanil, alfentanil produced less synchronization of the EEG as well as spindle activity in most patients.²⁰¹ Like fentanyl, alfentanil can increase epileptiform EEG activity in patients with intractable temporal lobe epilepsy having surgery under general anesthesia.¹³² Like fentanyl and sufentanil, alfentanil can produce intense muscle rigidity accompanied by loss of consciousness. In 90–100% of patients, induction doses of 150–175 mg · kg⁻¹ were associated with muscle rigidity, which was not limited to the chest wall or trunk. Rather, electromyography has shown increased activity of comparable magnitude in muscles of the neck, extremities, chest wall, and abdomen.^{44,202} Studies in rats suggest that specific nuclei of the reticular formation, including the periaqueductal gray, are important in alfentanil-mediated rigidity.⁴⁶

Alfentanil has been reported to increase cerebrospinal fluid pressure in patients with brain tumors, whereas fentanyl does not.¹²⁷ This effect is thought to be due to cerebrovasodilation, but a study in dogs failed to confirm this hypothesis. Mayberg *et al*²⁰³ examined the effect of 25 and 50 mg · kg⁻¹ of alfentanil on cerebral blood flow velocity and intracranial pressure in neurosurgical and orthopedic patients under general anesthesia with isoflurane and 50% N₂O. Ventilation was controlled to maintain normocapnea, and blood pressure was maintained at baseline for neurosurgical patients. No clinically significant changes in ICP and no evidence of cerebral vasodilation or vasoconstriction were seen.

Respiratory Depression

The relationships among plasma alfentanil concentration, analgesia, and respiratory depression have been examined in animals and human subjects.^{49,204} In dogs, 50% maximal nociceptive and ventilatory responses were seen at plasma alfentanil concentrations between 20 and 80 ng · ml⁻¹, and maximal responses at 200 ng · ml⁻¹.²⁰⁴ Importantly, antinociceptive effects could not be separated from respiratory depression. A human study involving normal volunteers reported similar findings. Mild ventilatory depression (increased end-tidal CO₂; decreased slope of the CO₂ response curve) was seen at plasma concentrations as low as 20 ng · ml⁻¹. At plasma concentrations associated with 50% reduction in pain intensity, respiratory depression was equivalent for alfentanil, fentanyl, and morphine.⁴⁹ A clinical study examined analgesia and respiratory effects of alfentanil administered by a patient-controlled analgesia system for postoperative pain control.²⁰⁵ In patients who received a continuous alfentanil infusion at 900 mg · h⁻¹ plus 100–200-mg doses as needed, 3 of 10 patients developed respiratory depression (respiratory rate < 8/min). Mean alfentanil blood concentration in this group of patients was 80 ng · ml⁻¹.

Two clinical studies have examined the intensity and duration of respiratory depressant effects of alfentanil in the immediate postoperative period.^{206,207} Intraoperative anesthesia was maintained with alfentanil 20–100 mg · kg⁻¹ · h⁻¹ and 67% N₂O with or without 0.5% halothane. At the end of surgery the infusion was decreased to 20 mg · kg⁻¹ · h⁻¹, which produced plasma alfentanil concentrations between 106 and 120 ng · ml⁻¹, and good analgesia. With this regimen, ventilatory response to CO₂ was decreased to 50% of the baseline value, but PaCO₂ was only moderately elevated (42–48 torr). By 2 hours after alfentanil was discontinued, respiratory function was near baseline. When compared to fentanyl, the recovery of ventilatory function was faster with alfentanil.²⁰⁷ Another comparison found that for anesthetics of 1.5–2 hours duration, recovery of respiratory function was similar with alfentanil and fentanyl.²⁰⁸ Like its congeners, alfentanil has been associated with apnea and unconsciousness after apparent recovery from anesthesia.²⁰⁹

Cardiovascular Effects

The cardiovascular effects of alfentanil are influenced by preoperative medication, the muscle relaxant used, the method of administration, and the degree of surgical stimulation.²¹⁰ In general, heart rate and mean arterial pressure are unchanged or slightly decreased during induction with alfentanil 40–120 mg · kg⁻¹,^{197,210} but rapid induction with 150–175 mg · kg⁻¹ alfentanil can decrease mean arterial pressure by 15–20 torr.²⁰² After induction with etomidate, alfentanil 120 mg · kg⁻¹ decreased mean arterial pressure by approximately 30 torr,²¹¹ and following thiopental (3–5 mg · kg⁻¹) induction, a smaller dose of alfentanil (40 mg · kg⁻¹) decreased mean arterial pressure by approximately 40 torr.²¹² In combination with lorazepam premedication or thiopental induction, moderate doses (10–50 mg · kg⁻¹) of alfentanil blunt the cardiovascular and catecholamine responses to laryngoscopy and intubation,^{200,212} but for patients over 70 years old, doses greater than 10 mg · kg⁻¹ given with thiopental can produce significant hypotension after induction.²¹³ Alfentanil can also cause bradycardia, but this effect is minimized by premedication with atropine, and by the vagolytic effect of pancuronium.²¹⁰ Alfentanil is commonly administered with propofol for induction and maintenance of anesthesia, but both of these agents act centrally to produce bradycardia. Skues *et al*²¹⁴ found that patients who received alfentanil 50 mg · kg⁻¹ plus propofol 1 mg · kg⁻¹ for induction of anesthesia experienced significant bradycardia, accompanied by hypotension, after intubation. Premedication with both atropine and glycopyrrolate prevented the bradycardia, but only glycopyrrolate prevented hypotension. Like fentanyl, alfentanil does not appear to have negative inotropic effects,²¹¹ but severe hypotension has been observed when alfentanil is given after 0.125 mg · kg⁻¹ diazepam.²¹⁵

Nausea and Vomiting

Early clinical reports noted frequent nausea during recovery from balanced anesthesia using alfentanil, and suggested that perhaps this side effect was worse with alfentanil compared to fentanyl.²¹⁶ However, a clinical comparison between alfentanil and sufentanil in combination with N₂O revealed the same incidence of nausea and vomiting with both drugs.²¹⁷ Similarly, fentanyl and alfentanil with N₂O both produced a similar degree of nausea in pediatric patients undergoing appendectomy.²¹⁸ In normal volunteers receiving computer-controlled opioid infusions, the severity of nausea at equianalgesic plasma concentrations was equivalent for alfentanil, fentanyl, and morphine.⁴⁹ Furthermore, alfentanil-induced nausea and vomiting in volunteers resolves more quickly than morphine- or fentanyl-induced vomiting (Coda BA, unpublished observations).

Disposition Kinetics

Alfentanil pharmacokinetics differ from those of fentanyl and sufentanil in several respects (see Table 14-3). A unique characteristic is that alfentanil is a weaker base than other opioids. Whereas other opioids have pK_a above 7.4, the pK_a of alfentanil is 6.8; consequently, nearly 90% of unbound plasma alfentanil is nonionized at pH 7.4.¹⁴⁶ This property, together with its moderate lipid solubility, enables alfentanil to cross the blood–brain barrier rapidly and accounts for its rapid onset of action. Compared to fentanyl and sufentanil, which have mean plasma–brain equilibration half-times of 6.4 and 6.2 minutes, respectively,^{110,158} alfentanil has a blood–brain equilibration half-time of 1.1 minutes.¹¹⁰ Alfentanil also has a smaller volume of distribution than fentanyl, which is a result of lower lipid solubility and high protein binding.²¹⁹ Approximately 92% of alfentanil is protein-bound, mostly to α_1 -acid glycoprotein.^{146,150}

After a bolus dose or rapid iv infusion, plasma alfentanil concentration falls rapidly; 90% of the administered dose has left the plasma by 30 minutes.²²⁰ This initial rapid decline is mostly due to alfentanil's distribution to highly perfused tissues. Plasma concentration decay curves in patients most often fit a three-compartment model.^{23,220} Like fentanyl, alfentanil is quickly distributed, with rapid and slow distribution half-times of 1.0–3.5 minutes and 9.5–17 minutes, respectively. However, alfentanil has a terminal elimination half-life of 84–90 minutes, which is considerably shorter than those of fentanyl and sufentanil. Clearance of alfentanil, 6.4 ml · kg⁻¹ · min⁻¹, is just half that of fentanyl, but because alfentanil's volume of distribution is 4 times smaller than fentanyl's, relatively more of the body burden is available to the liver for metabolism.²²¹ Chauvin *et al*²²² found that alfentanil has an intermediate hepatic extraction coefficient (32–53%) in humans, and that its elimination is dependent on hepatic plasma flow.

In animals, alfentanil undergoes *N*-dealkylation and *O*-demethylation in the liver to form inactive metabolites.¹⁴⁶ Liver disease can significantly prolong the elimination half-life of alfentanil. Patients with moderate hepatic insufficiency due to cirrhosis have reduced binding to α_1 -acid glycoprotein, and a plasma clearance one half that of control patients. These changes result in a marked increase in the elimination half-life, 219 minutes *versus* 90 minutes in controls.²²³ Renal disease also decreases alfentanil protein binding, but does not result in decreased plasma clearance or a prolonged terminal elimination half-life.²²⁴ Alfentanil's elimination half-life is prolonged by about 30% in the elderly, and appears to be much shorter (about 40 minutes) in children 5–8 years old.²²⁵ Obesity is also associated with a 50% decrease in alfentanil clearance and a prolonged (172 minutes) elimination half-life.²²⁵

The combination of moderate lipid solubility and short elimination half-life suggests that both redistribution and elimination are important in the termination of alfentanil's effects.²²¹ After a single bolus dose, redistribution will be the most important mechanism, but after a very large dose, repeated small doses, or a continuous infusion, elimination will be a more important determinant of the duration of alfentanil's effects.

Dosage and Administration of Alfentanil

Because of its rapid onset, alfentanil has been used as an induction agent alone or in combination with other drugs. In healthy patients, doses of about $120 \text{ mg} \cdot \text{kg}^{-1}$ produce unconsciousness in 2–2.5 minutes. Premedication with a benzodiazepine (e.g., lorazepam $0.08 \text{ mg} \cdot \text{kg}^{-1}$) is associated with a lower dose requirement, $40\text{--}50 \text{ mg} \cdot \text{kg}^{-1}$, and a faster onset of unconsciousness, within 1.5 minutes,¹⁹⁷ but may also produce hypotension.

Alfentanil is used as a supplement to maintain general anesthesia and, owing to its brief duration of action, can be useful in short surgical procedures, particularly in outpatient surgery. In this setting, loading doses of $5\text{--}10 \text{ mg} \cdot \text{kg}^{-1}$ provide good analgesia with rapid recovery.²¹⁹ For longer procedures, alfentanil can be administered as needed in repeated small bolus doses, but its pharmacokinetic properties make it ideal for administration as a continuous infusion. After induction of anesthesia, a loading dose of alfentanil $10\text{--}50 \text{ mg} \cdot \text{kg}^{-1}$ is followed with supplemental bolus doses of $3\text{--}5 \text{ mg} \cdot \text{kg}^{-1}$ as needed or a continuous infusion starting at $25\text{--}100 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ with $60\text{--}70\% \text{ N}_2\text{O}$ ^{194,195,219} or a propofol infusion.

When high-dose alfentanil is used as the sole anesthetic agent for cardiac surgery, a continuous infusion of up to $150\text{--}600 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ is adjusted according to the patient's responses to stimuli.¹⁹⁸ Others have reported that much lower doses can be effective for cardiac surgery if adequate premedication is given.¹⁹⁹

Remifentanil

Remifentanil (initially known as GI 87084B), a 4-anilidopiperidine with a methyl ester side chain (see Fig. 14-6) first described in 1990 and approved for clinical use in 1996, was developed to meet the need for an ultrashort-acting opioid. Because its ester side chain is susceptible to metabolism by blood and tissue esterases, remifentanil is rapidly metabolized to a substantially less active compound. Thus, because its ultrashort action is due to metabolism rather than to redistribution, it does not accumulate with repeated dosing or prolonged infusion. Remifentanil demonstrates potent, naloxone-reversible m-opioid agonist activity in guinea pig ileum and mouse vas deferens assays.²²⁶ Testing with k- and d-selective antagonists yielded no evidence that remifentanil is active at either of these opioid receptor subtypes.

Analgesia

In animals and humans, remifentanil produces dose-dependent analgesic effects. In a volunteer study, Glass *et al.*²²⁷ quantified analgesic and side effects of increasing doses of remifentanil and compared them to the effects of alfentanil. Across a range of $0.0625\text{--}2.0 \text{ mg} \cdot \text{kg}^{-1}$, remifentanil produced dose-dependent analgesia, measured as an increase in tolerance to tibial pressure, with a peak analgesic effect between 1 and 3 minutes. On a milligram basis, the relative analgesic potency of single doses of remifentanil was 22–47 times as potent as alfentanil. Remifentanil $1.5 \text{ mg} \cdot \text{kg}^{-1}$ and alfentanil $32 \text{ mg} \cdot \text{kg}^{-1}$ produced a similar magnitude and duration (approximately 10 minutes) of analgesia.

Effect on MAC of Volatile Anesthetics and Use in Anesthesia

The effect of remifentanil on MAC of volatile anesthetics is characterized by steep dose–effect or concentration–effect curves typical of other m-opioid agonists. In a canine study, continuous infusion of remifentanil decreased enflurane MAC in a dose-dependent fashion up to a maximum near 65%, similar to the maximum reduction of MAC seen with fentanyl.²²⁸ In humans who received computer-assisted continuous infusions (CACI) of remifentanil to achieve target blood concentrations of $0\text{--}32 \text{ ng} \cdot \text{ml}^{-1}$, isoflurane MAC was reduced logarithmically in a concentration-dependent fashion,²²⁹ and was influenced by age. Isoflurane MAC was reduced by 50% at a whole blood remifentanil concentration of approximately $1.3 \text{ ng} \cdot \text{ml}^{-1}$, and a ceiling effect on MAC reduction was seen at 85% with a remifentanil concentration of $8\text{--}12 \text{ ng} \cdot \text{ml}^{-1}$. In 1999, Peacock and Philip²³⁰ summarized results from an early clinical study²³¹ that evaluated various combinations of remifentanil and propofol. Remifentanil concentration (EC_{50}) and dosage (ED_{50}) to prevent patient responses to intubation and skin incision in 50% of patients were determined at different target propofol concentrations achieved with CACI. At a propofol target plasma concentration of $1 \text{ mg} \cdot \text{ml}^{-1}$ (mean infusion rate $44 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), remifentanil EC_{50} was $14.3 \text{ ng} \cdot \text{ml}^{-1}$ (infusion rate $0.44 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) for intubation, while at a propofol target concentration of $4 \text{ mg} \cdot \text{ml}^{-1}$ (mean infusion rate $200 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), remifentanil EC_{50} was $1.4 \text{ ng} \cdot \text{ml}^{-1}$ (infusion rate $0.07 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) for intubation. Response to intubation was prevented in 80% of patients by approximately doubling the remifentanil doses or concentrations.

The rapid onset and brief duration of remifentanil suggest that it is suitable for induction of anesthesia. A clinical study comparing a range of remifentanil doses ($2\text{--}20 \text{ mg} \cdot \text{kg}^{-1}$) to alfentanil ($40\text{--}200 \text{ mg} \cdot \text{kg}^{-1}$) for induction of anesthesia²³² showed that loss of consciousness was not reliably achieved with opioids alone. The median dose of remifentanil required for loss of consciousness in 50% of patients was $12 \text{ mg} \cdot \text{kg}^{-1}$,²³² while doses less than $5 \text{ mg} \cdot \text{kg}^{-1}$ did not produce loss of consciousness in any patients. Furthermore, as is common with other opioids, a high incidence of muscle rigidity and purposeless movement was seen. Even at the lowest remifentanil dose, moderate muscle rigidity was seen in 40% of patients, and at the highest dose, 60% of patients had severe muscle rigidity. This effect limits the utility of opioids as sole agents for induction of anesthesia.

Early clinical experience suggested that for maintenance of anesthesia with 66% N_2O , an infusion rate of $0.05 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ prevents motor and hemodynamic responses to tracheal intubation and skin incision in 50% of patients.²³³ Higher infusion rates ($0.6 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) are necessary to prevent responses to subsequent surgical stimuli. Randel *et al.*²³⁴ similarly found that a remifentanil infusion rate of $0.4 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ was reliably associated with prevention of response to surgical stimuli in the presence of 66% N_2O . In this study, remifentanil EC_{50} for no responses to intubation and incision were approximately 2.0 and $1.5 \text{ ng} \cdot \text{ml}^{-1}$, respectively. It is important to note that these studies included induction with propofol $2\text{--}2.5 \text{ mg} \cdot \text{kg}^{-1}$, and supplementation with low-dose isoflurane if titration of remifentanil alone could not control hemodynamics. Drover and Lemmens²³⁵ used computer-assisted infusions to determine the blood concentrations of remifentanil required to supplement 66% N_2O in patients having abdominal surgery. A range of $0.5\text{--}7.8 \text{ ng} \cdot \text{ml}^{-1}$ target concentrations was used, and other than premedication with 1–2 mg midazolam, no sedatives or hypnotics were given. These investigators were unable to determine an EC_{50} for either intubation or incision because they could not identify a concentration low enough to result in a consistent response to stimuli, or a concentration high enough to consistently prevent a response. During surgery, however, the remifentanil blood concentration associated with a 50% probability of adequate anesthesia (EC_{50}) was $4.1 \text{ ng} \cdot \text{ml}^{-1}$ for men and $7.5 \text{ ng} \cdot \text{ml}^{-1}$ for women. The reason for gender differences in these results was not clear, but could have been related to different types of surgeries. Thus propofol, and perhaps other agents, used for induction appear to reduce subsequent remifentanil requirements by as much as 2–4-fold.

Another increasingly common clinical use of remifentanil is in conjunction with propofol infusion for maintenance of total intravenous anesthesia (TIVA). This combination has been used successfully for a variety of inpatient procedures, including CABG, other major thoracic, abdominal, and orthopedic procedures^{236,237} as well as for ambulatory surgery procedures.^{230,238,239} Optimum regimens are still being evaluated.

Recovery from remifentanil is rapid, with return of spontaneous ventilation in 2–5 minutes, even when it is continued until after skin closure is complete.²³³ The drawback of this characteristic is that patients require analgesics very soon after remifentanil is discontinued. This problem can be overcome by continuing a low dose of remifentanil until the patient arrives in the recovery room.

Other CNS Effects

Remifentanil produces classic m-opioid agonist effects on the EEG, *i.e.*, a concentration-dependent slowing. The plasma concentration associated with 50% maximal EEG changes (EC_{50}) is $15\text{--}20 \text{ ng} \cdot \text{ml}^{-1}$.^{240,241} Remifentanil has an onset of action similar to that of alfentanil, but the duration is much shorter. This is seen as an extremely close tracking of changes in EEG spectral edge with plasma remifentanil concentration.^{240,241} In dogs anesthetized with 1% isoflurane and 50% nitrous oxide in oxygen, low- and high-dose remifentanil and alfentanil infusions produced a similar magnitude of EEG slowing, and similar decreases in cerebral blood flow and intracranial pressure.²⁴² Mean arterial pressure also decreased in response to both opioids, but when blood pressure was maintained with phenylephrine, remifentanil produced similar decreases in cerebral blood flow and intracranial pressure.²⁴²

Several clinical reports have described cerebral hemodynamics in humans. In the first clinical report,²⁴³ bolus doses of remifentanil (0.5 or $1.0 \text{ mg} \cdot \text{kg}^{-1}$) or alfentanil (10 or $20 \text{ mg} \cdot \text{kg}^{-1}$) were given after the first burr hole was drilled. Under conditions of background isoflurane/ N_2O anesthesia and controlled ventilation, neither opioid affected intracranial pressure and both produced modest, dose-dependent decreases in mean arterial pressure. A multicenter clinical trial followed, in which remifentanil/ N_2O anesthesia was compared to fentanyl/ N_2O anesthesia.²⁴⁴ Opioid infusions were started prior to induction; then the rates were decreased after intubation and titrated to maintain stable hemodynamics. Intracranial pressure (remifentanil 13 ± 10 ; fentanyl $14 \pm 13 \text{ mm Hg}$) and cerebral perfusion pressure (remifentanil 78 ± 14 ; fentanyl $76 \pm 19 \text{ mm Hg}$) were similar with the two regimens. Under conditions of controlled ventilation and maintenance of blood pressure with vasoactive adjuvants as necessary, cerebral blood flow was similar, and cerebral vascular reactivity to CO_2 was found to be intact during both remifentanil/ N_2O and

fentanyl/N₂O anesthesia²⁴⁵ for craniotomy. Another report described the effect of two infusion rates of remifentanyl on cerebral blood flow velocity in patients scheduled for coronary artery bypass graft surgery.²⁴⁶ No inhalation agents were used, ventilation was controlled to maintain isocapnea, and mean arterial pressure was maintained with phenylephrine. Cerebral blood flow velocity decreased significantly in patients who received high dose (5 mg · kg⁻¹, followed by 3 mg · kg⁻¹ · min⁻¹) but not in those with modest dose (2 mg · kg⁻¹, followed by 1 mg · kg⁻¹ · min⁻¹) remifentanyl.

Respiratory Depression

Remifentanyl produces dose-dependent respiratory depression as measured by increases in end-tidal CO₂ and decreased oxygen saturation. In a dose-escalation study in normal volunteers, the respiratory depressant effects of remifentanyl and alfentanil were compared.²²⁷ Peak respiratory depression occurred at 5 minutes after each dose of remifentanyl and alfentanil, and the maximal respiratory depressant effect seen after 2 mg · kg⁻¹ remifentanyl was similar to that caused by 32 mg · kg⁻¹ alfentanil. The duration of respiratory depression, measured as time to return of blood gases to within 10% of baseline values, was 10 minutes after 1.5 mg · kg⁻¹ and 20 minutes after 2 mg · kg⁻¹ remifentanyl compared to 30 minutes after 32 mg · kg⁻¹ alfentanil. During continuous opioid infusion, minute ventilation, in the presence of 8% inspired CO₂, decreased by approximately 30, 45, and 60% in response to 4-hour remifentanyl infusions of 0.025, 0.050, and 0.075 mg · kg⁻¹ · min⁻¹, respectively.²⁴⁷

Recovery from remifentanyl-induced respiratory depression was rapid, and minute ventilation returned to baseline by 8 (range 5–15) minutes after the infusion was stopped for all infusion rates. In contrast, a 50% decrease in minute ventilation produced by a 4-hour continuous infusion of alfentanil at 0.5 mg · kg⁻¹ · min⁻¹ required 61 (range 5–90) minutes to return to baseline.²²⁸ In a volunteer study, Glass *et al* reported that the blood remifentanyl concentration needed to depress minute ventilation in the presence of 8% inspired CO₂ by 50% (EC₅₀) was 1.17 ng · ml⁻¹.²⁴⁸

While the time course for recovery of normal ventilatory drive is rapid in patients as well as volunteers, maintenance of spontaneous respiration during general anesthesia with remifentanyl and volatile agents or propofol may not be feasible unless low doses of remifentanyl are used.²⁴⁹ Clinical experience in spontaneously breathing humans receiving remifentanyl combined with either isoflurane or propofol has demonstrated dose-dependent respiratory depression.²³⁰ Respiratory depression is seen in 10–35% of patients receiving remifentanyl at 0.025 mg · kg⁻¹ · min⁻¹. It increases to nearly 50% in patients receiving 0.05 mg · kg⁻¹ · min⁻¹ and to >90% in patients receiving remifentanyl at 0.075 mg · kg⁻¹ · min⁻¹.

Hemodynamic Effects

In healthy volunteers, remifentanyl in bolus doses greater than 1.0 mg · kg⁻¹ produces brief increases in systolic blood pressure (5–20 torr) and heart rate (10–25 beats/min), which return to baseline by 10 minutes.²²⁷ In patients anesthetized with isoflurane and 66% N₂O in oxygen, remifentanyl (up to 5 mg · kg⁻¹) produces dose-dependent decreases in systolic blood pressure and heart rate. These effects are attenuated by premedication with glycopyrrolate 0.3–0.4 mg, and are readily reversed with ephedrine or phenylephrine.²⁵⁰ Sebel *et al*²⁵¹ evaluated hemodynamic responses in patients receiving 2–30 mg · kg⁻¹ (escalating doses) given during general anesthesia. Remifentanyl was associated with systolic heart rate decreases in excess of 20% for doses greater than 2 mg · kg⁻¹. There were no alterations in histamine concentrations, indicating that hemodynamic effects are not mediated by histamine release. Another series of case reports²⁵² described severe bradycardia (HR < 30 beats/min) and hypotension (systolic BP < 80 mm Hg) in six patients scheduled for coronary artery bypass grafting, who received remifentanyl 1 mg · kg⁻¹ followed by a continuous infusion at 0.1–0.2 mg · kg⁻¹ · min⁻¹. Of particular note, the bolus dose was given more rapidly than is recommended, *i.e.*, over less than 30 seconds *versus* 30–60 seconds. Hypotension in all cases was effectively treated by ephedrine and temporary discontinuation of remifentanyl. Preoperative use of beta blockers or calcium channel blockers did not predispose patients to bradycardia. Smaller bolus doses of remifentanyl (0.3–0.5 mg · kg⁻¹) are apparently not associated with severe bradycardia and hypotension. The most likely mechanisms for these hemodynamic effects include centrally mediated decrease in sympathetic tone and vagally induced bradycardia.

Other Side Effects

Like other m agonists, remifentanyl can cause nausea and vomiting. Preliminary results suggested that the incidence of nausea and vomiting with remifentanyl might be lower than with alfentanil after single bolus doses in volunteers²²⁷ as well as in patients sedated with low-dose opioid infusions (0.05 mg · kg⁻¹ · min⁻¹ remifentanyl) during regional anesthesia.²⁵³ With high infusion rates (1–8 mg · kg⁻¹ · min⁻¹) nausea occurred in 70% of subjects, and muscle rigidity was noted in all subjects.²⁴⁰ In pediatric patients who received desflurane with and without remifentanyl 0.2 mg · kg⁻¹ · min⁻¹,²⁵⁴ nausea and vomiting on emergence from general anesthesia was evaluated. In this study, the addition of remifentanyl produced no increase in the incidence of postoperative nausea or vomiting after dental surgery; nausea and vomiting occurred in <5% of patients who received remifentanyl. Philip *et al*²³⁸ compared nausea and vomiting at multiple time points in outpatient adults for laparoscopic surgery who received remifentanyl or alfentanil combined with propofol. In this study remifentanyl was infused at 0.25–0.5 mg · kg⁻¹ · min⁻¹ and alfentanil was infused at 1–2 mg · kg⁻¹ · min⁻¹ after induction. Overall, the incidence of nausea was 44% and 53% for remifentanyl and alfentanil, respectively; the incidence of vomiting was 21% and 29% for remifentanyl and alfentanil, respectively. Thus, remifentanyl appears to produce dose-dependent nausea and vomiting similar to other short-acting m-agonist opioids.

Disposition Kinetics

The key structural feature of remifentanyl is an ester functional group that is susceptible to hydrolysis by blood and tissue nonspecific esterases, which results in very rapid metabolism. Because butyrylcholinesterase (pseudocholinesterase) does not appear to metabolize remifentanyl, plasma cholinesterase deficiency and anticholinergic administration were not expected to affect remifentanyl clearance. This expectation has been confirmed.²⁵⁵ Unlike other opioids, remifentanyl clearance is mainly due to enzymatic hydrolysis, with redistribution playing only a minor role. This property reduces its pharmacokinetic variability compared to other opioids. Several investigators have evaluated the pharmacokinetics of remifentanyl in humans.^{227,240,241,256,257} Both two- and three-compartment models have been used to describe the plasma concentration decay curve of remifentanyl. Glass *et al*²²⁷ administered bolus doses of up to 2 mg · kg⁻¹ to normal volunteers. They reported a small volume of distribution, 0.39 l · kg⁻¹, and a high clearance, 41 ml · kg⁻¹ · min⁻¹. A rapid distribution phase of 0.9 minutes and a very short terminal elimination half-life of 9.5 minutes characterized a two-compartment model. Westmoreland *et al*²⁵⁷ found similar pharmacokinetic parameters in anesthetized patients given 2–30 mg · kg⁻¹, but observed that a three-compartment model best described the pharmacokinetics of remifentanyl. The rapid and slow distribution half-times were 0.4–0.5 and 2–3.7 minutes, respectively, and the elimination half-time was 10–20 minutes. The investigators reported a similar volume of distribution (approximately 0.3–0.5 l · kg⁻¹) and high total clearance (250–300 l · h⁻¹), approximately 3–4 times normal hepatic blood flow.

Although pharmacokinetic parameters of remifentanyl are unchanged in patients with severe liver disease²⁵⁸ or renal failure,²⁵⁹ patients with hepatic disease appear to be more sensitive to remifentanyl-induced respiratory depression (measured by hypercarbic challenge). As for other fentanyl congeners, gender does not affect remifentanyl pharmacokinetics, but advanced age is associated with a decrease in clearance and volume of distribution, as well as an increase in potency.²⁶⁰ Egan *et al* demonstrated that remifentanyl pharmacokinetics are similar in lean (within 20% ideal body weight) and obese (at least 80% over ideal body weight) patients, and recommended that remifentanyl dosing should be based on lean body mass.²⁶¹

Dosage and Administration of Remifentanyl

Clinical trials to develop ideal dosage combinations and regimens for a variety of inpatient and ambulatory procedures are ongoing. However, since its approval for clinical use, numerous reports have described dosing regimens for remifentanyl alone or in combination with other agents for induction and maintenance of general anesthesia, and as a component of sedation and monitored anesthesia care. Because of its extremely short duration of action, remifentanyl is best administered as a continuous infusion, although administration as repeated bolus doses has also been reported to be effective.

As described earlier, remifentanyl alone has not been found to be a satisfactory single agent for induction of anesthesia because of unreliability in loss of consciousness as well as significant muscle rigidity. Several clinical trials have described dosing regimens of remifentanyl and propofol for induction of anesthesia. Hogue *et al*²³⁷ described a dose of remifentanyl 1 mg · kg⁻¹ followed by an infusion of 1 mg · kg⁻¹ · min⁻¹; 3 minutes later, propofol 0.5–1 mg · kg⁻¹ was given. This regimen resulted in minimal hemodynamic response to tracheal intubation, but 15% of patients experienced hypotension (systolic BP < 80 mm Hg or MAP < 60 mm Hg). Song *et al*²⁶² compared bolus doses of fentanyl 1 mg · kg⁻¹, remifentanyl 0.5 mg · kg⁻¹, and remifentanyl 1 mg · kg⁻¹ followed 1 minute later by propofol 2 mg · kg⁻¹. Both remifentanyl doses compared favorably to the fentanyl dose; remifentanyl 1 mg · kg⁻¹ provided the best hemodynamic control without hypotension.

Early experience with remifentanyl suggests that when administered as part of a balanced anesthetic with 66% N₂O, remifentanyl infusion rates of 0.3–1 mg · kg⁻¹ · min⁻¹ are optimal to prevent hemodynamic responses to surgical stimuli.^{233,234} When infusion rates as high as 2 mg · kg⁻¹ · min⁻¹ are continued until placement of the last suture, spontaneous ventilation returns within 7 minutes. Peacock and Philip²³⁰ have suggested that an infusion of remifentanyl at 0.02–0.05 mg · kg⁻¹ · min⁻¹ administered with isoflurane at an end-tidal concentration of 0.8–1.3% will provide adequate maintenance of anesthesia. Combined with a propofol infusion of 75 mg · kg⁻¹ · min⁻¹, mean remifentanyl infusion rates of approximately 0.25–0.4 mg · kg⁻¹ · min⁻¹ appear to provide good hemodynamic control and allow for rapid emergence from anesthesia.^{237,238} With higher propofol infusion rates, 120–140 g · kg⁻¹ · min⁻¹, the remifentanyl infusion can be reduced to 0.02–0.05 mg · kg⁻¹ · min⁻¹.²³⁰ For

cardiac surgery, remifentanyl infusion rates from 1 to 3 mg · kg⁻¹ · min⁻¹ combined with a low-dose propofol infusion of 50 mg · kg⁻¹ · min⁻¹ effectively suppressed responses to skin incision, sternotomy, and aortic cannulation.²³⁶

A potential disadvantage of remifentanyl is also related to its short duration of action. Upon emergence from anesthesia, patients may experience substantial pain. Thus, if moderate to severe postoperative pain is anticipated, continuing the remifentanyl infusion at a lower rate may prevent this problem. Bowdle *et al* used this approach in patients undergoing a variety of orthopedic, abdominal, and thoracic procedures.²⁶³ At the time of the completion of skin sutures, the infusion rate was decreased to 0.05 mg · kg⁻¹ · min⁻¹, and subsequently titrated to patient comfort (pain rated as “none” to “mild”). Nearly half of these patients required no further adjustment of the remifentanyl rate for immediate postoperative analgesia; 78% had adequate analgesia with remifentanyl infusion rates from 0.05 to 0.15 mg · kg⁻¹ · min⁻¹. When only mild postoperative pain is anticipated, intraoperative administration of a nonsteroidal anti-inflammatory drug 30–60 minutes before the end of surgery may provide effective analgesia without additional opioids.

Remifentanyl can also be used as an adjunct for sedation or analgesia during regional anesthesia, for block placement, or as part of monitored anesthesia care (MAC). A dose of 1 mg · kg⁻¹ with or without a subsequent infusion of 0.2 mg · kg⁻¹ · min⁻¹ administered 90 seconds prior to placement of ophthalmologic block resulted in up to 80% of patients reporting no pain at the time of the block.²⁶⁴ However, 14% of patients who received an infusion experienced respiratory depression. During regional anesthesia, a maintenance infusion rate in the range of 0.05–0.1 mg · kg⁻¹ · min⁻¹ can provide adequate sedation and analgesia during surgery performed under local or regional nerve block.²⁶⁵ In general, bolus doses of remifentanyl during MAC have been discouraged because of the increased risk of respiratory depression and muscle rigidity, but this may be reduced somewhat by administering single doses slowly, *i.e.*, over >30 seconds. Finally, the dose requirement of remifentanyl for sedation/analgesia is reduced substantially when combined with midazolam or propofol. Gold *et al*²⁶⁶ found that remifentanyl requirement was reduced by approximately 50% (0.06 vs. 0.12 mg · kg⁻¹ · min⁻¹) when 1–2 mg of midazolam was given at the beginning of procedures performed under local anesthesia. A clinical study evaluated several regimens of remifentanyl plus propofol for extracorporeal shock wave lithotripsy. Combined with propofol 50 mg · kg⁻¹ · min⁻¹, small intermittent remifentanyl doses (25 mg · kg⁻¹), administered over 15–30 seconds, or a low-dose continuous infusion (0.05 mg · kg⁻¹ · min⁻¹) supplemented by 12.5 mg · kg⁻¹ bolus doses provided good analgesia, without an undue risk of respiratory depression.²⁶⁷

Partial Agonists and Mixed Agonist–Antagonists

The partial agonist and mixed agonist–antagonist opioids are synthetic or semisynthetic compounds that are structurally related to morphine. They are characterized by binding activity at multiple opioid receptors and their differential effects (agonist, partial agonist, or antagonist) at each receptor type. The clinical effect of a partial agonist at the m-opioid receptor is complex (Fig. 14-13). Administered alone, a partial agonist has a more shallow dose–response curve and a lower maximal effect than a full agonist (see Fig. 14-1 and the lowermost curve in Fig. 14-13). Combined with a low concentration (*cf.* curve indicated by [Ag] = 0.25 in Fig. 14-13) of a full agonist, the effects of the partial agonist are additive up to the maximum effect of the partial agonist. Combined with increasing concentrations ([Ag] = 0.67–256) of full agonist, the partial agonist will act as an antagonist. These drugs mediate their clinical effects via m- and k-opioid receptors, as summarized in Table 14-4. The classification scheme presented may change as our understanding of these drugs and of opioid receptors continues to grow. Bowdle extensively reviewed the pharmacology and clinical uses of these and other drugs in this class.²⁶⁸ Only nalbuphine, butorphanol, and buprenorphine are considered in this chapter.

Figure 14-13 Hypothetical log dose–effect curves for the combination of a partial agonist, B (intrinsic efficacy of 0.4), with a range of concentrations of a full agonist, A. The observed effect of the combination of A and B is expressed as a fraction of the maximal effect of the full agonist. As the concentration of the partial agonist increases, the effect of the combination converges on the maximum effect of the partial agonist. When added to a low concentration (*e.g.*, [A] eq 0.25) of agonist, the partial agonist increases the response; but when added to a large concentration of the agonist, the response decreases—that is, B acts like an antagonist. (Modified with permission from Bowdle TA: Partial agonist and agonist–antagonist opioids: Basic pharmacology and clinical applications. *Anaesth Pharmacol Rev* 1:135, 1993.)

| Drug | μ Receptor | κ Receptor |
|---------------|-----------------|-----------------|
| Nalbuphine | Partial agonist | Partial agonist |
| Butorphanol | Partial agonist | Partial agonist |
| Buprenorphine | Partial agonist | ?Antagonist |

Although nalbuphine and butorphanol have been reported to be antagonists at the μ-opioid receptor, they do cause respiratory depression, which is not a function of κ agonists. Thus, they appear to have at least partial agonist activity at the μ-opioid receptor. Adapted from Bowdle TA: Partial agonist and agonist–antagonist opioids: Basic pharmacology and clinical applications. *Anesth Pharmacol Rev* 1:135, 1993.

Table 14-4. ACTIONS OF THE NALBUPHINE, BUTORPHANOL, AND BUPRENORPHINE AT OPIOID RECEPTORS

The major role of the opioid agonist–antagonist and partial agonist drugs continues to be in the provision of postoperative analgesia, but they have also been used for intraoperative sedation, as adjuncts during general anesthesia, and to antagonize some of the effects of full m-opioid agonists.

Nalbuphine

Nalbuphine is a phenanthrene opioid derivative. Although it is often classified as a κ agonist and m antagonist, it is more accurately described as a partial agonist at both κ and m receptors.²⁶⁸ While MAC [minimum alveolar concentration] reduction studies have not been done in humans, Murphy and Hug²⁵ reported that a 0.5 mg · kg⁻¹ dose reduced enflurane MAC by 8% in dogs. However, increasing the dose 8-fold produced no further reduction in enflurane MAC. This modest MAC reduction, compared to 65% for morphine, suggests that nalbuphine may not be a useful adjunct for general anesthesia. However, several investigators have examined its effectiveness as a component of balanced anesthesia for cardiac²⁶⁹ and lower abdominal surgery.^{25,270} Combined with diazepam 0.4 mg · kg⁻¹ and 50% N₂O in oxygen, a loading dose of 3 mg · kg⁻¹ was followed by additional doses of 0.25 mg · kg⁻¹ as needed throughout surgery. No significant increases in blood pressure, stress hormones, or histamine were seen, and emergence from anesthesia was uncomplicated.²⁶⁹ Nalbuphine 0.2 mg · kg⁻¹ was compared to meperidine 0.5 mg · kg⁻¹ as an adjuvant to general anesthesia with 1% halothane and 70% N₂O in oxygen in spontaneously breathing patients undergoing inguinal hernia repair.²⁷¹ Both drugs produced a similar degree of respiratory depression as well as postoperative analgesia and side effects. The most common side effect was drowsiness. In a double-blind comparison with fentanyl for gynecologic surgery, fentanyl was found to better attenuate hypertensive responses to intubation and surgical stimulation.²⁷⁰ However, significant respiratory depression was seen in 8 of 30 patients who received fentanyl, and 4 required naloxone, compared to no respiratory depression in the nalbuphine group. Analgesia was similar, and as in other studies, postoperative sedation was common in the nalbuphine group.

The respiratory depression produced by nalbuphine, an effect most likely mediated by m-opioid receptors, has a ceiling effect equivalent to that produced by 30 mg/70 kg morphine.²⁶⁸ Analgesia is mediated by both κ and m receptors. Because of these effects, nalbuphine has been used to antagonize the respiratory depressant effects of full agonists while still providing analgesic effects. In a double-blind comparison, nalbuphine and naloxone both effectively antagonized fentanyl-induced postoperative respiratory depression.²⁷² However, patients who received naloxone subsequently required analgesics more often than did those who received

nalbuphine. Nalbuphine has also been effective in antagonizing respiratory depression due to residual fentanyl effect following high-dose (100–120 mg · kg⁻¹) fentanyl anesthesia for cardiac surgery.²⁷³ Only 3 of 21 patients experienced pain after nalbuphine administration, and this was adequately treated with additional nalbuphine. However, in a volunteer study, nalbuphine 0.21 mg · kg⁻¹ did not antagonize the respiratory depressant effects of 0.21 mg · kg⁻¹ morphine.²⁷⁴

While nalbuphine and other agonist–antagonists have ceiling analgesic effects as well as respiratory depressant effects, they can be as effective as full m agonists in providing postoperative analgesia. Nalbuphine 5–10 mg has also been used to antagonize pruritus induced by epidural and intrathecal morphine. The usual adult dose of nalbuphine is 10 mg as often as every 3 hours. It is important to be aware that nalbuphine can precipitate withdrawal symptoms in patients who are physically dependent on opioids.

Butorphanol

Butorphanol, a morphinan congener, has partial agonist activity at k and m opioid receptors, similar to those of nalbuphine. Compared to nalbuphine and similar drugs, however, butorphanol has a pronounced sedative effect, which is probably mediated by k receptors. In a laboratory study as well as in clinical use as a premedicant, butorphanol produced dose-dependent sedation comparable to that of midazolam.²⁷⁵ Like nalbuphine, butorphanol decreases enflurane MAC, in dogs, by a modest amount: 11%, at the lowest dose evaluated (0.1 mg · kg⁻¹).²⁵ Increasing the butorphanol dose 40-fold does not produce a further reduction. However, like nalbuphine, butorphanol has also been reported to be an effective component of balanced general anesthesia in cardiac surgery patients. Combined with diazepam and nitrous oxide, butorphanol and morphine provided equally satisfactory anesthesia.²⁶⁸

Given alone, butorphanol produces respiratory depression; but like nalbuphine, it has a ceiling effect below that of full m agonists. In postoperative patients a parenteral dose of 3 mg produces respiratory depression approximately equal to that of 10 mg morphine.¹ It has been used to antagonize the respiratory depressant effects of fentanyl.²⁷⁶ Patients who had been anesthetized with isoflurane, nitrous oxide, and fentanyl 5 mg · kg⁻¹ followed by an infusion of 3 mg · kg⁻¹ · h⁻¹ received three sequential doses of butorphanol 1 mg at 10–15-minute intervals. After the first 1-mg dose, respiratory rate and ventilatory response to CO₂ increased, while end-tidal CO₂ decreased significantly. Further progressive changes in all parameters were not significantly different from the initial response to butorphanol. Analgesia was not significantly affected in 21 of 22 patients.

In contrast to morphine, fentanyl, and even meperidine, butorphanol does not produce significant elevation in intrabiliary pressure⁸⁹ (see Fig. 14-7). Butorphanol has also been shown to be effective in the treatment of postoperative shivering,⁹⁶ but the mechanism for this effect is unknown.

Butorphanol is indicated for sedation as well as treatment of moderate to severe postoperative pain. Preliminary clinical experience suggests that butorphanol administered as patient-controlled analgesia is associated with a lower incidence of opioid-induced ileus compared to m-selective opioids (Dunbar PJ, personal communication). A dose as low as 0.5 mg can provide clinically useful sedation, while single analgesic doses range from 0.5 to 2 mg. Butorphanol has also been administered epidurally and transnasally.

Buprenorphine

Buprenorphine is a highly lipophilic thebaine derivative, which at small to moderate doses is 25–50 times more potent than morphine.¹ Unlike nalbuphine and butorphanol, buprenorphine does not appear to have agonist, and may have antagonist, activity at the k-opioid receptor (see Table 14-4).²⁶⁸ Another unique characteristic of buprenorphine is its slow dissociation from m receptors, which can lead to prolonged effects not easily antagonized by naloxone. Buprenorphine also appears to have an unusual bell-shaped dose–response curve such that, at very high doses, buprenorphine produces progressively less analgesia.²⁶⁸ In a clinical study, Pedersen²⁷⁷ found that patients who received 10 or 20 mg · kg⁻¹ buprenorphine during surgery were pain-free postoperatively, but half of the patients who received 30 or 40 mg · kg⁻¹ had significant postoperative pain. This observation is consistent with buprenorphine's bell-shaped dose–effect curve. Patients who received very high buprenorphine doses probably had plasma drug concentrations in the range at which declining analgesia is seen.

Buprenorphine also appears to have a ceiling effect to its respiratory depressant dose–response curve. However, although buprenorphine-induced respiratory depression can be prevented by prior naloxone administration, it is not easily reversed by naloxone once the effects have been produced.¹ A dose of 0.3 mg buprenorphine reduces CO₂ responsiveness to about 50% of control values.²⁷⁸ Large doses of naloxone (5–10 mg) were required to antagonize buprenorphine respiratory depression in volunteers, while 1-mg doses were not effective. In addition, the maximum antagonist effect did not occur until 3 hours after naloxone administration, an observation consistent with buprenorphine's slow dissociation from m receptors. Buprenorphine has been compared to naloxone in its ability to antagonize fentanyl-induced respiratory depression, and appears to increase respiratory rate without antagonizing analgesic effects in slowly administered doses up to 0.5 mg.²⁷⁹

Buprenorphine can be effective in treatment of moderate to severe pain. Its onset can be slow, but analgesic duration can be more than 6 hours. A single dose of 0.3–0.4 mg appears to produce analgesia equivalent to 10 mg morphine.¹

Antagonists (Naloxone and Naltrexone)

Under normal conditions, opioid antagonists produce few effects. They are competitive inhibitors of the opioid agonists, so the effect profile depends on the type and dose of agonist administered as well as the degree to which physical dependence on the opioid agonist has developed. The most widely used opioid antagonist is naloxone, which is structurally related to morphine and oxymorphone, and is a pure antagonist at m-, k-, and d-opioid receptors.¹ Naltrexone is a long-acting oral agent, which also has relatively pure antagonist activity. In some circumstances, naloxone can antagonize effects that appear to be mediated by endogenous opioids. For example, naloxone can reverse “stress analgesia” in animals and man; it can antagonize analgesia produced by low-frequency stimulation with acupuncture needles, and it can also reverse analgesia produced by placebo medications.¹

In clinical anesthesia practice, naloxone is administered to antagonize opioid-induced respiratory depression and sedation. Because opioid antagonists will reverse all opioid effects, including analgesia, naloxone should be carefully titrated to avoid producing sudden, severe pain in postoperative patients. Sudden, complete antagonism of opioid effects with naloxone has been reported to cause severe hypertension, tachycardia, ventricular dysrhythmias, and acute, sometimes fatal, pulmonary edema.²⁸⁰ Naloxone-induced pulmonary edema can occur even in healthy young patients who have received relatively small doses (80–500 mg) of naloxone.^{281,282} The mechanism for this phenomenon is thought to be centrally mediated catecholamine release, which causes acute pulmonary hypertension. Because most patients with opioid-induced respiratory depression will often breathe on command, it is important to stimulate them in addition to administering carefully titrated naloxone doses in the immediate postoperative period. It is also essential to monitor vital signs and oxygenation closely after naloxone is administered in order to detect occurrence of any of these potentially serious complications.

Naloxone will precipitate opioid withdrawal symptoms in opioid-dependent individuals. Clinicians tend to be aware of this risk when treating patients with known opioid addiction, but it is important to consider the potential for opioid withdrawal syndrome when treating nonaddicts who use opioids chronically, such as cancer patients and severe burn and trauma patients with protracted recovery courses.

Naloxone has a very fast onset of action, and thus is easily titrated. Peak effects occur within 1–2 minutes, and duration is dose-dependent, but total doses of 0.4–0.8 mg generally last 1–4 hours.¹ Suggested incremental doses for intravenous titration are 20–40 mg given every few minutes until the patient's ventilation improves, but analgesia is not completely reversed. Because naloxone has a short duration of action, respiratory depression may recur if large doses and/or long-acting opioid agonists have been administered. When prolonged ventilatory depression is anticipated, an initial loading dose followed by a naloxone infusion can be used. Infusion rates between 3 and 10 mg · h⁻¹ have been effective in antagonizing respiratory depression from systemic as well as epidural opioids.^{39,283}

USE OF OPIOID AGONISTS IN CLINICAL ANESTHESIA

Opioids are used alone or in combination with other agents, such as sedatives or anticholinergic agents, as “premedications.” For this purpose, longer acting opioids such as morphine are administered as single doses that are generally within the “analgesic” range. The goal of opioid premedication is to provide moderate sedation, anxiolysis, and analgesia while maintaining hemodynamic stability. Potential risks of opioid premedication include oversedation, respiratory depression, and nausea and vomiting. For induction of anesthesia, opioids are often used to blunt or prevent the hemodynamic responses to tracheal intubation. Opioids with rapid onset of action, such as fentanyl and its derivatives, are appropriate for this use.

Intraoperatively, opioids are administered as components of balanced anesthesia and neuroleptanesthesia, or alone in high-dose opioid anesthesia. During maintenance of general anesthesia, opioid dosage is titrated to the desired effect based on the surgical stimulus as well as individual patient characteristics, such as age, volume status, neurologic status, liver dysfunction, or other systemic disease states. Plasma opioid concentrations required to blunt hemodynamic responses to

laryngoscopy, tracheal intubation, and various surgical stimuli, as well as plasma opioid concentration associated with awakening from anesthesia, have been determined for several opioids. Titration to achieve these plasma concentrations (see [Table 14-3](#)), which reflect brain (effect site) concentrations, can be accomplished by administering repeated small bolus doses or by infusing the opioid at variable rates.

Fentanyl and its derivatives sufentanil and alfentanil are the opioids most widely used as supplements to general anesthesia. All of these opioids are more easily titrated than morphine because of their rapid onset of action. However, Shafer and Varvel¹² have emphasized that making a rational choice among these opioids requires an understanding of the relationships between their pharmacokinetics and pharmacodynamics. They have used elegant computer models to simulate the rate of decrease in plasma and effect site (brain) concentrations after various administration methods, including bolus doses, brief infusion, and prolonged infusion. Decreases in effect site concentration will determine time to recovery from various opioid effects. Comparable simulations have also been done for the newer opioid remifentanil.²⁴⁰ Important pharmacokinetic differences among these opioids include volumes of distribution and intercompartmental (distributional) and central (elimination) clearances. A smaller distribution volume tends to shorten recovery time, and a reduction in clearance tends to increase recovery time.¹² The major pharmacodynamic differences among these opioids are potency and the equilibration times between the plasma and the site of drug effect. Equilibration half-times between plasma and effect site are 5–6 minutes for fentanyl and sufentanil and 1.3–1.5 minutes for alfentanil and remifentanil.^{12,227} Computer simulations demonstrate that simply comparing elimination half-lives will not predict the relative rate of decline in drug concentration at the effect site after either bolus doses or continuous infusion of fentanyl, sufentanil, and alfentanil. The rate of recovery after a continuous infusion will depend on the duration of the infusion as well as the magnitude of decline that is required. [Figure 14-14](#) demonstrates how the times required for 20, 50, and 80% decrements in effect site (*i.e.*, brain) concentrations vary with each opioid depending on infusion duration. If only a 20% drop in effect site concentration is required (upper panel), recovery from all three opioids will be rapid, although recovery time increases for fentanyl after 3 hours of drug infusion. However, if a 50% decrease is required, recovery from sufentanil will be fastest for infusions less than 6–8 hours in duration, but more rapid for alfentanil if infusions are continued for more than 8 hours.

Context-Sensitive Half-time

Hughes *et al*¹³ expanded the concepts of Shafer and Varvel to define the relative contributions of distribution compartments to central compartment (plasma) drug distribution. These relative contributions vary according to infusion duration. Hughes devised the concept of “context-sensitive half-time,” which is defined as the time required for the drug concentration in the central compartment to decrease by 50%, and demonstrated how this half-time changes as drug infusion duration increases. During an infusion, the peripheral (fast and slow) compartments begin to fill up. After the infusion is stopped, drug will be eliminated, but will also continue to be redistributed as long as the concentration in a peripheral compartment is lower than that in the central compartment. This leads to a rapid drop in central compartment drug concentration. When central compartment (plasma) concentration drops below that of the peripheral compartment(s), the direction of drug redistribution will reverse, and will slow the decline in plasma concentration. The degree to which redistribution will affect the rate of drug elimination depends on the ratio of the distributional to elimination time constants. Thus, a drug that can rapidly redistribute will have a correspondingly larger contribution from the peripheral compartment(s), and plasma concentration will drop progressively more slowly as infusion duration continues. [Figure 14-15](#) illustrates the context-sensitive half-times for fentanyl, alfentanil, sufentanil, and remifentanil. This model predicts the time to a 50% concentration decrease in the plasma, which will reflect but not be equal to, effect site concentrations depicted in [Figure 14-14](#).

Figure 14-14 Recovery curves for fentanyl, sufentanil, and alfentanil showing the time required for decreases of 20% (A), 50% (B), and 80% (C) from maintained intraoperative effect site (brain) concentrations after termination of the infusion. (Reprinted with permission from Shafer SL, Varvel JR: Pharmacokinetics, pharmacodynamics, and rational opioid selection. *Anesthesiology* 74:53, 1991.)

Figure 14-15 Context-sensitive half-times for fentanyl, sufentanil, alfentanil, and remifentanil. This computer simulation depicts the time necessary to achieve a 50% reduction in plasma opioid concentration as a function of infusion duration. (Reprinted with permission from Egan TD, Lemmens HJM, Fiset P *et al*: The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. *Anesthesiology* 79:881, 1993.)

It is important to point out that these are theoretical predictions based on computer models, which require testing in humans for validation. Kapila *et al*²⁸⁴ compared modeled context-sensitive half-times with measured decreases in drug concentration and drug effect (respiratory depression) in volunteers receiving remifentanil and alfentanil. After 3-hour opioid infusions, measured whole blood opioid concentrations and recovery of ventilatory drive corresponded closely to modeled values for both drugs. To date, these predictions have not been validated during anesthesia for surgical procedures. Although the concept of a context-sensitive half-time appears to be useful, Hughes *et al*¹³ noted that it is unknown whether a decrement of 50% provides the most clinically useful description of the rate of offset of opioid effects. If one closely titrates infusions so that minimum effective concentrations are achieved, perhaps much smaller decrements will be necessary. In practice, it is relatively easy to administer higher than necessary doses of opioids, particularly to mechanically ventilated patients, because hemodynamic consequences are minimal. Titrating against a quantifiable parameter, such as minute ventilation in a spontaneously breathing patient, may allow a tighter dose titration. It does seem clear, however, that some context-sensitive index is more useful than the elimination half-life. Understanding these concepts can be useful when deciding which opioid to use, as well as in adapting guidelines for opioid dosage and infusion rates depending on the duration of anesthesia.

Inhalation anesthetics are the most common drugs used for the provision of general anesthesia. Adding as little as 1% of a volatile anesthetic to the inspired oxygen results in a state of unconsciousness and amnesia, which are essential components of general anesthesia. When combined with intravenous adjuvants, such as opioids or benzodiazepines, a balanced technique is achieved that results in further sedation/hypnosis and analgesia. The popularity of the inhaled anesthetics for establishing general anesthesia is based upon their ease of administration (*i.e.*, *via* inhalation) and the ability to predictably monitor their effects (*i.e.*, clinical signs and end-tidal concentrations). In contrast to intravenous anesthetics, the tissue concentrations of the inhaled anesthetics can be closely estimated from the end-tidal concentrations of these agents. In addition, the volatile anesthetic gases are relatively inexpensive in terms of the overall cost of the anesthesia care of the patient. The most significant nonideal characteristic of the inhaled anesthetics is the narrow range between therapeutic and lethal doses. This is easily dealt with, however, by monitoring tissue concentrations and by titrating to common clinical endpoints.

The most popular potent inhaled anesthetics used in adult surgical procedures are isoflurane and the two new volatile anesthetics, sevoflurane and desflurane ([Fig. 15-1](#)). In pediatrics, halothane and sevoflurane are most commonly employed. Although there are many similarities in terms of the overall effects of the volatile anesthetics (*e.g.*, they all have a dose-dependent effect to decrease blood pressure), there are some unique differences that affect the clinician's selection for use. These differences are balanced with the patient's health and with the particular effects of the planned surgical procedure. Discussion of the four most popular inhaled anesthetics provides the major emphasis of this chapter. For the sake of completeness and for historical purposes related to metabolism and renal toxicity, reasonably detailed comments on both enflurane and methoxyflurane are included.

Figure 15-1. Chemical structure of inhaled anesthetics. Halothane is an alkane, a halogen-substituted ethane derivative. Isoflurane and enflurane are isomers that are methyl ethyl ethers. Desflurane differs from isoflurane in the substitution of a fluorine for a chlorine atom and sevoflurane is a methyl isopropyl ether.

HISTORY

The volatile anesthetics in early clinical use consisted of flammable gases, including diethyl ether, cyclopropane, and divinyl ether. Several nonflammable compounds were available, including chloroform and trichloroethylene, but these were associated with hepatic toxicity and neurotoxicity and enjoyed but a brief period of clinical use. In the early 1930s studies on derivatives of the halogenated compound chloroform indicated that noncombustible anesthetic gases might be derived using organic fluoride compounds. Advances in fluorine chemistry in the 1940s allowed safe incorporation of fluorine into molecules at a reasonable expense. The advances in fluorine chemistry were driven by an appreciation of the role of fluorine in the production of high-octane aviation fuel and in the enrichment of uranium-235, both important issues in the war time effort. These advances proved to be pivotal to the development of modern-day anesthetics. There were approximately 46 fluorine-containing compounds synthesized by Dr. Earl McBee in research supported from the secret Manhattan project and from the Mallinkrodt Company. Although none of these ultimately proved to be useful as anesthetics in humans, several were very close in structure to what we now know as halothane. Fluorine is the halogen with the lowest atomic weight (18.998; chlorine = 35.45; bromine = 79.90; iodine = 126.9). Fluorine substitutions for other halogens on the ether molecule lowered the boiling point, increased stability, and generally decreased toxicity. The fluoride ion also damped the flammable hydrocarbon of the ether anesthetic framework.

In 1951, halothane was synthesized and extensively tested in animals by Suckling, working at ICI Laboratory in England.¹ Halothane was introduced into clinical practice in 1956 and was rapidly embraced, owing in part to its nonflammability and in part to its lower tissue solubility. Halothane also had a relatively low pungency and a high potency; thus, it could be administered in high inspired concentrations (relative to its potency) to induce anesthesia. It proved to be well accepted *via* inhalation in both adults and children. Another advantage of halothane over the older volatile anesthetics was the lower incidence of nausea and vomiting associated with its use.

Despite these desirable properties of halothane, some concerns and drawbacks remained. Most notable were the effects of halothane on sensitizing the myocardium to catecholamines and the later described role of its intermediate metabolite in hepatic necrosis. Thus, the search for better agents continued. Between 1959 and 1966, Terrell and colleagues at Ohio Medical Products (subsequently called Anaquest, Ohmeda, and most currently, Baxter) synthesized more than 700 compounds.^{2,3 and 4} The 347th and 469th compounds in the series were the methyl ethyl ethers enflurane and isoflurane, which were halogenated with fluorine and chlorine. Clinical trials of enflurane and isoflurane proceeded nearly in parallel, involving both human volunteer and patient studies. Years later, several compounds in Terrell's series were reexamined. One of these (the 653rd) was difficult to synthesize because of a potentially explosive step using elemental fluorine, and because the compound had a vapor pressure close to 1 atm, making it impossible to deliver with a standard wick vaporizer. However, this particular compound was completely halogenated with fluorine and hence was predicted to have a very low solubility in blood. As synthesis and delivery problems were resolved, this compound, now known as desflurane, was introduced into clinical practice in 1993.

Other new compounds were described in the early 1970s by Wallin and colleagues at Travenol Laboratories during the course of evaluating fluorinated isopropyl ethers. One of these proved to be a potent anesthetic agent and became known as sevoflurane.⁵ Like desflurane, it had a low solubility owing to fluorination of the ether molecule. It was noted that sevoflurane released organic and inorganic fluorides in both animals and humans; thus, the drug was not aggressively developed and marketed. When the patent rights were transferred to Ohio Medical Products, further testing revealed significant breakdown of sevoflurane in the presence of soda lime, raising safety concerns that limited further evaluation. As the patent rights expired, Maruishi Pharmaceutical in Japan undertook testing and development of sevoflurane, releasing the drug for general use in Japan in July, 1990. Because of the rapid acceptance and safety record of sevoflurane in Japan, Abbott Laboratories began pursuing laboratory and clinical trials with sevoflurane in the United States. After its safety was established, sevoflurane was introduced in U.S. clinical practice in 1995.

The new inhaled anesthetics sevoflurane and desflurane differ from isoflurane most importantly in their kinetic behavior. They both have significantly lower solubility in blood, which increases their speed for wash-in/wash-out and their speed in adjustment of anesthetic depth (Table 15-1). These characteristics mesh well with the ambulatory anesthesia environment of modern-day practice.

| | Sevoflurane | Desflurane | Isoflurane | Enflurane | Halothane | N ₂ O |
|--|-------------|------------|------------|-----------|-----------|------------------|
| Boiling point (°C) | 58 | 24 | 48 | 57 | 59 | -88 |
| Vapor pressure at 25°C (mm Hg) | 237 | 669 | 238 | 172 | 261 | 887.0 |
| Molecular weight (g) | 200 | 184 | 184 | 198 | 197 | 44 |
| Oil/gas partition coefficient | 47 | 59 | 91 | 87 | 24 | 1.4 |
| Blood/gas partition coefficient | 1.45 | 0.42 | 1.48 | 1.9 | 2.4 | 0.46 |
| Brain/blood solubility | 17 | 13 | 14 | 14 | 13 | 11 |
| Arterial solubility | 473 | 272 | 463 | 36 | 51.1 | 23 |
| Water/blood solubility | 11 | 11 | 24 | 17 | 14 | 11 |
| MIC in O ₂ , 35-40% at 1% (MAC) (%) | 1.8 | 4.6 | 1.07 | 1.65 | 0.75 | 3.84 |
| MIC in 40-75% N ₂ O (%) | 0.66 | 2.38 | 0.56 | 0.57 | 0.29 | — |
| MIC, >40% N ₂ O (%) | 1.45 | 3.07 | 1.1 | 1.05 | 0.64 | — |

Table 15-1. PHYSIOCHEMICAL PROPERTIES OF VOLATILE ANESTHETICS

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics as a discipline began with the study of noninhaled drugs before the concepts were applied to the inhaled anesthetics. Kety in 1950 was the first to examine the pharmacokinetics of inhaled agents in a systematic fashion.⁶ Eger and colleagues accomplished much of the early research in the field, leading to his landmark text on the subject in 1974.⁷ The inhaled anesthetics differ substantially from nearly all other drugs because they are gases given *via* inhalation. This makes their pharmacokinetics unique as well, and most major textbooks of anesthesia continue to devote considerable space to pharmacokinetic principles of currently used agents. Before delving into the particulars of inhaled anesthetic pharmacokinetics, however, a review of basic pharmacokinetic concepts is useful.

Drug pharmacology is classically divided into two disciplines, pharmacodynamics and pharmacokinetics. *Pharmacodynamics* can be defined as what drugs do to the body. It describes the desired and undesired effects of drugs, as well as the cellular and molecular changes leading to these effects. *Pharmacokinetics* can be defined as what the body does to drugs. It describes where drugs go, how they are transformed, and the cellular and molecular mechanisms underlying these processes.

Systemic drug pharmacokinetics has four phases: absorption, distribution, metabolism, and excretion. *Absorption* is the phase in which drug is transferred from the administration site (*e.g.*, digestive tract, lung, muscle) into the bloodstream. Intravenous drugs have no absorption phase because they are delivered directly into the bloodstream. *Distribution* is the phase in which drug is transferred to tissue sites throughout the body. *Metabolism* refers to the physiochemical processes by which substances in a living organism are synthesized (anabolism) or altered (catabolism); but in the context of anesthetic drugs, only drug alteration is pertinent. Finally, *excretion* is the phase in which changed or unchanged drug is transferred from tissues or blood into some vehicle (*e.g.*, bile, exhaled air, urine) for removal from the body.

Tissues are often grouped into hypothetical *compartments* based on perfusion. An important implication of different compartments and perfusion rates is the concept of *redistribution*. After a given amount of drug is administered, it reaches highly perfused tissue compartments first where it can equilibrate rapidly and exert its effects. With time, however, compartments with lower perfusion rates receive the drug and additional equilibria are established between blood and these tissues. As the tissues with lower perfusion absorb drug, maintenance of equilibria throughout the body requires drug transfer from highly perfused compartments back into the bloodstream. This lowering of drug concentration in one compartment by delivery into another compartment is called redistribution.

In discussions of the inhaled anesthetics, the terminology just described is subject to some minor differences. The absorption phase is usually called *uptake*, the metabolic phase is usually called *biotransformation*, and the excretion phase is usually called *elimination*. The terms are completely interchangeable.

Unique Features of Inhaled Anesthetics

Speed, Gas State, and Route of Administration

The inhaled anesthetics are among the most rapidly acting drugs in existence, and when administering a general anesthetic this speed provides a margin of safety. The ability to quickly increase or decrease anesthetic levels as necessary can mean the difference between an anesthetic state and an anesthetic misadventure. Speed

also means efficiency. Rapid induction and recovery may lead to faster operating room turnover times, shorter recovery room stays, and earlier discharges to home.

Technically, nitrous oxide is the only true gas, while the potent anesthetics are the vapors of volatile liquids. But for simplicity, all of them are called gases because they are all in the gas phase when administered *via* the lungs. As gases, none deviates significantly from ideal-gas behavior. These agents are all nonionized and have low molecular weights. This allows them to diffuse rapidly without the need for facilitated diffusion or active transport from bloodstream to tissues. The other advantage of gases is that they can be delivered to the bloodstream *via* a unique route available in all patients: the lungs.

The lung route of administration is unique to the inhaled anesthetics, except for bronchodilators or endotracheal administration of cardiac resuscitation drugs. These exceptions are, however, a “one-way street” because their route of delivery is different from their elimination route. Inhaled anesthetics have a “two-way street” in the lungs; they are delivered and primarily eliminated *via* this route.

Speed, gaseous state, and the lung route of administration combine to form the major beneficial feature of the inhaled anesthetics—the ability to decrease plasma concentrations as easily and as rapidly as they are increased.

Physical Characteristics of Inhaled Anesthetics

The goal of delivering inhaled anesthetics is to produce the anesthetic state by establishing a specific concentration of anesthetic molecules in the central nervous system (CNS). This is done by establishing the specific partial pressure of the agent in the lungs, which ultimately equilibrates with the brain and spinal cord. Equilibration is due to three factors:

1. Inhaled anesthetics are gases rapidly transferred bidirectionally *via* the lungs to and from the bloodstream, and subsequently to and from CNS tissues as partial pressures equilibrate.
2. Plasma and tissues have a low capacity to absorb the inhaled anesthetics relative to the amount we can deliver to the lungs, allowing us to quickly establish or abolish anesthetizing concentrations of anesthetic in the bloodstream and, ultimately, the CNS.
3. Metabolism, excretion, and redistribution of the inhaled anesthetics are minimal relative to the rate at which they are delivered or removed from the lungs. This permits easy maintenance of blood and CNS concentrations.

At equilibrium, CNS partial pressure equals blood partial pressure, which in turn equals alveolar partial pressure:

$$P_{\text{CNS}} = P_{\text{blood}} = P_{\text{alveoli}} \quad (15-1)$$

where P is partial pressure. The physical characteristics of inhaled anesthetics are shown in [Table 15-1](#).

Inhaled anesthetics are delivered to the lung as gases and follow the ideal gas law, $PV = nRT$, where P is pressure, V is volume, n is number of moles of gas, R is the gas constant, and T is absolute temperature. If a gas is heated in a fixed volume, pressure will increase. If a gas is heated or if molecules of gas are added while keeping its pressure constant, its volume must increase. If the number of molecules of gas is increased into a fixed volume, pressure will increase.

Just about any substance at a high enough temperature (if the substance is not destroyed by that temperature) can exist as a gas. The so-called *permanent gases*, such as oxygen and nitrogen, exist only as gases at ambient temperatures. Gases such as nitrous oxide can be compressed into liquids under high pressure at ambient temperature. Most *potent volatile anesthetics* are liquids at ambient temperature and pressure. Some molecules with sufficient energy escape the liquid and enter a gas phase above the surface of the liquid as a vapor. If left open to air, gas molecules rapidly diffuse, seeking to equalize with atmospheric pressure until all of the liquid is gone. Pure gases always diffuse from an area of high pressure to an area of low pressure because of their *chemical potential*, m . Chemical potential, also called the escaping tendency, is a thermodynamic concept. It is similar to an electrical potential. In this case, however, it is gases that continue to seek equilibration until m is equal throughout the system. Chemical potential depends on the substance and characteristics of the system in which it exists, such as temperature, pressure, and presence of other substances.

If the system in which the volatile liquid resides is a closed container, molecules of the substance will equilibrate between the liquid and gas phases (to equalize m). At equilibrium the pressure exerted by molecular collisions of the gas against the container walls is the *vapor pressure*. One important property of vapor pressure is that as long as *any* liquid remains in the container, the vapor pressure is independent of the volume of that liquid. As with any gas, however, vapor pressure is proportional to temperature.

For all of the potent agents at 20°C the vapor pressure is below atmospheric pressure. Thus, transfer of molecules between liquid and gas phases occurs only at the liquid:gas interface at the surface of the liquid. If the temperature is raised, however, the vapor pressure increases. The *boiling point* of a liquid is the temperature at which its vapor pressure exceeds atmospheric pressure in an open container. Above this temperature molecules convert into the gas phase within the liquid, rising through the liquid because of their lower density; that is, the substance boils. Desflurane is bottled in a special container because its boiling point of 23.5°C makes it boil at typical room temperatures. Boiling does not occur within the bottle because it is countered by build-up of vapor pressure within the bottle; but once opened to air, the desflurane would quickly boil away. The bottle is designed to allow transfer of desflurane from bottle to vaporizer without exposure to the atmosphere.

Gases in Mixtures

For any mixture of gases in a closed container, each gas exerts a pressure proportional to its *fractional mass* (or *fractional volume* according to $PV = nRT$, since “volume” is a more familiar term when dealing with gases). This is its *partial pressure*. The sum of the partial pressures of each gas in a mixture of gases equals the total pressure of the entire mixture (Dalton's law):

$$P_{\text{total}} = P_{\text{gas1}} + P_{\text{gas2}} + \dots + P_{\text{gasN}} \quad (15-2)$$

The entire mixture behaves just as if it were a single gas according to the ideal gas law.

Gases in Solution

Partial pressures of gases in solution are more complicated. Any gas/vapor dissolved in a liquid exerts a force to drive molecules out of solution and into the gas phase. Molecules in the gas phase counter this by exerting a force that drives them into the liquid phase. Only at a given concentration of molecules in the gas phase will the forces (hence chemical potentials) be equal and the system in equilibrium. This force is called the *tension*, and the concentration of molecules in the gas phase at equilibrium will determine the pressure of that phase according to the ideal gas law. Tension is conveniently described by the partial pressure of the gas in equilibrium with the liquid phase. The terms “tension” and “partial pressure” are used synonymously in this chapter.

The *concentration* of gas molecules in solution is more complicated still, owing to intermolecular interaction. Gas molecules within a liquid interact with solvent molecules to a much larger extent than do molecules in the gas phase, in which there are almost no intermolecular interactions. The gas molecules will be present in the liquid only to the extent that this equalizes the chemical potential between the liquid and gas phases. The chemical potential of the gas in a liquid depends dramatically on the liquid itself and the energy state of that liquid. *Solubility* is the term used to describe the tendency of a gas to equilibrate with a solution, hence determining its concentration in solution. The solubility coefficient, λ , is an expression of this tendency:

$$\lambda = V_{\text{dissolved gas}}/V_{\text{liquid}} \quad (\text{at } 37^\circ\text{C}) \quad (15-3)$$

where V = volume.

The principles of partial pressures and solubility apply in mixtures of gases in solution. That is, the concentration of any one gas in a mixture of gases in solution depends upon two factors: (1) its partial pressure in the gas phase in equilibrium with the solution, and (2) its solubility within that solution. Thus, the partial pressure of a particular gas is proportional to its fractional volume in the gas phase, but is *not* proportional to its fractional volume in solution.

The implications of these properties are profound. Anesthetic gases administered *via* the lungs diffuse into blood until the partial pressures in alveoli and blood are equal. The concentration of anesthetic in the blood depends upon the partial pressure at equilibrium and the blood solubility. Likewise, transfer of anesthetic from blood to target tissues also proceeds toward equalizing partial pressures. The concentration of anesthetic in target tissue depends on the partial pressure at equilibrium and

the target tissue solubility. Because inhaled anesthetics are gases, and because partial pressures of gases equilibrate throughout a system, monitoring the alveolar concentration of inhaled anesthetics provides an index of their effects in the brain.

In summary:

1. Inhaled anesthetics equilibrate based on their partial pressures in each tissue (or tissue compartment), *not* based on their concentrations.
2. The partial pressure of a gas in solution is always defined by the partial pressure in the gas phase with which it is in equilibrium.
3. The concentration of anesthetic in a tissue depends on its partial pressure and tissue solubility.

Finally, the particular terminology used when referring to gases in the gas phase or absorbed in plasma or tissues is important. Inspired concentrations or fractional volumes of inhaled anesthetic are typically used rather than partial pressure. For most drugs, concentration is expressed as mass (mg) per volume (ml), but it can also be expressed in percent by weight or volume. Since volume of a gas in the gas phase is directly proportional to mass according to the ideal gas law, it is easier to express this fractional concentration as a percent by volume. Tension and partial pressure, on the other hand, are expressed in mm Hg, or torr (1 torr = 1 mm Hg), or kPa (kilopascals). In the gas phase, fractional concentration is equal to the partial pressure (or tension) divided by ambient pressure, usually atmospheric, or:

$$\text{Fractional volume} = P_{\text{anesthetic}} / P_{\text{barometric}} \quad (15-4)$$

Anesthetic Transfer: Machine to CNS

Anesthetics follow a multistep route from anesthesia machine to patient (and back). Each of these steps represents a transfer point or interface between hypothetical compartments. The compartments are organized by location or pharmacokinetic properties in an effort to simplify the concept of anesthetic flow. For example, one-way flow occurs from the fresh gas outlet to the anesthesia circuit and to the waste gas scavenging system. Equilibrium flow occurs between the anesthesia circuit and the airways (and alveoli) and between the alveoli and pulmonary blood. Bulk flow of blood accounts for anesthetic transfer to systemic blood, and equilibrium flow occurs between systemic blood and tissues. The flow of anesthetic from compartment to compartment can be characterized by pharmacokinetics. Technically, the flow from fresh gas outlet (FGO) to circuit is not a pharmacokinetic concern because it does not characterize what the body does to the drug. But it is typically discussed as a pharmacokinetic parameter because it has important clinical implications.

When the fresh gas flow and the vaporizer are turned on, fresh gas with a fixed fractional concentration of anesthetic leaves the FGO and mixes with the gas in the circuit—the bag, tubing, absorbent canister, and piping. It is immediately diluted to a lower fractional concentration, then slowly rises as this compartment equilibrates with the fresh gas flow. With spontaneous patient ventilation by mask, the anesthetic gas passes from circuit to airways. The fractional concentration of anesthetic leaving the circuit is designated as F_I (fraction inspired). In the lungs the gas comprising the dead space in the airways (trachea, bronchi) and the alveoli further dilutes the circuit gas. The fractional concentration of anesthetic present in the alveoli is designated as F_A (fraction alveolar). The anesthetic then passes across the alveolar–capillary membrane and dissolves in pulmonary blood according to the partial pressure of the gas and its solubility. It is further diluted and travels *via* bulk blood flow throughout the vascular tree. The anesthetic then passes *via* simple diffusion from blood to tissues as well as between tissues.

The general direction of *diffusion* of gas at all times depends on partial pressure gradients. *Bulk gas flow*, on the other hand, is generally one-way, depending on the phase of the respiratory cycle. Various equilibria are being established between the compartments *via* diffusion during and between periods of bulk flow.

The vascular system delivers blood to three physiologic tissue groups: the vessel-rich group (VRG), the muscle group, and the fat group. The VRG includes the brain, heart, kidney, liver, digestive tract, and glandular tissues. The percent body mass and perfusion of each are shown in [Table 15-2](#). The CNS tissues of the VRG are referred to as *tissues of desired effect*. The other tissues of the VRG comprise the compartment frequently referred to as *tissues of undesired effects*. The tissues of the muscle and fat groups comprise the *tissues of accumulation*.

| Group | % Body Mass | % Cardiac Output | Perfusion (ml·min ⁻¹ ·100 g ⁻¹) |
|-------------|-------------|------------------|---|
| Vessel-rich | 10 | 25 | 25 |
| Muscle | 50 | 19 | 3 |
| Fat | 20 | 6 | 3 |

Table 15-2. CHARACTERISTICS OF PHYSIOLOGIC TISSUE COMPARTMENTS

Anesthetic is delivered most rapidly to the VRG, where it diffuses according to partial pressure gradients. CNS tissue takes in the anesthetic according to the tissue solubility, and at a high enough tissue concentration unconsciousness is achieved. Increasing CNS tissue concentrations cause progressively deeper stages of anesthesia. As this is occurring, anesthetic is also distributing to other VRG tissues, mostly causing undesired effects, which must be monitored closely and sometimes treated. Also coincident with delivery to the CNS, anesthetic is being delivered—albeit more slowly owing to lower perfusion—to muscle and fat where it accumulates and can affect the speed of emergence from the anesthetic. The concentration of inhaled anesthetic in a given tissue at a particular time during the administration depends not only on tissue blood flow, but also on tissue solubility, which governs how the inhaled anesthetics partition themselves between blood and tissue. Partitioning depends on the relative solubilities of the anesthetic for each compartment. These relative solubilities are expressed by a partition coefficient, d , which is the ratio of dissolved gas (by volume) in two tissue compartments at equilibrium. Alternatively, it is the ratio of tissue:gas solubilities in the two compartments. For a pure gas in the gas phase, $d = 1$; that is, $V_{\text{dissolved gas}}/V_{\text{gas}} = 1$. Thus, the blood:gas partition coefficient is the same as blood solubility:

$$d_{b/g} = \lambda_{\text{blood}} / \lambda_{\text{gas}} = \lambda_{\text{blood}} / 1 = \lambda_{\text{blood}} \quad (15-5)$$

where $d_{b/g}$ is the blood:gas partition coefficient. For other partition coefficients such as brain:blood ($d_{br/bl}$), the volume of anesthetic dissolved in brain is divided by the volume of anesthetic dissolved in blood:

$$d_{br/bl} = \lambda_{\text{brain}} / \lambda_{\text{blood}} \quad (15-6)$$

Some of the partition coefficients for the inhaled anesthetics are shown in [Table 15-1](#).

As explained earlier, one of the reasons why inhaled anesthetics are rapidly titratable is that their tissue solubilities are low relative to delivery rate; thus delivery of a desired partial pressure to the CNS is possible despite redistribution and accumulation of anesthetic in other tissues. Over a longer delivery period, however, accumulation in the non-VRGs becomes significant for some anesthetics and can delay emergence.

Uptake and Distribution

F_A/F_I

A simple, common way to assess anesthetic uptake is to follow the ratio of fractional concentration of alveolar anesthetic to inspired anesthetic (F_A/F_I) over time. Experimentally derived data for F_A/F_I versus time during induction are shown in [Figure 15-2](#).

The inhaled anesthetics with the lowest solubilities in blood show the fastest rise in F_A/F_I . The shape of these curves has several regions with different origins. As fresh

gas carrying anesthetic begins to flow into the air-filled circuit (assuming complete mixing), the concentration in the circuit (F_I) will rise according to first-order kinetics:

$$F_I = F_{FGO}(1 - e^{-T/\tau}) \quad (15-7)$$

F_{FGO} is the fraction of inspired anesthetic in the gas leaving the fresh gas outlet (*i.e.*, the vaporizer setting), T is time, and τ is a time constant. Because all anesthetics in the circuit are in the gas phase, F (fractional volume or concentration) is also P (partial pressure) divided by P_B (barometric pressure), and inspired anesthetic can be expressed as either F_I or P_I . The time constant is simply the volume or “capacity” of the circuit (V_C) divided by the fresh gas flow (FGF) or $\tau = V_C/\text{FGF}$. For example, if the bag, tubing, absorbent canister, and piping comprise 8 l, and the fresh gas flow is 2 l, the time constant $\tau = 8/2 = 4$. One of the characteristics of first-order kinetics is that 95% of maximum is reached after three time constants—in this case, $3 \times 4 = 12$ minutes.

Because 12 minutes is relatively long, the rate of rise of F_I can be increased by starting with a higher F_{FGO} . Using the example above with $\tau = 4$, by first-order kinetics 63% of maximum is reached after one time constant, or 4 minutes. To attain an F_I of 2% at 4 instead of 12 minutes, the F_{FGO} can be set to 3.2% (2% divided by 0.63) and then lowered to 2% at the 4-minute mark.

Other ways to speed the increase in F_I include increasing the fresh gas flow (FGF), thus decreasing τ . Furthermore, the rebreathing bag can be collapsed prior to starting the FGF, such that the capacity in the circuit (V_C) is less, which also decreases τ . Finally, at high flows ($>4 \text{ l} \cdot \text{min}^{-1}$) there is far less mixing because fresh gas pushes “old” gas out of the circuit *via* the pop-off valve before complete mixing occurs, causing F_I to increase at a greater rate.

One factor that delays the rate of rise of F_I arises from the fact that CO_2 absorbent can adsorb and decompose the inhaled anesthetics. From a practical standpoint, this does not affect the rate of rise in F_I to a significant extent compared to other factors. Another factor that delays the rate of rise of F_I is solubility of the inhaled anesthetics in some of the plastic and rubber parts of the anesthesia circuit. This absorption has been quantified,^{8,9} but plays only a small role in decreasing the rate of rise of F_I . More significant is its tendency to delay emergence at the end of an anesthetic.

Rise in F_A in the Absence of Uptake

The rate of rise in F_I discussed above assumes that no anesthetic is mixing with gas in the patient's lungs. In reality, circuit gas mixes with exhaled gases from the lung with each breath. If extremely high fresh gas flows (producing a high volume of gas at the desired concentration) are used, little mixing with exhaled air occurs and F_I is relatively fixed. In this situation, circuit gas enters the lungs where it mixes with alveolar gas. If there were no blood flow to the lungs, F_A would rise in a fashion analogous to F_I ; that is:

$$F_A = F_I(1 - e^{-T/\tau}) \quad (15-8)$$

In this equation, τ is the time constant for alveolar rise in anesthetic concentration and equals the functional residual capacity (FRC) of the patient's lungs divided by minute ventilation, \dot{V}_A . There are two ways to speed the equilibration of F_A with F_I , that is, to decrease τ . One way is to increase minute ventilation, and the other is to decrease FRC. Both of these methods can be used to speed induction by mask: the patient can exhale deeply before applying the mask (to decrease the initial FRC), and the patient can breathe deeply and rapidly (to increase \dot{V}_A) after the mask is applied. One of the reasons that pediatric inductions by spontaneous breathing of inhaled anesthetics are so much quicker than adult inductions is that the low FRC relative to \dot{V}_A of children makes for a low time constant, and hence a rapid increase in F_A/F_I . One important caveat about the relationship of F_A to FRC is that FRC includes airway dead space; thus, in reality, F_A by Eq. (15-8) is not just the concentration of inhaled anesthetic in the alveoli but the concentration in the entire lung. However, it is simply called the alveolar concentration because the dead space in the airways is relatively insignificant and only the alveolar gas is exchanging anesthetic with the blood.

Rise in F_A in the Presence of Uptake

Because in reality there *is* pulmonary blood flow, the most important factor in the rate of rise of F_A/F_I is uptake of anesthetic from the alveoli into the bloodstream. The rate of rise of F_A/F_I (the slope of the curves seen in Fig. 15-2) reflects the speed at which alveolar anesthetic (F_A) equilibrates with that being delivered to the lungs (F_I). F_A is not solely a function of F_I and time. Inhaled anesthetics so avidly transfer into and are diluted by the bloodstream that uptake into blood is a primary determinant of F_A . The greater the uptake, the slower the rate of rise of F_A/F_I . Uptake is proportional to tissue solubility. The more soluble the anesthetic (such as halothane), the greater its uptake and the slower it is to reach equilibrium. For any fixed volume of halothane delivered to the lungs, a greater number of molecules of halothane are transferred from alveoli to bloodstream as partial pressures equilibrate when compared to the less soluble anesthetics, desflurane and sevoflurane.

Figure 15-2. The rise in alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least soluble anesthetics nitrous oxide, desflurane, and sevoflurane. It rises most slowly with the more soluble anesthetics, *e.g.*, halothane. All data are from human studies. (Adapted from Yasuda N, Lockhart SH, Eger EI II *et al*: Kinetics of desflurane, isoflurane, and halothane in humans. *Anesthesiology* 74:489, 1991; and Yasuda N, Lockhart SH, Eger EI II *et al*: Comparison of kinetics of sevoflurane and isoflurane in humans. *Anesth Analg* 72:316, 1991.)

Consider a hypothetical example. Suppose that halothane and desflurane are soluble in blood, but insoluble in all other tissues. Suppose further that total lung capacity and blood volume are both 5 l. If a fixed volume of anesthetic is delivered to the lungs (by asking the patient to take one deep breath and hold it), according to partition coefficients, 70.6% of the delivered halothane will be transferred to the blood while 29.4% remains in the alveoli ($70.6/29.4 = 2.4$). In contrast, 29.6% of the desflurane will be transferred to the blood while 70.4% remains in the alveoli ($29.6/70.4 = 0.42$). Therefore, 2.4 times ($70.6/29.6$) more halothane than desflurane (by volume or number of molecules) will be transferred from alveoli to bloodstream before partial pressures equilibrate. At equilibrium, the partial pressures of halothane and desflurane are 29.4% and 70.4% of their inhaled values, respectively.

But anesthetics *are* soluble in tissues, and they are delivered *continuously* rather than in a “one-shot” fashion; thus they are again characterized by first-order kinetics:

$$P_{bl} = P_A \times (1 - e^{-T/\tau}), \quad \text{where } P_A = F_A \times P_B \quad (15-9)$$

Here, P_B is the barometric pressure, and the time constant, τ , equals “capacity” (volume of anesthetic dissolved in blood at the desired alveolar partial pressure) divided by flow (volume of anesthetic delivered per unit time). For any given flow of anesthetic into the system, this capacity for the more soluble halothane is greater than the capacity for the less soluble desflurane; thus, τ for halothane is greater than that for desflurane. The more soluble an inhaled anesthetic, the larger the capacity of the blood and tissues for that anesthetic, and the longer it takes to saturate at any given delivery rate.

Anesthetic flow can be described by a series of first-order rate equations: F_I as a function of F_{FGO} , F_A as a function of F_I , blood uptake as a function of F_A , and so on. These differential equations can then be solved to determine any value as a function of time. Relatively straightforward equations help describe which parameters determine the rate of rise of F_A/F_I .

Let $\dot{V}_{inspired}$ be the rate of anesthetic delivery to the alveoli. Assuming an ideal situation in which inspired gas is not diluted in the circuit by expired gas, $\dot{V}_{inspired}$ equals the inspired fraction of anesthetic, F_I , multiplied by the alveolar ventilation, \dot{V}_A :

$$\dot{V}_{inspired} = F_I \times \dot{V}_A \quad (15-10)$$

Let $\dot{V}_{expired}$ be the flow of anesthetic not participating in gas exchange with the bloodstream and let \dot{V}_B be the rate of anesthetic uptake into the bloodstream. Then

$$\dot{V}_{expired} = \dot{V}_{inspired} - \dot{V}_B \quad (15-11)$$

During any given period of time, the alveolar anesthetic fraction, F_A , as a proportion of the inspired anesthetic fraction, F_I , will equal the ratio of $\dot{V}_{expired}$ to $\dot{V}_{inspired}$; that is:

$$F_A/F_I = \dot{V}_{expired}/\dot{V}_{inspired} \quad (15-12)$$

For example, at steady state, if 10 ml of an inhaled anesthetic were inspired and 5 ml were expired (5 ml transferred to the blood), then the alveolar fraction (F_A) would be only half of the inspired fraction (F_I) since 50% of the anesthetic is taken up. Substituting for $\dot{V}_{expired}$ according to [Eq. \(15-11\)](#), we have

$$F_A/F_I = (\dot{V}_{inspired} - \dot{V}_B)/\dot{V}_{inspired} = 1 - \dot{V}_B/\dot{V}_{inspired} \quad (15-13)$$

Substituting for $\dot{V}_{inspired}$ according to [Eq. \(15-10\)](#),

$$F_A/F_I = 1 - \dot{V}_B/F_I \times \dot{V}_A \quad (15-14)$$

If F_A/F_I is zero and starts to increase as inhaled anesthetic reaches the alveoli from the circuit but uptake of anesthetic in the pulmonary blood (\dot{V}_B) nearly equals its delivery to the alveoli ($F_I \times \dot{V}_A$), then F_A/F_I will not rise. All of the anesthetic arriving at alveoli is transferred immediately to the blood. Since blood capacity to absorb anesthetic is finite, F_A will eventually begin to rise relative to F_I . \dot{V}_B can never exceed $F_I \times \dot{V}_A$ by definition. If, on the other hand, blood uptake is very small, F_A and F_I quickly become nearly equal.

Blood uptake of anesthetic is expressed by the equation

$$\dot{V}_B = d_{b/g} \times Q \times ((P_A - P_V)/P_B) \quad (15-15)$$

where \dot{V}_B is blood uptake, $d_{b/g}$ is the blood:gas partition coefficient, Q is cardiac output, P_A is alveolar partial pressure of anesthetic, P_V is mixed venous partial pressure of anesthetic, and P_B is barometric pressure. This is the Fick equation applied to blood uptake of inhaled anesthetics. Combining [Eq. \(15-14\)](#) and [Eq. \(15-15\)](#) gives

$$F_A/F_I = 1 - (d_{b/g}/F_I)(Q/\dot{V}_A)((P_A - P_V)/P_B) \quad (15-16)$$

Based on [Eq. \(15-16\)](#), the parameters that increase or decrease the rate of rise in F_A/F_I during induction can be clearly defined and these important factors have been substantiated in experimental models ([Table 15-3](#)).

| Increase | Decrease | |
|--------------------|-------------------|--|
| Low λ_b | High λ_b | The lower the blood:gas solubility, the faster the rise in F_A/F_I ⁽¹⁵⁻¹⁶⁾ |
| Low Q | High Q | The lower the cardiac output, the faster the rise in F_A/F_I ⁽¹⁵⁻¹⁶⁾ |
| High \dot{V}_A | Low \dot{V}_A | The higher the minute ventilation, the faster the rise in F_A/F_I ⁽¹⁵⁻¹⁶⁾ |
| High $(P_A - P_V)$ | Low $(P_A - P_V)$ | At the beginning of induction, P_V is zero but rises rapidly (thus $[P_A - P_V]$ falls rapidly) and F_A/F_I increases rapidly. Later during induction and maintenance, P_V rises more slowly so F_A/F_I rises more slowly. |

Parameters as described in Eq. (15-16): λ_b = blood solubility; Q = cardiac output; \dot{V}_A = minute ventilation; P_A , P_V = pulmonary arterial and venous blood partial pressures

Table 15-3. FACTORS THAT INCREASE OR DECREASE THE RATE OF RISE OF F_A/F_I

Before induction, P_V is zero because no anesthetic is present in the bloodstream. P_A is established with the first inspiration of anesthetic, and the alveolar to pulmonary blood partial pressure gradient, $P_A - P_V$, determines the rate of increase in F_A/F_I . Initially, P_A climbs at a much greater rate than P_V because circulation and dilution as well as tissue uptake together keep P_V low. As significant tissue concentrations of anesthetic start to accumulate, P_V rapidly climbs as the pulmonary blood, originally carrying no anesthetic, becomes saturated with anesthetic. This early rapid rise in F_A/F_I followed by slowing is seen in [Figure 15-2](#).

Distribution (Tissue Uptake)

Until P_V starts to increase, the maximum F_A/F_I at a given inspired concentration of anesthetic, cardiac output, and minute ventilation is entirely dependent on the solubility of that drug in the blood as characterized by the blood:gas partition coefficient $d_{b/g}$. This can be seen in the time curves for the rise in F_A/F_I during induction for the various inhalation anesthetics shown in [Figure 15-2](#). The first "knee" in each curve in [Figure 15-2](#) represents the point at which the rapid rise in P_V begins to taper off, that is, when significant inhaled anesthetic concentrations begin to build up in the bloodstream because of distribution to and equilibration with the various tissue compartments.

Each of the three perfusion compartments—VRG, muscle, and fat—takes up anesthetic based on the Fick equation:

$$\dot{V}_{\text{compartment}} = \lambda_{\text{compartment}} \times Q_{\text{compartment}} \times ((P_{a\text{compartment}} - P_{v\text{compartment}})/P_B) \quad (15-17)$$

where $P_{a\text{compartment}}$ and $P_{v\text{compartment}}$ are arterial and venous partial pressures in the tissue compartment. Mixed venous partial pressure of anesthetic in the pulmonary outflow, P_V , depends on the relative uptake in each of these perfusion compartments. To the extent that the mass and blood flow to each of these compartments differ,

anesthetic uptake will differ.

As blood is equilibrating with alveolar gas, it also begins to equilibrate with the VRG, muscle, and, more gradually, the fat compartments based on perfusion. Muscle is not that different from the VRG, having partition coefficients that range from 1.2 (nitrous oxide) to 3.4 (halothane), just under a threefold difference; and for each anesthetic except nitrous oxide, the muscle partition coefficient is approximately double that for the VRG. Although both VRG and muscle are lean tissues, the muscle compartment equilibrates far more slowly than the VRG. The explanation comes from Eq. (15-17) and the mass of the compartments relative to perfusion. The perfusion of the VRG is about $75 \text{ ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ of tissue, whereas it is only $3 \text{ ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ of tissue in the muscle (see Table 15-2). This 25-fold difference in perfusion between VRG (especially brain) and muscle means that even if the partition coefficients were equal, the muscle would still take 25 times longer to equilibrate with blood.

Fat is perfused to an extent similar to muscle but its time for equilibration with blood is considerably slower because the partition coefficients are so much greater. All of the potent agents are highly lipid-soluble. Partition coefficients range from 27 (desflurane) to 51 (halothane). On average, the solubility for these agents is about 25 times greater in fat than in the VRG group. Thus fat equilibrates far more slowly with the blood and does not play a significant role in determining speed of induction. However, after long anesthetic exposures, the high saturation of fat tissue can play a significant role in delaying emergence.

Nitrous oxide represents an exception. Its partition coefficients are fairly similar in each tissue, it does not accumulate to any great extent, and it is not a very potent anesthetic. Its utility lies as an adjunct to the potent agents, and as a vehicle to speed induction.

Metabolism

Data suggest that the enzymes responsible for biotransformation of inhaled anesthetics become saturated at less than anesthetizing doses of these drugs, such that metabolism plays little role in opposing induction.¹⁰ It may, however, have some significance to recovery from anesthesia, as discussed later.

Overpressurization and the Concentration Effect

There are several ways to speed uptake and induction of anesthesia with the inhaled anesthetics. The first is *overpressurization*, which is analogous to an iv bolus. This is the administration of a higher partial pressure of anesthetic (F_I) than the alveolar concentration (F_A) actually desired for the patient.

Inspired anesthetic concentration (F_I) can influence both F_A and the *rate of rise* of F_A/F_I .^{11,12} The greater the inspired concentration of an inhaled anesthetic, the greater the rate of rise. This *concentration effect* has two components. The first is a concentrating effect, and the second is an augmented gas inflow effect.

For example, consider the administration of 10% anesthetic (10 parts anesthetic and 90 parts other gas) to a patient in which 50% of the anesthetic in the alveoli is absorbed by the blood. In this case, 5 parts (0.5×10) anesthetic remain in the alveoli, 5 parts enter the blood, and 90 parts remain as other alveolar gas. The alveolar concentration is now $5/(90 + 5) = 5.3\%$. Consider next administering 50% anesthetic with the same 50% uptake. Now 25 parts anesthetic remain in alveoli, 25 parts pass into blood, and 50 parts remain as other alveolar gas. The alveolar concentration becomes $25/(50 + 25) = 33\%$. Giving 5 times as much anesthetic leads to an alveolar concentration that is $33\%/5.3\% = 6.2$ times greater. The higher the F_I , the greater the effect. Thus, nitrous oxide, typically given in concentrations of 50–70%, has the greatest concentrating effect. This is why the F_A/F_I versus time curve in Figure 15-2 rises most quickly with nitrous oxide, even though desflurane has a lower blood:gas solubility. However, this concentrating effect becomes most prominent with the most soluble anesthetic. Therefore, halothane and isoflurane *should* benefit most at any particular concentration of anesthetic, F_I . But because equipotent concentrations for halothane and isoflurane are lower than those of the less soluble anesthetics, sevoflurane and desflurane, these agents benefit from the concentration effect less than expected—that is, *concentration outweighs solubility*. The typical inspired concentrations of N_2O are so much greater than the potent anesthetics that its low tissue solubility is of no consequence.

This isn't the complete picture; there is yet another factor to consider. As gas is leaving the alveoli for the blood, new gas at the original F_I is entering to replace that which is lost. This other aspect of the concentration effect has been called *augmented gas inflow*. Again, take the example of 10% anesthetic delivered with 50% uptake into the bloodstream. The 5 parts anesthetic absorbed by the bloodstream are replaced by gas in the circuit that is still 10% anesthetic. The 5 parts anesthetic and 90 parts other gas left in the lungs mix with 5 parts replacement gas, or $5 \times 0.10 = 0.5$ parts anesthetic. Now the alveolar concentration is $(5 + 0.5)/(100\%) = 5.5\%$ (as compared to 5.6% without augmented inflow). For 50% anesthetic and 50% uptake, 25 parts of anesthetic removed from the alveoli are replaced with 25 parts of 50% anesthetic, giving a new alveolar concentration of $(25 + 12.5)/(100\%) = 37.5\%$ (as compared to 33% without augmented inflow). Thus 5 times the F_I leads to $37.5/5.5 = 6.8$ times greater F_A (compared to 6.2 times without augmented gas inflow). Of course, this cycle of absorbed gas being replaced by fresh gas inflow is continuous and has a finite rate, so our example is a simplification.

Second-Gas Effect

A special case of concentration effect applies to administration of a potent anesthetic with nitrous oxide—that is, two gases simultaneously. Along with the concentration of potent agent in the alveoli *via* its uptake, there is further concentration *via* the uptake of nitrous oxide. This process, called the *second-gas effect*, has been confirmed in dogs.¹³ Some confusion attends the question of which is the second gas, the nitrous oxide or the potent anesthetic. As originally proposed¹⁴ the second gas is the potent agent. Terminology aside, the principle is simple (Fig. 15-3 and Fig. 15-4). Consider, for example, administering 2% of a potent anesthetic in 70% nitrous oxide and 28% oxygen. In this case, nitrous oxide, with its extremely high vapor pressure (despite low solubility), partitions into the blood more rapidly than the potent anesthetic, decreasing the alveolar N_2O concentration by some amount (e.g., by 50%). Ignoring uptake of the potent anesthetic, the uptake of N_2O is 35 parts, leaving 35 parts N_2O , 28 parts O_2 , and 2 parts potent agent in the alveoli. The second gas is now present in the alveoli at a concentration of $2/(2 + 35 + 28) = 3.1\%$. The second gas has been concentrated.

Figure 15-3. The second-gas effect. In this hypothetical example, the second gas is set at 2% of a potent anesthetic and the model is set for 50% uptake of the first gas (N_2O) in the first inspired breath. The second gas is concentrated because of the uptake of N_2O (middle panel). On replenishing the inspired second gas ($F_I = 2\%$) in the next breath, the second gas has been concentrated to be 2.7% because of the uptake of N_2O in the previous breath.

Figure 15-4. The concentration and second-gas effects in dogs receiving nitrous oxide. (*Upper curves*) The concentration effect: Administration of 70% N₂O produces a more rapid rise in the F_A/F_I ratio of nitrous oxide than does administration of 10% N₂O. (*Lower curves*) The second-gas effect: The F_A/F_I ratio for 0.5% halothane rises more rapidly when given with 70% N₂O than when given with 10% N₂O. (Adapted from Epstein R, Rackow H, Salanitro E *et al*: Influence of the concentration effect on the uptake of anesthetic mixtures: The second-gas effect.

Ventilation Effects

As indicated by [Figure 15-2](#) and [Eq. \(15-16\)](#), inhaled anesthetics with very low tissue solubility have an extremely rapid rise in F_A/F_I with induction. This suggests that there is very little room to improve this rate by increasing or decreasing ventilation. This is consistent with the experimental evidence shown in [Figure 15-5](#).¹⁵ The greater the solubility of an inhaled anesthetic, the more rapidly it is absorbed by the bloodstream, such that anesthetic delivery to the lungs may be rate-limiting. Therefore, for more soluble anesthetics, augmentation of anesthetic delivery by increasing minute ventilation also increases the rate of rise in F_A/F_I .

Figure 15-5. The F_A/F_I ratio rises more rapidly if ventilation is increased from 2 to 8 L · min⁻¹. Solubility modifies this impact of ventilation; e.g., the effect is least with the least soluble anesthetic, nitrous oxide, and greatest with the more soluble anesthetic, halothane. (Adapted from Eger EI II: Ventilation, circulation and uptake. In Anesthetic Uptake and Action, p 123. Baltimore, Williams & Wilkins, 1974.)

Spontaneous minute ventilation is not static, however, and to the extent that the inhaled anesthetics depress spontaneous ventilation with increasing inspired concentration, \dot{V}_A will decrease and so will the rate of rise of F_A/F_I .^{16,17,18} and ¹⁹ This negative feedback should not be considered a drawback of the inhaled anesthetics, because the respiratory depression produced at high anesthetic concentrations essentially slows the rise in F_A/F_I . This might arguably add a margin of safety in preventing an overdose.

Perfusion Effects

As with ventilation, cardiac output is not static during the course of induction. For the insoluble agents, changes in cardiac output do not affect the rate of rise of F_A/F_I to a great extent, but for the more soluble agents the effect is noticeable, as seen in [Figure 15-6](#).²⁰ However, as inspired concentration increases, greater cardiovascular depression reduces anesthetic uptake and actually increases the rate of rise of F_A/F_I . This positive feedback can rapidly lead to profound cardiovascular depression.

[Figure 15-6](#) presents experimental data in which lower cardiac outputs lead to a much more rapid rise in F_A/F_I when \dot{V}_A is held constant.²¹ This more rapid rise is greater than can be accounted for just by concentration effect.

Figure 15-6. If ventilation is fixed, an increase in cardiac output from 2 to 18 L · min⁻¹ will decrease the alveolar anesthetic concentration by augmenting uptake, thereby slowing the rise of the F_A/F_I ratio. This effect is most prominent with the more soluble anesthetics (halothane) than with the less soluble anesthetics (nitrous oxide). (Adapted from Eger EI II: Ventilation, circulation and uptake. In Anesthetic Uptake and Action, p 131. Baltimore, Williams & Wilkins, 1974.)

Ventilation–Perfusion Mismatching

Ventilation and perfusion are normally fairly well matched in healthy patients such that P_A (alveolar partial pressure)/ P_I and P_a (arterial partial pressure)/ P_I are the same curve. If significant intrapulmonary shunt occurs, however, as in the case of inadvertent bronchial intubation, the rate of rise of alveolar and arterial anesthetic partial pressures can be affected. The effects, however, depend on the solubility of the anesthetic, as seen in [Figure 15-7](#). Ventilation of the intubated lung is dramatically increased while perfusion increases slightly. The nonintubated lung receives no ventilation, while perfusion decreases slightly. For the less soluble anesthetics, increased ventilation of the intubated lung cannot appreciably increase alveolar partial pressure relative to inspired concentration on that side, but alveolar partial pressure on the nonintubated side is essentially zero. Pulmonary mixed venous blood therefore comprises nearly equal parts blood containing normal amounts of anesthetic and blood containing no anesthetic, that is, diluted relative to normal. Thus the rate of rise in P_a relative to P_I is significantly reduced. There is less total anesthetic uptake, so the rate of rise of P_a relative to P_I increases even though induction of anesthesia is slowed because CNS partial pressure equilibrates with P_a . For the more soluble anesthetics, increased ventilation of the intubated lung *does* increase the alveolar partial pressure relative to inspired concentration on that side. Pulmonary venous blood from the intubated side contains a higher concentration of anesthetic that lessens the dilution by blood from the nonintubated side. Thus the rate of rise of P_a/P_I is not as depressed as that for the less soluble anesthetics, and induction of anesthesia is less delayed.

Figure 15-7. When no ventilation/perfusion abnormalities exist, the alveolar (P_A) or end-tidal (P_{ET}) and arterial (P_a) anesthetic partial pressures rise together (continuous lines) toward the inspired partial pressure (P_I). When 50% of the cardiac output is shunted through the lungs, the rate of rise of the end-tidal partial pressure (dashed lines) is accelerated while the rate of rise of the arterial partial pressure (dot-dashed lines) is retarded. The greatest effect of shunting is found with the least soluble anesthetic, cyclopropane. (Adapted from Eger EI II, Severinghaus JW: Effect of uneven pulmonary distribution of blood and gas on induction with inhalation anesthetics. *Anesthesiology* 25:620, 1964.)

Elimination

Percutaneous and Visceral Loss

Although the loss of inhaled anesthetics via the skin is very small, it does occur^{22,23,24} and 25 and is the greatest for nitrous oxide. These anesthetics also pass across gastrointestinal viscera and the pleura. During open abdominal or thoracic surgery there is some anesthetic loss via these routes.²⁶ Relative to losses by all other routes, losses via percutaneous and visceral routes are insignificant.

Diffusion between Tissues

Using more elaborate mathematical modeling of inhaled anesthetic pharmacokinetics than presented here, several laboratories have derived a five-compartment model that best describes tissue compartments.^{27,28,29} and 30 These compartments are the alveoli, the VRG, the muscle, the fat, and one additional compartment. Current opinion is that this fifth compartment represents adipose tissue adjacent to lean tissue that receives anesthetic via intertissue diffusion. This transfer of anesthetic is not insignificant and may account for up to one-third of uptake during long administration.

Metabolism

Inhaled anesthetic biotransformation is discussed in more depth elsewhere in this chapter. Metabolism is greatest for halothane, up to 50% of loss.³¹ In fact, there is evidence that decreases in the alveolar concentrations of halothane during emergence outpace those for isoflurane, presumably because of this significant metabolism.^{27,28} Experimentally, it has been determined that metabolism does not significantly affect recovery from isoflurane and desflurane,^{29,30} but may have a slight influence for sevoflurane.³²

Exhalation and Recovery

Recovery from anesthesia, like induction, depends on anesthetic solubility, cardiac output, and minute ventilation. Solubility is the primary determinant of the rate of fall of F_A (Fig. 15-8).³³ The greater the solubility of inhaled anesthetic, the larger the capacity for absorption in the bloodstream and tissues. The “reservoir” of anesthetic in the body at the end of administration depends on tissue solubility (which determines the capacity) and the dose and duration of anesthetic (which determine how much of that capacity is filled). Recovery from anesthesia, or “washout,” is usually expressed as the ratio of expired fractional concentration of anesthetic (F_E) to the expired concentration at time zero (F_{E0}) when the anesthetic was discontinued (or F_A/F_{A0}). Elimination curves of nitrous oxide and halothane are shown in Figure 15-9. The longer the duration of anesthetic, the greater the reservoir of anesthetic in the body, and the higher the curve seen in Figure 15-9.

Figure 15-8. Elimination of anesthetic gases is defined as the ratio of end-tidal anesthetic concentration (F_A) to the last F_A during administration and immediately before the beginning of elimination (F_{A0}). During the 120-min period after ending the anesthetic delivery, the elimination of sevoflurane and desflurane is 2–2.5 times faster than that of isoflurane or halothane (note logarithmic scale for the ordinate). (Adapted from Yasuda N, Lockhart SH, Eger EI II *et al*: Kinetics of desflurane, isoflurane, and halothane in humans. *Anesthesiology* 74:489, 1991; and Yasuda N, Lockhart SH, Eger EI II *et al*: Comparison of kinetics of sevoflurane and isoflurane in humans. *Anesth Analg* 72:316, 1991.)

Figure 15-9. Both solubility and duration of anesthesia affect the decrease of the alveolar concentration (F_A) from its value immediately preceding the cessation of anesthetic administration (F_{A0}). A longer anesthetic time (from 15 min to 240 min) slows the decrease, as does a greater solubility of the agent (halothane). (Adapted from Stoelting RK, Eger EI II: The effects of ventilation and anesthetic solubility on recovery from anesthesia: An *in vivo* and analog analysis before and after equilibrium. *Anesthesiology* 30:290, 1969.)

There are two major pharmacokinetic differences between recovery and induction. First, whereas overpressurization can increase the speed of induction, there is no “underpressurization.” Both induction and recovery rates depend on the P_A to P_V gradient, and P_A can never fall below zero. Second, whereas all tissues begin induction with zero anesthetic, each begins recovery with quite different anesthetic concentrations. The VRG tissues begin recovery with the same anesthetic partial pressure as that in alveoli, since $P_{CNS} = P_{blood} = P_{alveoli}$. The partial pressures in muscle and fat depend on the inspired concentration during anesthesia, the duration of administration, and the anesthetic tissue solubilities. As long as an arterial-to-tissue partial pressure gradient exists, these tissues will absorb anesthetic—especially fat, since it is a huge potential reservoir whose anesthetic partial pressures are typically low after hours of anesthesia. After discontinuation of anesthesia, muscle and fat may continue to absorb anesthetic, even hours later. This is essentially redistribution, which continues until blood/alveolar anesthetic partial pressure falls below tissue partial pressure. This redistribution causes the early rate of decline in alveolar anesthetic concentration during recovery to exceed its increase during induction.^{34,35}

Because VRG tissues are highly perfused and washout of anesthetic is mostly *via* elimination from these tissues early in recovery, all anesthetics, regardless of duration of administration, have approximately the same rate of elimination to 50% of F_{E0} .³⁶ Unfortunately, halving the CNS concentration of anesthetic is rarely sufficient for waking the patient. More commonly, 80–90% of inhaled anesthetic must be eliminated before emergence. At these amounts of washout, the more soluble anesthetics are eliminated much more slowly than less soluble agents.³⁶

Diffusion Hypoxia

During recovery from anesthesia, washout of high concentrations of nitrous oxide can lower alveolar concentrations of oxygen^{37,38} and carbon dioxide,³⁹ a phenomenon called *diffusion hypoxia*. The resulting alveolar hypoxia can cause hypoxemia, and alveolar hypocarbia can depress respiratory drive, which may exacerbate hypoxemia. It is therefore appropriate to initiate recovery from nitrous oxide anesthesia with 100% oxygen rather than less concentrated O₂/air mixtures.

CLINICAL OVERVIEW OF CURRENT INHALED ANESTHETICS

Halothane

Halothane, a relatively nonflammable liquid, is the most potent of the currently used volatile anesthetics. It is an alkane—a halogen-substituted ethane derivative (see Fig. 15-1)—that was placed into clinical use in 1956. The halogenated structure provided nonflammability. It has an intermediate blood solubility and is relatively nonpungent; hence it can be inhaled *via* the facemask. The carbon–fluorine bond is important in providing nonflammability of halothane at room temperature and the trifluorocarbon group contributes to its molecular stability. Despite its chemical stability, halothane oxidizes spontaneously and is broken down by ultraviolet light. It decomposes to hydrochloric acid (HCl), hydrobromic acid (HBr), chloride (Cl⁻), bromide (Br⁻), and phosgene (COCl₂). To prevent this decomposition, halothane is stored in amber-colored bottles and 0.01% thymol is added as a preservative to prevent spontaneous oxidative decomposition. The thymol preservative can “gum up” vaporizers, mandating a more difficult and more frequent cleaning schedule than that for vaporizers specific to other volatile anesthetics. Halothane also is adsorbed by contact with dry soda lime and broken down to BCDFE (2-bromo-2-chloro-1,1-difluoroethene), which has organ toxicity in animal models. In humans, halothane has been associated with an immune-mediated hepatitis and a sensitization to epinephrine resulting in arrhythmias. It also has been associated with bradycardia when used in the pediatric population.

Enflurane

Enflurane, a halogenated methyl ethyl ether, is an isomer of isoflurane (see Fig. 15-1). It is a nonflammable liquid at room temperature and is pungent. Its use in high concentrations has been associated with seizure-like activity on the EEG. Its metabolism has resulted in an increase in blood fluoride concentration and, rarely, with a renal concentrating deficiency. Its popularity has generally been reserved owing to competition from isoflurane—the near-simultaneously introduced volatile anesthetic, which has proven to be associated with very few side effects. In recent years, the use of enflurane has been further diminished with the introduction of new anesthetics with lower solubilities.

Isoflurane

Isoflurane, a halogenated methyl ethyl ether, is a clear, nonflammable liquid at room temperature and has a high degree of pungency (see Fig. 15-1). The second most potent of the volatile anesthetics in clinical use, isoflurane has great physical stability and undergoes essentially no deterioration during storage for up to five years or on exposure to sunlight. It has become the “gold standard” anesthetic since its introduction in the 1970s. There has been a brief period of controversy concerning the use of isoflurane in patients with coronary disease because of the possibility for coronary “steal,” arising from isoflurane's potent effects on coronary vasodilation. In clinical use, however, this has been, at most, a rare occurrence.

Desflurane

Desflurane is a fluorinated methyl ethyl ether that differs from isoflurane by just one atom: a fluorine atom is substituted for a chlorine atom on the α -ethyl component of isoflurane (see Fig. 15-1). The process of completely fluorinating the ether molecule has several effects. It decreases blood and tissue solubility (the blood:gas solubility of desflurane equals that of nitrous oxide), and it results in a loss of potency (the MAC of desflurane is 5 times higher than that of isoflurane). Moreover, the complete fluorination of the methyl ether molecule results in a high vapor pressure (owing to decreased intermolecular attraction). Thus, a new vaporizer technology has been developed to deliver a regulated concentration of desflurane as a gas. A heated, pressurized vaporizer requiring electrical power is required. One of the advantages of desflurane is the near-absent metabolism to serum trifluoroacetate. This makes immune-mediated hepatitis extremely unlikely. The most pungent of the volatile anesthetics, desflurane cannot be administered *via* the facemask as it results in coughing, salivation, breath holding, and laryngospasm. In extremely dry CO₂ absorbers, desflurane (and, to a lesser extent, isoflurane and enflurane) degrades to form carbon monoxide. Desflurane has the lowest blood:gas solubility of the potent volatile anesthetics; moreover, its fat solubility is roughly half that of the other volatile anesthetics. Thus, desflurane offers a theoretical advantage in long surgical procedures by virtue of decreased tissue saturation. Desflurane also has been associated with transient periods of sympathetic activation, hypertension, and tachycardia when used in high concentrations or when rapidly increasing the inspired concentration.

Sevoflurane

Sevoflurane is a sweet-smelling, completely fluorinated methyl isopropyl ether (see Fig. 15-1). Its vapor pressure is most similar to that of enflurane and it can be used in a conventional vaporizer. The blood:gas solubility of sevoflurane is second only to desflurane in terms of potent volatile anesthetics. Sevoflurane is approximately half as potent as isoflurane, and some of the preservation of potency, despite fluorination, is due to the bulky propyl side chain on the ether molecule. Sevoflurane has minimal odor, no pungency, and is a potent bronchodilator. These attributes make sevoflurane an excellent candidate for administration *via* the facemask on induction of anesthesia in both children and adults. As a coronary vasodilator, sevoflurane is half as potent as isoflurane, but it is 10–20 times more vulnerable to metabolism than isoflurane. Like that of enflurane and methoxyflurane, the metabolism of sevoflurane results in inorganic fluoride; but the increase in plasma fluoride after sevoflurane administration has not been associated with renal concentrating defects, as is the case with methoxyflurane. Unlike other potent volatile anesthetics, sevoflurane is not metabolized to trifluoroacetate; rather, it is metabolized to an acyl halide (hexafluoro-isopropanol). This does not stimulate formation of antibodies, and immune-mediated hepatitis has not been reported with sevoflurane. Sevoflurane does not form carbon monoxide during exposure to dry CO₂ absorbents. Rather, sevoflurane breaks down in the presence of the carbon dioxide absorber to form a vinyl halide called compound A. Compound A has been shown to be a dose-dependent nephrotoxin in rats, but has not been associated with renal injury in human volunteers and patients, even when fresh gas flows are 1 l · min⁻¹ or less.

Xenon

Xenon is an inert gas. Difficult to obtain, and hence extremely expensive, it has received considerable interest in the last few years because it has many characteristics approaching those of an “ideal” inhaled anesthetic.^{40,41} Its blood:gas partition coefficient is 0.14; and unlike the other potent volatile anesthetics (except methoxyflurane), xenon provides some degree of analgesia. Unfortunately, the MAC in humans is 71%, which might prove to be a limitation. It is nonexplosive, nonpungent, and odorless, and thus can be inhaled with ease. In addition, it does not produce significant myocardial depression.⁴¹ Because of its scarcity and high cost, new anesthetic systems need to be developed to provide for recycling of xenon. If this proves to be too difficult from either a technical or patient safety standpoint, it may be necessary to use it in a very low, or closed, fresh gas flow system to reduce wastage.

Nitrous Oxide

Nitrous oxide is a sweet-smelling, nonflammable gas of low potency (MAC = 104%) and is relatively insoluble in blood. It is most commonly administered as an anesthetic adjuvant in combination with opioids or volatile anesthetics during the conduct of general anesthesia. Although not flammable, nitrous oxide will support

combustion. Unlike the potent volatile anesthetics in clinical use, nitrous oxide does not produce significant skeletal muscle relaxation, but it does have documented analgesic effects. Despite a long track record of use, controversy has surrounded nitrous oxide in four areas: its role in postoperative nausea and vomiting, its potential toxic effects on cell function *via* inactivation of vitamin B₁₂, its adverse effects related to absorption and expansion into air-filled structures and bubbles, and its effect on embryonic development. The one concern that seems most valid and most clinically relevant is the ability of nitrous oxide to expand air-filled spaces because of its greater solubility in blood compared to nitrogen. Several closed gas spaces, such as the bowel and middle ear, exist in the body and other spaces, such as a pneumothorax, may occur as a result of disease or surgery. Nitrogen cannot be removed readily *via* the bloodstream. Unfortunately, nitrous oxide delivered to a patient diffuses from the blood into these closed gas spaces quite easily, in which case the spaces must increase pressure and may expand.⁴² Movement of nitrous oxide into these spaces continues until the partial pressure equals that of the blood and alveoli. Compliant spaces will continue to expand until sufficient pressure is generated to oppose further N₂O flow into the space. The higher the inspired concentration of nitrous oxide, the higher the partial pressure required for equilibration.

Seventy-five percent N₂O can expand a pneumothorax to double or triple its size in 10 and 30 minutes, respectively.⁴² Air-filled cuffs of pulmonary artery catheters and endotracheal tubes also expand with the use of N₂O, possibly causing tissue damage *via* increased pressure in the pulmonary artery or trachea, respectively.^{43,44} and ⁴⁵ In a rabbit model, the volume of air required to create an air embolus that results in cardiovascular compromise is less during coadministration of nitrous oxide.⁴⁶ Accumulation of nitrous oxide in the middle ear can diminish hearing postoperatively,⁴⁷ and is relatively contraindicated for tympanoplasty because the increased pressure can dislodge a tympanic graft.⁴⁸

NEUROPHARMACOLOGY OF INHALED ANESTHETICS

The inhaled anesthetics establish the anesthetic state by effects on spontaneous neuronal activity and metabolism. The exact anesthetic mechanisms of inhaled agents remain poorly understood, and the associated nervous system effects may be mediated in part by undetermined mechanisms. Therefore, as a whole, the current understanding of inhaled anesthetic neuropharmacology tends to be more descriptive than mechanistic in nature.

The mechanisms of anesthesia are elusive partly because no uniform definition exists as to when the brain is anesthetized; however, the anesthetized brain may be usefully defined as one that is incapable of self-awareness or subsequent recall.⁴⁹ This definition is helpful conceptually, but practical questions remain: How do we know when the brain is no longer self-aware or will have no recall? And what is the dose of inhaled anesthetic at this point? The ability to determine, establish, and maintain this level of anesthesia is part of the art of anesthesia. It depends on the integration of knowledge of inhaled anesthetic pharmacokinetics and pharmacodynamics and direct observation of the patient and interpretation of data from a complex array of monitors. The BIS monitor, the first, albeit crude, index of anesthetic "depth" *via* continuous real-time analysis of the patient's electroencephalogram (EEG) might provide relevant information. The utility of this device remains controversial, however.

Minimum Alveolar Concentration (MAC)

The pharmacodynamic effects of inhaled anesthetics must be based on a dose, and this dose is the *minimum alveolar concentration* (MAC). MAC is the alveolar concentration of an anesthetic at 1 atm (1 atm = 760 mm Hg) that prevents movement in response to a surgical stimulus in 50% of patients.^{50,51} It is analogous to the ED₅₀ expressed for intravenous drugs. A variety of surgical stimuli have been used to establish the MAC for each inhaled anesthetic, but the classic defining noxious stimulus is incision of the abdomen. Likewise, skeletal muscle movement is the defining patient response, but other responses have been used to establish MAC as well. Experimentally determined MAC values for humans for the inhaled anesthetics are shown in [Table 15-1](#).

The 95% confidence ranges for MAC are approximately $\pm 25\%$ of the listed MAC values. Manufacturers' recommendations and clinical experience establish 1.2–1.3 times MAC as a dose that consistently prevents patient movement during surgical stimuli. Presumably, loss of consciousness precedes the absence of stimulus-induced movement by a wide margin. While these 1.2–1.3 MAC values do not *absolutely* ensure the defining criteria for brain anesthesia (the absence of self-awareness and recall), vast clinical experience suggests it is extremely unlikely for a patient to be aware of, or to recall, the surgical incision at these anesthetic concentrations.

Concentrations of inhaled anesthetics that provide loss of self-awareness and recall are about 0.4–0.5 MAC. Several lines of reasoning lead to this conclusion. First, most patients receiving only 50% nitrous oxide (approximately 0.4–0.5 MAC), as in a typical dentist's office, will have no recall of their procedure during N₂O administration. Second, various studies have shown that a shift in EEG dominance to the anterior leads (*i.e.*, the shift from self-aware to non-self-aware) accompanies loss of consciousness; and in primates, the EEG shift and loss of consciousness occur at 0.5 MAC.⁵² Third, in dogs, loss of consciousness accompanies a sudden nonlinear fall in cerebral metabolic rate at approximately 0.5 MAC ([Fig. 15-10](#)).

Figure 15-10. The effects of halothane on CMRO₂ (cerebral metabolic rate) as a percentage of control ("awake"). CMRO₂ is plotted versus end-tidal isoflurane concentration. Regression lines for changes in CMRO₂ are drawn for each EEG-determined area. The pattern depicted here is characteristic of all of the anesthetics examined (enflurane, halothane, and isoflurane). (Adapted from Stullken EH Jr, Milde JH, Michenfelder JD *et al*: The non-linear responses of cerebral metabolism to low concentrations of halothane, enflurane, isoflurane and thiopental. *Anesthesiology* 46:28, 1977.)

MAC values can be established for any measurable response. MAC-awake, the alveolar concentration of anesthetic at which a patient opens his or her eyes to command, varies from 0.15 to 0.5 MAC.^{53,54} Interestingly, transition from awake to unconscious and back typically shows some hysteresis, in that it quite consistently takes 0.4–0.5 MAC to lose consciousness, but less than that (as low as 0.15 MAC) to regain consciousness. MAC-BAR, the alveolar concentration of anesthetic that blunts adrenergic responses to noxious stimuli, has likewise been established and is approximately 50% higher than standard MAC.⁵⁵ MAC also has been established for discrete levels of EEG activity, such as onset of burst suppression or isoelectricity. Attempts to establish MAC values for particular EEG bispectral index (BIS) values are underway.

Standard MAC values are roughly additive.^{56,57} Administering 0.5 MAC of a potent agent and 0.5 MAC of nitrous oxide is equivalent to 1 MAC of potent agent in terms of preventing patient movement, although this does not hold over the entire range of N₂O doses.⁵⁸ MAC effects for other response parameters are not necessarily additive. Because MAC-movement probably differs from MAC for various secondary side effects (such hypothetical situations as "MAC-dysrhythmia," "MAC-hypotension," or "MAC-tachycardia"), combinations of a potent agent and nitrous oxide may decrease or increase these secondary effects relative to potent agent alone. For example, combining 0.6 MAC of nitrous oxide with 0.6 MAC of halothane produces less hypotension than 1.2 MAC of halothane alone because halothane is a more potent vasodilator and myocardial depressant than N₂O at equivalent MAC.

Various factors increase ([Table 15-4](#)) or decrease ([Table 15-5](#)) MAC. Unfortunately, no single mechanism explains these alterations in MAC, supporting the view that anesthesia is the net result of numerous and widely varying physiologic alterations. In general, factors that increase CNS metabolic activity and neurotransmission,^{59,60} increase CNS neurotransmitter levels,⁶¹ and up regulate CNS responses to chronically depressed neurotransmitter levels (as in chronic alcoholism) seem to increase MAC. And factors that decrease CNS metabolic activity and neurotransmission,^{62,63} and ⁶⁴ decrease CNS neurotransmitter levels, and down regulate CNS responses to chronically elevated neurotransmitter levels⁶⁵ seem to decrease MAC. But many notable factors do *not* alter MAC, including duration of inhaled anesthetic administration, gender, type of surgical stimulation, thyroid function, hypo- or hypercarbia, metabolic alkalosis, hyperkalemia, and magnesium levels.

- Increased central neurotransmitter levels (monoamine oxidase inhibitors, acute dextroamphetamine administration, cocaine, ephedrine, levodopa)
- Hyperthermia
- Chronic ethanol abuse (determined in humans)
- Hypertatemia

Table 15-4. FACTORS THAT INCREASE MAC

- Increasing age
- Metabolic acidosis
- Hypoxia (Pac₂: 30 mm Hg)
- Induced hypotension (MAP < 50 mm Hg)
- Decreased central neurotransmitter levels (α-methyltyrosine, reserpine, chronic dextroamphetamine administration, levodopa)
- Alpha-2 agonists
- Hypothermia
- Hypocapnia
- Lithium
- Hypocapnia
- Pregnancy
- Acute ethanol administration*
- Ketamine
- Propofol
- Phenytoin (30 times clinical doses)
- Nitroglycerin (10 times clinical doses)
- Lidocaine
- Cyclofla
- Opioid agonist-antagonist analgesics
- Barbiturates*
- Chloroquine*
- Quinidine*
- Hydrocortisone*
- S-N-Tetrahydrocannabinol
- Vinorelbine
- Arterial (P = 4.3 mm Hg, pH = 7.35)

Table 15-5. FACTORS THAT DECREASE MAC

Effect of Age on MAC

The MAC for each of the potent anesthetic gases shows a clear, age-related change (Fig. 15-11).^{64,66,67} MAC decreases with age and there are similarities between agents in the decline in MAC and age. Excluding data in patients less than 1 year of age (where MAC can be lower⁶⁰), there is a linear model that describes the decrease in MAC with increasing age.⁶⁷ The slope of this model is $MAC = a(10^{bx})$, where a is the MAC at age 40, x is the difference in age in years from 40, and $b = -0.00269$. This equation defines a change in MAC of ~6% per decade, a 22% decrease in MAC from age 40 to age 80, and a 27% decrease in MAC from age 1 to 40 years. MAC is typically expressed for an intermediate age (40 years), and these are:

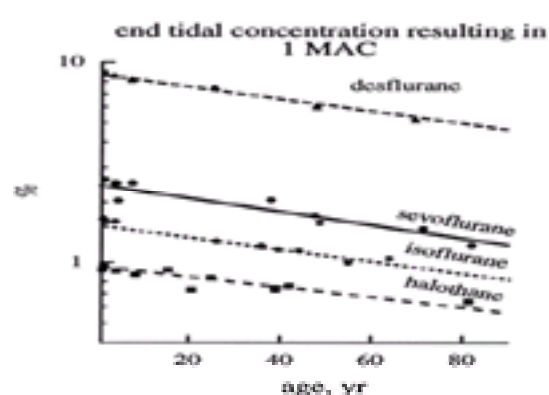

Figure 15-11. Effect of age on MAC. Regression lines are fitted to published values from separate studies. Data are from patients aged 1 to 80 years. (Adapted from Mapleson WW: Effect of age on MAC in humans: A meta-analysis. Br J Anaesth 76:179, 1996.)

| | |
|---------------|-------|
| Halothanexs | 0.75% |
| Isoflurane | 1.17% |
| Enflurane | 1.63% |
| Sevoflurane | 1.8% |
| Desflurane | 6.6% |
| Nitrous oxide | 104% |

Other Alterations in Neurophysiology

The four potent agents currently in widespread use—halothane, isoflurane, desflurane, and sevoflurane—all have qualitatively similar effects on a wide range of parameters, including cerebral metabolic rate (CMR), the electroencephalogram (EEG), cerebral blood flow (CBF), CBF autoregulation, and flow–metabolism coupling. There are notable differences in effects on intracerebral pressure (ICP), cerebrospinal fluid (CSF) production and reabsorption, CO₂ vasoreactivity, and cerebral protection. Nitrous oxide departs from the potent agents in several important respects, and is therefore discussed separately.

Cerebral Metabolic Rate (CMR) and EEG

All of the potent agents depress CMR to varying degrees in a nonlinear fashion. In isoflurane-anesthetized dogs, there is a sudden decrease in CMRO₂ paralleling a change in the EEG from an awake to anesthetized pattern at about 0.4–0.6 MAC as seen in Figure 15-10.⁶⁸ For most of the potent agents, CMR is decreased only to the extent that spontaneous cortical neuronal activity (as reflected in the EEG) is decreased.⁶⁹ With gradually increasing inspired concentrations of anesthetic, after spontaneous cortical neuronal activity vanishes (an isoelectric EEG), no further decreases in CMR are generated. Halothane is the exception. Halothane causes a 20–30% decrease in CMR at normal clinical concentrations.⁷⁰ However, halothane at 4.5% produces an isoelectric EEG, and further increases in inspired concentration cause further decreases in CMRO₂. This further depression of CMRO₂ is due to toxic effects on oxidative phosphorylation. Toxic effects begin at concentrations as low as 2.3%, at which point brain lactate concentrations increase,⁷¹ but this dose is typically well above those used clinically for halothane.

Isoflurane causes a larger MAC-dependent depression of CMR than halothane does, and does not depress CMRO₂ once an isoelectric EEG is produced.⁷² Because of this greater depression in neuronal activity on a per-MAC basis, isoflurane abolishes EEG activity at doses used clinically and can usually be tolerated from a hemodynamic standpoint.⁶⁹ Desflurane and sevoflurane both cause decreases in CMR similar to that of isoflurane.^{73,74} and ⁷⁵ Interestingly, while both desflurane and sevoflurane depress the EEG and abolish activity at clinically tolerated doses of approximately 2 MAC,^{75,76} in *dogs* desflurane-induced isoelectric EEG reverts to continuous activity with time despite an unchanging MAC—a property unique to desflurane.⁷⁶ In *cats*, sevoflurane at isoelectric EEG concentrations is not associated with a reversion to continuous EEG activity, although species differences could account for the differing results.⁷⁷ The reversion of an isoelectric to continuous EEG does not occur in desflurane-anesthetized swine,⁷⁸ and there are no case reports of this phenomenon in humans.

Potential for cerebral toxicity has been studied for sevoflurane as compared to halothane. At normal CO₂ and blood pressure no evidence of sevoflurane toxicity exists.⁷⁹ With extreme hyperventilation to decrease cerebral blood flow by half, brain lactate levels increase, but significantly less so than with halothane. There are conflicting data as to whether sevoflurane has a proconvulsant effect.^{75,77,80} Many neuroanesthesiologists use sevoflurane routinely since any proconvulsant effects do

not appear to be clinically relevant.

Cerebral Blood Flow (CBF), Flow–Metabolism Coupling, and Autoregulation

All of the potent agents increase CBF in a dose-dependent manner. Halothane is a very potent cerebral vasodilator^{70,81,82} and causes the greatest increase in CBF per MAC multiple. Because of this, halothane is rarely used in neurosurgery today, even though it was the dominant anesthetic for these cases until the early 1970s. Despite causing the greatest increase in CBF, the vasodilating effects of halothane are blunted by hyperventilating subjects to a PaCO₂ of 25 mm Hg prior to or simultaneous with the administration of halothane.⁸³

Isoflurane causes far less cerebral vasodilation per MAC multiple than does halothane,^{82,84,85} and is the predominant volatile anesthetic used in neurosurgical cases today (Fig. 15-12). In human studies, isoflurane produces insignificant⁸⁶ or no changes in CBF.⁸⁷ Desflurane and sevoflurane both influence CBF in a fashion similar to isoflurane.^{73,74} and ^{75,88} All of these inhaled anesthetic agents affect CBF in a time-dependent as well as a dose-dependent manner. In both goats and dogs, an initial dose-dependent increase in CBF with halothane and isoflurane administration recovers to preinduction levels approximately 2–5 hours after induction.^{89,90} and ⁹¹ The mechanism of this recovery is unclear.

Figure 15-12. Cerebral blood flow measured in the presence of normocapnia and in the absence of surgical stimulation in volunteers. At light levels of anesthesia, enflurane or halothane (but not isoflurane) increased cerebral blood flow. All three agents increased cerebral blood flow at 1.6 MAC. (Adapted from Eger EI II: Isoflurane (Forane): A compendium and reference. Madison, Ohio Medical Products, 1985.)

The increase in CBF with increasing dose caused by the potent agents occurs despite decreases in CMR. This phenomenon has been called “uncoupling,” but from a mechanistic standpoint, true uncoupling of flow from metabolism may not occur. That is, as CMR is depressed by the volatile anesthetics, there is still a coupled decline in tonic vasodilating influences on the cerebral vasculature, but a coincident direct vasodilatory effect on the cerebral blood vessels. The net effect on the cerebral vessels depends on the sum of indirect “vasoconstricting” and direct vasodilating influences.

This view is supported by several facts. First, at low doses, both halothane (< 0.375%) and isoflurane (0.5%) can actually decrease CBF.^{92,93} This probably reflects intact coupling of CBF to CMR, with the depression in neuronal activity and metabolism causing a coupled decline in perfusion. At higher doses, increases in CBF occur presumably because direct vasodilation at these doses outweighs indirect vasoconstriction. Second, if CMR is maximally or near-maximally depressed with a barbiturate, halothane and isoflurane produce similar increases in CBF.⁹⁴ This is consistent with the greater depression of CMR seen with isoflurane. From a starting point of normal CMR, isoflurane causes a greater dose-dependent decrease in CMR, resulting in greater indirect vasoconstriction and less vasodilation. When CMR is maximally depressed prior to isoflurane or halothane administration, no further indirect vasoconstriction is possible, and the two agents dilate cerebral vessels to a similar extent. Third, CBF:CMRO₂ ratios are the same for many volatile anesthetics at equivalent MAC, and increase with increasing dose in a similar fashion.⁹⁵ Finally, regional CBF–CMR relationships are arguably better indicators of coupling than the global CBF:CMR ratio, and both isoflurane and halothane show strong coupling between decreases in CMR and CBF in individual brain regions.⁹⁶

Autoregulation is the intrinsic myogenic regulation of vascular tone. In normal brain, the mechanisms of autoregulation of CBF over a range of mean arterial pressures from 50 to 150 mm Hg are incompletely understood. Because the volatile anesthetics are direct vasodilators, all are considered to diminish autoregulation in a dose-dependent fashion such that CBF is essentially pressure-passive at high anesthetic doses. There are data documenting impaired autoregulation with halothane and relatively preserved autoregulation with isoflurane in studies specifically aimed at investigating the relationship between the two (Fig. 15-13).^{97,98} Sevoflurane preserves autoregulation up to approximately 1 MAC.⁷⁵

Figure 15-13. Autoregulation of cerebral blood flow (mean \pm SE) is preserved in animals receiving isoflurane, but impaired during halothane anesthesia. (Adapted from Eger EI II: Pharmacology of isoflurane. Br J Anaesth 56:71S, 1984.)

Intracerebral Pressure (ICP)

Probably the area of greatest clinical interest to the anesthesiologist is the effect of volatile anesthesia on ICP. In general, ICP will increase or decrease in proportion to changes in cerebral blood flow.^{99,100} Halothane increases ICP to the greatest extent, reflecting its effects on CBF which are the largest of the potent agents.^{82,83} In fact, brain protrusion during craniotomy is greater with halothane than with isoflurane, consistent with the greater increase in ICP by halothane.¹⁰¹ At concentrations of 0.5 MAC or less, halothane alone insignificantly increases ICP; above this, however, halothane has the propensity to increase CBF and ICP. This, in association with a tendency to lower mean arterial blood pressure, may cause profound decreases in cerebral perfusion pressure. Preinduction hyperventilation prevents—and simultaneous hyperventilation with induction blunts—the increases in ICP seen with halothane administration.⁸³ Barbiturate coadministration likewise blunts or prevents halothane-induced increases in ICP.

In contrast to halothane, isoflurane increases ICP minimally in animals both with and without brain pathology, including those with an already elevated ICP.⁸² In human studies there usually are mild increases in ICP with isoflurane administration that, as with halothane, are blocked or blunted by hyperventilation or barbiturate coadministration.^{102,103} There are some contradictory data, however. In an animal model, edema caused by cryogenic brain lesions was greater with isoflurane anesthesia than with halothane anesthesia¹⁰⁴; and in another, hypocapnia prior to the lesions did not prevent increases in ICP under isoflurane anesthesia. In one human study, hypocapnia did not prevent elevations in ICP with isoflurane administration in patients with space-occupying brain lesions.¹⁰⁵ In any case, the increase in ICP with or without brain pathology is far less for isoflurane than for halothane. Furthermore, any isoflurane-induced increases in ICP tend to be of short duration—in one study, just 30 minutes¹⁰⁶—as opposed to halothane, in which case the ICP increase may last for hours.

Like isoflurane, both sevoflurane and desflurane produce mild increases in ICP, paralleling their mild increases in CBF.^{74,75} and ⁷⁶ One potential advantage of

sevoflurane is that its lower pungency and airway irritation may diminish the risk of coughing and bucking and the associated rise in ICP as compared to desflurane or isoflurane. Ultimately, all four potent agents may be used at appropriate doses, especially with compensatory therapies, in virtually any neurosurgical procedure. For example, many neuroanesthesiologists maintain that halothane can be safely used in neurosurgery at doses of 1 MAC or less, and perhaps slightly more with hyperventilation or barbiturate administration. However, patients with traumatic head injuries, elevated ICP, or space-occupying brain lesions are probably better served with isoflurane or the newer volatile anesthetics.

Cerebrospinal Fluid (CSF) Production and Reabsorption

Studies indicate that 1 MAC halothane decreases CSF production but increases resistance to reabsorption,^{107,108} the net effect being an increase in CSF volume.¹⁰⁰ Isoflurane does not appear to alter CSF production,^{106,107} but may increase, decrease, or leave unchanged the resistance to reabsorption depending on dose.¹⁰⁹ Sevoflurane at 1 MAC depresses CSF production up to 40%.¹¹⁰ Desflurane at 1 MAC leaves CSF production unchanged or increased.^{111,112} CSF dynamics may play a clinically relevant role in raising or lowering ICP, depending on the relationship of CSF production to CSF reabsorption and the associated changes in cerebral blood volume. At this time, however, no clear recommendations can be made as to which volatile anesthetics are better or worse for a given clinical situation. In general, anesthetic effects on ICP *via* changes in CSF dynamics are clinically much less important than anesthetic effects on CBF.

CBF Response to Hyper- and Hypocapnia

Significant hypercapnia is associated with dramatic increases in CBF, whether or not volatile anesthetics are administered. As discussed earlier, hypocapnia can blunt or abolish anesthetic-induced increases in CBF, depending on when the hypocapnia is produced. This vasoreactivity to CO₂ may be somewhat altered by the volatile anesthetics as compared to normal. Neither isoflurane nor halothane abolishes hypocapnic vasoconstriction, and at least two studies suggest that halothane actually enhances CO₂ reactivity.^{84,113} CO₂ vasoreactivity under desflurane anesthesia is normal up to 1.5 MAC,¹¹⁴ but CO₂ vasoreactivity for sevoflurane may be slightly less, relative to other potent agents.^{75,115}

Cerebral Protection

Because all of the potent agents significantly depress CMR, one might reason that each could offer some degree of neuroprotection. Unfortunately, this is not the case. In halothane-anesthetized dogs, focal ischemia caused by middle cerebral artery occlusion led to larger infarct size and worse neurologic outcome than for awake animals.¹¹⁶ Fortunately, it was shown that the well known neuroprotective effects of pentobarbital are preserved with halothane, since pentobarbital coadministration minimized the pathologic and functional damage.¹¹⁷

In comparison, isoflurane may provide some neuroprotective effects in both mice and dogs during hypoxemia or ischemia.^{118,119} In one study, cerebral hypoperfusion due to induced hypotension with isoflurane was associated with better tissue oxygen content than during hypotension by other means, consistent with the profound decrease in CMRO₂ seen with isoflurane.¹²⁰ The most compelling evidence for isoflurane's superiority to halothane for neuroprotection was shown in two studies of human carotid endarterectomy surgery. In these patients, the incidence of ischemic EEG changes was lower with isoflurane than with halothane,¹²¹ and ischemic EEG changes occurred at a lower CBF with isoflurane than with halothane.¹²²

Both sevoflurane and desflurane have been shown to improve neurologic outcome in comparison to N₂O–fentanyl after incomplete cerebral ischemia in a rat model.^{123,124} Desflurane has been shown to increase brain tissue PO₂ during administration and to maintain PO₂ to a greater extent than thiopental during temporary cerebral artery occlusion in humans undergoing cerebrovascular surgery.¹²⁵ No human neuroprotection outcome studies for sevoflurane and desflurane have been published. Interpretation of the published data suggests that surgical cases in which temporary cerebral arterial occlusion is planned or probable would benefit more from isoflurane (or sevoflurane or desflurane?) than halothane anesthesia, but further studies are necessary.

Nitrous Oxide

The effects of nitrous oxide on cerebral physiology are not clear. Both the MAC for N₂O and its effects on CMR vary widely depending on species.^{126,127,128,129} and ¹³⁰ The difference in CMR effects may in part be accounted for by differences in MAC, but MAC-equivalent effects on CMR also differ. According to several studies in dogs, goats, and swine, N₂O causes an increase in CMRO₂ and CBF,^{129,130} and ¹³¹ while in rodents no such increases^{127,132,133} or only slight increases occur.^{126,132} In human studies, N₂O administration preserved CBF but decreased CMRO₂.⁹⁵

Another problem is the fact that N₂O is a co-anesthetic used to supplement potent agents, not a complete anesthetic in itself, so that CMR effects may differ depending on presence or absence of potent agent as well as the particular agent and dose. N₂O causes a greater increase in CBF and CMR in dogs at 0.2% halothane than at 0.8% halothane. In contrast, addition of N₂O to 1 or 2.2 MAC isoflurane does not alter CMRO₂,¹³⁴ but does increase CBF at 1 MAC and not at 2.2 MAC.

Barbiturates,¹³⁰ narcotics,¹³⁵ or combinations of the two¹³⁶ appear to decrease or eliminate the increases in CMR and CBF produced by N₂O. The effect of pentobarbital/N₂O is dose-dependent, with preserved increases in CMR by N₂O at low-dose pentobarbital, and no changes in CMR at high-dose pentobarbital.¹³⁷ N₂O and benzodiazepine coadministration is particularly confusing. Midazolam/N₂O in dogs increased CBF but did not alter CMRO₂¹³⁸ while the opposite was true in rats,¹³⁹ and both CBF and CMRO₂ declined in rats given diazepam/N₂O. N₂O administration increases ICP,¹³⁰ but as is the case for CMR and CBF, changes in ICP are decreased or eliminated by a variety of co-anesthetics and, more importantly, by hypocapnia.^{130,140}

N₂O appears to have an anti-neuroprotective effect, as addition of N₂O to isoflurane during temporary ischemia is associated with greater tissue damage and worsened neurologic outcome.¹⁴¹ In a study in mice, survival time after a hypoxic event was decreased by addition of N₂O.¹⁴² Given the conflicting data on the effects of N₂O on CMR, CBF, and ICP, and its apparent anti-neuroprotective effect, avoidance or discontinuation of its use should be considered in surgical cases with a high likelihood of elevated ICP or significant cerebral ischemia.

THE CIRCULATORY SYSTEM

Hemodynamics

The cardiac vascular and autonomic effects of the volatile anesthetics have been carefully defined by a number of studies carried out in human volunteers not undergoing surgery.^{143,144,145,146,147,148,149,150,151} and ¹⁵² In general, the information from these volunteer studies has translated well to the patient population commonly exposed to these anesthetics during elective and emergent surgeries. There are clearly modifying factors in describing the volatile anesthetic effects on the circulation, such as interactions with anesthetic adjuvants and modifications in response due to underlying disease.

A very clear and common effect of the potent volatile anesthetics halothane, enflurane, isoflurane, desflurane, and sevoflurane has been a dose-related decrease in arterial blood pressure.^{153,154} No essential differences are seen among the volatile anesthetics when examining their effect on blood pressure at steady-state equi-anesthetic concentrations (Fig. 15-14). However, the mechanism by which they decrease arterial blood pressure is somewhat more specific for each anesthetic. Halothane is notable for its decrease in cardiac output—an effect that contributes importantly to its blood pressure lowering effect (Fig. 15-15).^{143,155,156} The mechanism by which halothane decreases cardiac output primarily involves a profound depression of myocardial contractility and has been associated with an increase in right atrial pressure (Fig. 15-15).^{143,157} In contrast, desflurane, sevoflurane, and isoflurane are known to maintain cardiac output.^{149,153,154,158} Their primary mechanism to decrease blood pressure with increasing dose is related to their potent effects on regional and systemic vascular resistance (Fig. 15-15).^{145,150,159} Enflurane falls somewhere between halothane and the newer volatile anesthetics in terms of its effects on cardiac output and peripheral resistance. Enflurane is associated with some myocardial depression, a decrease in cardiac output, and a measurable increase in right atrial pressure.^{144,160,161} and ¹⁶²

Figure 15-14. Heart rate and blood pressure changes (from awake baseline) in volunteers receiving general anesthesia with a potent anesthetic. Halothane and sevoflurane produced little change in heart rate at less than 1.5 MAC. All anesthetics caused similar decreases in blood pressure. (Adapted from Calverley RK, Smith NT, Prys-Roberts C *et al*: Cardiovascular effects of enflurane anesthesia during controlled ventilation in man. *Anesth Analg* 57:619, 1978; Weiskopf RB, Cahalan MK, Eger EI II *et al*: Cardiovascular actions of desflurane in normocarbic volunteers. *Anesth Analg* 73:143, 1991; and Malan TP, DiNardo JA, Isner RJ *et al*: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers. *Anesthesiology* 83:918, 1995.)

Figure 15-15. Cardiac index, systemic vascular resistance, and central venous pressure (or right atrial pressure) changes (from awake baseline) in volunteers receiving general anesthesia with a potent anesthetic. Increases in central venous pressure from halothane and desflurane might be due to different mechanisms. With halothane, the increase might be due to myocardial depression, whereas with desflurane, the increase is more likely due to venoconstriction. (Adapted from Calverley RK, Smith NT, Prys-Roberts C *et al*: Cardiovascular effects of enflurane anesthesia during controlled ventilation in man. *Anesth Analg* 57:619, 1978; Weiskopf RB, Cahalan MK, Eger EI II *et al*: Cardiovascular actions of desflurane in normocarbic volunteers. *Anesth Analg* 73:143, 1991; and Malan TP, DiNardo JA, Isner RJ *et al*: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers. *Anesthesiology* 83:918, 1995.)

In terms of the effects of the volatile anesthetics on heart rate, data from animal studies indicate that desflurane consistently increases heart rate,^{161,163,164} and ¹⁶⁵ whereas sevoflurane provides a relatively stable heart rate.^{88,166,167} and ¹⁶⁸ In volunteers, sevoflurane and halothane up to about 1 MAC result in minimal, if any, changes in steady-state heart rate (Fig. 15-14).^{149,153,154} In contrast, both enflurane and isoflurane have been associated with an increase in heart rate of 10–20% at 1 MAC.¹⁵⁴ At anesthetic levels >1 MAC, desflurane has been associated with an increase in heart rate equal to that of isoflurane.¹⁵⁹ This is generally reflected as a 10–15 beats/min increase in heart rate. Both desflurane and, to a lesser extent, isoflurane have been associated with transient and significant increases in heart rate during rapid increases in the inspired concentration of either anesthetic.^{159,169} Although the mechanism(s) underlying these transient heart rate surges are not known, it is conjectured that the relative pungency of these anesthetics activates airway receptors, leading to a reflex tachycardia.^{170,171} This tachycardia can be lessened with fentanyl or alfentanil pretreatment.^{172,173} and ¹⁷⁴

Myocardial Contractility

Myocardial contractility indices have been directly evaluated in animals and indirectly evaluated in humans during the administration of each of the volatile anesthetics. The older anesthetics, halothane and enflurane, have been studied in humans using a relatively imprecise technique called ballistocardiography which permits an indirect measure of contractility (IJ amplitude). At 1 MAC, enflurane caused a 40% decrease in IJ amplitude, whereas halothane caused a 30% decrease in IJ amplitude.^{143,144} At 1.5 MAC, greater depression of myocardial contractility was noted for both volatile anesthetics. These changes were noted in conjunction with approximately 20% decreases in cardiac output at 1 MAC halothane and enflurane. Animal and human studies indicate that the myocardial depression from halothane is greater than for isoflurane and enflurane.^{175,176,177,178,179} and ¹⁸⁰ In contrast, human studies with the newer volatile anesthetics, isoflurane, sevoflurane, and desflurane, have not demonstrated significant changes in echocardiographic-determined indices of myocardial function, including the more noteworthy measurement of the velocity of circumferential fiber shortening (Fig. 15-16).^{147,149} More precise indices of myocardial contractility have been obtained for sevoflurane, isoflurane, and desflurane in chronically instrumented dogs after autonomic innervation of the heart was blocked by pharmacologic means. This allowed the evaluation of the direct effects of the anesthetics on the heart. The data indicate that isoflurane, desflurane, and sevoflurane cause dose-dependent depression of myocardial function with no differences among the three anesthetics (Fig. 15-17).^{153,181,182} Thus, the direct effect of volatile anesthetics is a dose-dependent myocardial depression; however, halothane and enflurane have greater effects on myocardial contractility than do isoflurane, sevoflurane, and desflurane. Not unexpectedly, when the circulatory effects of isoflurane have been compared to halothane in patients with ischemic heart disease, similar effects on lowering blood pressure have been noted; however, cardiac output was decreased to a greater degree with halothane. Halothane also was associated with increases in systemic vascular resistance, whereas isoflurane caused no clinically relevant change in systemic vascular resistance.¹⁵⁵

Figure 15-16. Noninvasive assessment of myocardial contractility with echocardiography during anesthesia in volunteers. Sevoflurane, desflurane, and isoflurane did not cause changes suggestive of myocardial depression. (Adapted from Calverley RK, Smith NT, Prys-Roberts C *et al*: Cardiovascular effects of enflurane anesthesia during controlled ventilation in man. *Anesth Analg* 57:619, 1978; Weiskopf RB, Cahalan MK, Eger EI II *et al*: Cardiovascular actions of desflurane in normocarbic volunteers. *Anesth Analg* 73:143, 1991; and Malan TP, DiNardo JA, Isner RJ *et al*: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers. *Anesthesiology* 83:918, 1995.)

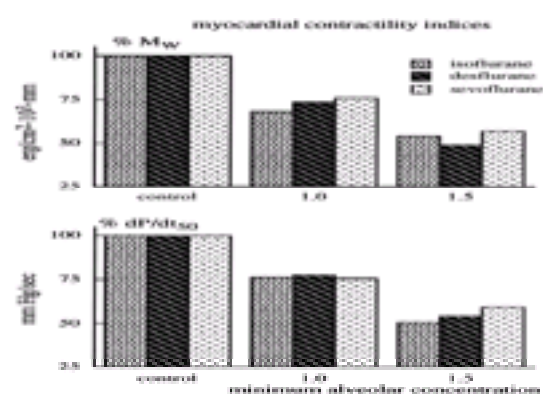

Figure 15-17. Myocardial contractility indices from chronically instrumented dogs. For these measurements, pharmacologic blockade of the autonomic nervous system was established to eliminate neural or circulating humoral influences on the inotropic state of the heart. The conscious control data were assigned 100%, and subsequent reductions in the inotropic state are depicted for both 1 and 1.5 minimum alveolar anesthetic concentrations of sevoflurane, desflurane, and isoflurane. There were no differences between these three volatile anesthetics. M_w = slope of the regional preload recruitable stroke work relationship; dP/dt_{50} = change in pressure per unit of time. (Adapted from Harkin CP, Pagel PS, Kersten JR *et al*: Direct negative inotropic and lusitropic effects of sevoflurane. *Anesthesiology* 81:156, 1994; and Pagel PS, Kampine JP, Schmeling WT *et al*: Influence of volatile anesthetics on myocardial contractility *in vivo*: Desflurane versus isoflurane. *Anesthesiology* 74:900, 1991.)

Other Circulatory Effects

The majority of the volatile anesthetics have been studied during both controlled and spontaneous ventilation.^{18,149,183,184} and ¹⁸⁵ The process of spontaneous ventilation results in a reduction of the high intrathoracic pressures associated with positive pressure ventilation. The negative intrathoracic pressure during the inspiratory phase of spontaneous ventilation augments venous return and cardiac filling and improves cardiac output and, hence, blood pressure. A second result of spontaneous ventilation is higher $PaCO_2$, and this change causes cerebral and systemic vascular relaxation and further contributes to an improved cardiac output *via* afterload reduction. Thus, there is a decrease in systemic vascular resistance and an increase in heart rate, cardiac output, and stroke volume when spontaneous ventilation is contrasted to positive pressure ventilation. It has been suggested that spontaneous ventilation might improve the safety of inhaled anesthetic administration because the concentration of the volatile anesthetics that produces cardiovascular collapse exceeds the concentration resulting in apnea.¹⁸⁶

A curious observation with the volatile anesthetics has been an alteration in the cardiovascular effects during prolonged anesthetic exposures. Prolonged exposures to halothane, enflurane, sevoflurane, isoflurane, and desflurane have been associated with small increases in heart rate, an improvement in cardiac index, and gradual decreases in systemic vascular resistance.^{144,147,149,154,185} There has been no evidence of worsening (or improvement) of myocardial contractility indices during prolonged anesthesia.^{147,149} Activation of β -sympathetic receptors has been suggested as a mechanism contributing to the increased heart rate and cardiac output from prolonged anesthesia with halothane¹⁸⁷; however, this possibility has been questioned based on recent studies with prolonged exposure to enflurane¹⁴⁴ and desflurane anesthesia.¹⁴⁷

Nitrous oxide is commonly combined with potent volatile anesthetics to maintain general anesthesia. Nitrous oxide has unique cardiovascular actions.^{151,152,188} It increases sympathetic nervous system activity when given in a 40% concentration.¹⁸⁸ At the same time, increases in forearm vascular resistance and circulating catecholamines can be observed.^{151,152} When nitrous oxide is combined with volatile anesthetics and compared to equipotent concentrations of the volatile anesthetic without nitrous oxide, there still is evidence of sympathetic nervous system activation, with an increased systemic vascular resistance and an improved arterial pressure with little effect on cardiac output.^{149,189,190,191} and ¹⁹² Some of these effects might not be due to the nitrous oxide *per se*, but may simply be attributed to a decrease in the concentration of the coadministered potent volatile anesthetic to achieve a MAC equivalent when using nitrous oxide.

Oxygen consumption is decreased approximately 10–15% during general anesthesia.¹⁹³ The distribution of cardiac output also is altered by anesthesia. Blood flow to liver, kidneys, and gut is decreased, particularly at deep levels of anesthesia. In contrast, blood flow to the brain, muscle, and skin is increased or unchanged during general anesthesia.^{163,194,195} With respect to changes in muscle blood flow, data from human volunteer studies comparing isoflurane to desflurane and sevoflurane indicate increases in blood flow with very little difference between anesthetics at equipotent concentrations.^{145,153}

In contrast to halothane, the ether-based anesthetics (isoflurane, enflurane, sevoflurane, and desflurane) have neither predisposed patients to ventricular arrhythmias nor sensitized the heart to the dysrhythmogenic effects of epinephrine (Fig. 15-18).^{196,197} and ¹⁹⁸ The use of iv lidocaine can lessen the epinephrine effect during halothane anesthesia.¹⁹⁷ Some of the differences between volatile anesthetics in their ability to promote dysrhythmias during epinephrine administration can be attributed to their direct effects on cardiac pacemaker cells and conduction pathways.¹⁹⁹ The volatile anesthetics slow the SA node discharge rate²⁰⁰; in addition, they prolong conduction in the His–Purkinje system and conduction pathways in the ventricle.^{199,201} A greater slowing by halothane over isoflurane in the His–Purkinje system might promote dysrhythmias *via* a re-entry phenomenon.²⁰¹

Figure 15-18. The dose of epinephrine associated with cardiac arrhythmias in animal and human models was least with halothane. The ether anesthetics, isoflurane, desflurane, and sevoflurane, required 3–6-fold greater doses of epinephrine to cause dysrhythmias. (Adapted from Hayashi Y, Sumikawa K, Tashiro C *et al*: Arrhythmogenic threshold of epinephrine during sevoflurane, enflurane, and isoflurane anesthesia in dogs. *Anesthesiology* 69:145, 1988; Weiskopf RB, Eger EI II, Holmes MA *et al*: Epinephrine-induced premature ventricular contractions and changes in arterial blood pressure and heart rate during I-653, isoflurane, and halothane anesthesia in swine. *Anesthesiology* 70:293, 1989; Navarro R, Weiskopf RB, Moore MA *et al*: Humans anesthetized with sevoflurane or isoflurane have similar arrhythmic response to epinephrine. *Anesthesiology* 80:545, 1994; and Moore MA, Weiskopf RB, Eger EI II *et al*: Arrhythmogenic doses of epinephrine are similar during desflurane or isoflurane anesthesia in humans. *Anesthesiology* 79:943, 1993.)

Coronary Steal

The fact that potent volatile anesthetics relax vascular smooth muscle and lead to vasodilation has raised concerns related to abnormal distribution of blood flow in coronary blood vessels of patients with ischemic heart disease. This effect, called *coronary steal*, became a concern with the introduction of isoflurane to clinical practice. Isoflurane (and most other potent volatile anesthetics) increases coronary blood flow many times beyond that of the myocardial oxygen demand, thereby creating potential for “steal.” “Steal” is the diversion of blood from a myocardial bed with limited or inadequate perfusion to a bed with more adequate perfusion—especially one that has a remaining element of autoregulation. In instrumented animal models, the pronounced coronary vasodilation produced by isoflurane was shown to cause steal,²⁰² and early patient studies provided additional support.^{203,204} However, more recent work in a chronically instrumented canine model of multivessel coronary artery obstruction has shown that isoflurane, sevoflurane, and desflurane at concentrations up to 1.5 MAC do not result in abnormal collateral coronary blood flow redistribution (steal), whereas adenosine, a potent coronary vasodilator, clearly resulted in abnormal flow distribution.^{181,205,206} and ²⁰⁷ Interestingly, sevoflurane preferentially increased collateral coronary blood flow in this instrumented animal model when aortic pressure was held constant (as might be seen with systemic blood pressure support).²⁰⁵ Isoflurane has been shown to increase the tolerance to pacing-induced myocardial ischemia in patients with coronary

disease.²⁰⁸

Myocardial Ischemia and Cardiac Outcome

Not surprisingly, the clinical relevance of coronary steal with isoflurane has been debated and is generally thought to be minimal.^{209,210} Outcome studies have failed to associate the use of isoflurane in patients undergoing coronary artery bypass operations with an increased incidence of myocardial infarction or perioperative death.^{210,211} and ²¹² Most studies suggest that determinants of myocardial oxygen supply and demand, rather than the anesthetic, are of far greater importance to patient outcomes.

Several studies have evaluated the two new anesthetics, sevoflurane and desflurane, to comparator anesthetics, in terms of myocardial ischemia and outcome in patients with coronary artery disease undergoing either noncardiac or coronary artery bypass graft (CABG) surgery.^{213,214} In both populations, sevoflurane appears to be essentially equivalent to isoflurane in terms of the incidence of myocardial ischemia and adverse cardiac outcomes. In cardiac patients having CABG, desflurane and isoflurane appear to result in similar outcome effects,²¹⁵ with one exception. When desflurane was given without opioids to patients with coronary artery disease requiring CABG, significant ischemia was noted, mandating the use of beta blockers.²¹⁶ Desflurane has not been evaluated in terms of ischemia and outcome in a patient population with coronary disease undergoing noncardiac surgery.

Autonomic Nervous System

Studies that have focused on the efferent activity of the parasympathetic and sympathetic nervous systems indicate that the volatile anesthetics depress their activity in a dose-dependent fashion.^{217,218} and ²¹⁹ However, because the autonomic nervous system is importantly modulated by baroreceptor reflex mechanisms, the effects of anesthetics on the efferent system cannot be reported without taking into account their effects on different components of the baroreflex arc. Thus, although both limbs of the autonomic nervous system have been shown to be attenuated by anesthetics, the afferent activity from the arterial baroreceptors has been found to be increased with some anesthetics, including halothane and isoflurane.^{218,220,221} This increased discharge of the baroreceptors actually contributes to the depression of the entire baroreflex arc by tonically lowering the overall level of outflow of the sympathetic nervous system. From the perspective of clinical relevance, studies have examined the behavior of the arterial baroreflex system during a hypotensive or hypertensive stimulus by evaluating changes in heart rate and sympathetic nerve activity. The arterial baroreflex is the most rapid system responding to blood pressure perturbations. Early investigations focused primarily on the regulation of heart rate (which reflects primarily a vagally mediated endpoint). Halothane,^{222,223} enflurane,^{223,224} and isoflurane^{223,225} all depress the arterial baroreflex control of heart rate in a dose-dependent fashion, although there was a suggestion that isoflurane had a less prominent effect than halothane or enflurane.²²⁵ Similar effects on the reflex control of heart rate have been demonstrated with sevoflurane and desflurane (Fig. 15-19).^{153,226,227} and ²²⁸

Figure 15-19. Summary data of the baroreflex regulation of heart rate (R–R interval) in response to a decreasing pressure stimulus (sodium nitroprusside) or in response to an increasing pressure stimulus (phenylephrine). These data were acquired in healthy volunteers who were randomized to receive isoflurane, desflurane, or sevoflurane. With increasing MAC, each of the volatile anesthetics led to a progressive reduction in the cardiac baroslope (an index of baroreflex sensitivity derived by relating changes in mean pressure to changes in R–R interval). There were no statistical differences between anesthetics. (Adapted from Ebert TJ, Harkin CP, Muzi M: Cardiovascular responses to sevoflurane: A review. *Anesth Analg* 81:S11, 1995.)

There is greater difficulty in evaluating the sympathetic component of the baroreflex arc in humans. Recently, a technique called sympathetic microneurography has been utilized to directly record vasoconstrictor impulses directed to blood vessels in humans.^{150,159,229} There is a dose-dependent depression of the reflex control of sympathetic outflow that appears to be relatively equivalent for isoflurane, sevoflurane, and desflurane (Fig. 15-20).^{153,228} Importantly, at low levels of anesthesia (e.g., 0.5 MAC), there is little if any depression of reflex function, and this might have important implications in the compromised patient population. Opioid and benzodiazepine adjuvants have only minimal effects on reflex function, and combining these with low levels of potent anesthetics might preserve reflex function.^{230,231} and ²³² Another important observation has been the more rapid return of baroreflex function with the less soluble anesthetic sevoflurane relative to isoflurane.²³³ This might add to hemodynamic stability in the postoperative period when tissue concentrations of the volatile anesthetics are declining.

Figure 15-20. The sympathetic baroreflex function of healthy volunteers randomized to receive isoflurane, desflurane, or sevoflurane. The slope (sensitivity) is the relationship between decreasing diastolic pressure and increasing efferent sympathetic nerve activity. The reflex regulation of sympathetic outflow was fairly well preserved at 0.5 and 1.0 MAC of anesthetic. At 1.5 MAC, there was a 50% decrease in the slope with all anesthetics. (Adapted from Ebert TJ, Harkin CP, Muzi M: Cardiovascular responses to sevoflurane: A review. *Anesth Analg* 81:S11, 1995.)

Desflurane has a unique and prominent effect on sympathetic outflow in humans—an effect that is not apparent in animal models. With increasing steady-state concentrations of desflurane, there is a progressive increase in resting sympathetic nervous system activity and plasma norepinephrine levels.^{150,159,234} Despite this increase in tonic sympathetic outflow, blood pressure decreases similarly to sevoflurane and isoflurane. This raises the question as to whether desflurane has the ability to uncouple neuroeffector responses. In addition, desflurane can cause marked activation of the sympathetic nervous system when the inspired concentration is increased, especially to concentrations above 5–6% (Fig. 15-21).^{150,159,169,234,235} There is a transient surge in sympathetic outflow, leading to hypertension and tachycardia. In addition, the endocrine axis is activated, as evidenced by 15–20-fold increases in plasma antidiuretic hormone and epinephrine (Fig. 15-22).¹⁶⁹ The hemodynamic response persists for 4–5 minutes and the endocrine response persists for 15–25 minutes. Administration of adequate concentrations of fentanyl prior to increasing the concentration of desflurane has been shown to attenuate these responses.^{172,173} The source of the neuroendocrine activation has been actively sought. It would appear that there are receptors in the upper and the lower airways—and/or perhaps in highly perfused tissue near the airways—that initiate the sympathetic activation.^{170,171} The possibility that desflurane activates airway irritant receptors is quite strong, since desflurane is the most pungent of the anesthetics available for clinical use.^{237,238} and ²³⁹

Figure 15-21. Consecutive measurements of sympathetic nerve activity (SNA; mean \pm SEM) from human volunteers during induction of anesthesia with propofol and the subsequent mask administration of sevoflurane or desflurane for a 10-min period. The inspired concentration of these anesthetics was increased at 1-min intervals beginning precisely 2 min after propofol administration (0.41 MAC of sevoflurane 1% and of desflurane 3%). In both groups, propofol reduced SNA and MAP. Desflurane resulted in significant increases in neurocirculatory variability that persisted throughout the 10-min mask administration period. (Adapted from Ebert TJ, Muzi M, Lopatka CW: Neurocirculatory responses to sevoflurane in humans. A comparison to desflurane. *Anesthesiology* 83:88, 1995.)

Figure 15-22. Stress hormone responses to a rapid increase in anesthetic concentration, from 4 to 12% inspired. Volunteers given desflurane (diamonds) showed a larger increase in plasma epinephrine and norepinephrine concentrations than when given isoflurane (squares). Data are mean \pm SE. (A) Awake value; (B) value after 32 min of 0.55 MAC. Time represents minutes after the first breath of increased anesthetic concentration. (Adapted from Weiskopf RB, Moore MA, Eger EI II *et al*: Rapid increase in desflurane concentration is associated with greater transient cardiovascular stimulation than with rapid increase in isoflurane concentration in humans. *Anesthesiology* 80:1035, 1994.)

Cardioprotection from Volatile Anesthetics

There is a new body of literature describing the potential for organ-protective effects (particularly cardioprotective effects) of the potent inhaled agents.^{240,241,242,243 and 244} Organ protection may be defined as “reducing tissue damage after hypoxic ischemia or toxic insult.” A standard model to reduce tissue damage after ischemia has been termed “ischemic preconditioning.” Preconditioning is a process that protects the myocardium by providing a brief episode of ischemia, which exerts a protective effect against subsequent, more prolonged ischemia. Numerous factors may be involved in preconditioning, including the sodium:hydrogen exchanger, the adenosine receptor (particularly α_1 and α_2 subtypes), inhibitory G proteins, protein kinase C, tyrosine kinase, map kinases, dag, and pkg. Blocking any of these compounds (e.g., with adenosine blockers, d_1 opioids, pertussis toxin, glibenclamide) reduces the cardioprotective effect of ischemic preconditioning and of the volatile anesthetics.

Alternatively, administration of certain drugs can mimic ischemic preconditioning. These include adenosine, opioid agonists, and potassium (K^+ -ATP) channel openers. Unlike volatile anesthetics, which can be safely administered *via* inhalation, these cardioprotective drugs must be given in a coronary artery because systemic administration has serious side effects. Among other cardioprotective effects, inhalation anesthetics are known to:

- Reduce vascular reperfusion damage
- Reduce infarct size
- Reduce ST segment depression
- Improve metabolism
- Reduce dysrhythmias
- Improve vasodilation
- Activate adenosine α_1 receptors
- Produce acidosis by inhibiting sodium:hydrogen exchange
- Spare ATP levels, allowing K^+ -ATP channels to open
- Depress calcium currents
- Reduce oxygen free radicals
- Reduce troponin I production

Approximately 30–40% of the cardioprotection from the volatile anesthetics appears to be related to a reduced loading of calcium into the myocardial cells during ischemia.²⁴³ As nearly all of these evolving data derive from animal models, a number of important questions remain for clinical studies in humans. What quantity of volatile anesthetic and what duration is needed to offer cardioprotective effects? How long is the “memory” of preconditioning after exposure to a volatile anesthetic? Are there dose-related effects? When is the best time to administer the anesthetic prior to the ischemic insult? These and other questions will undoubtedly be addressed and answered in the upcoming years, keeping in mind that good surgical technique might far outweigh any potential for cardiac protection from the volatile anesthetics.

THE PULMONARY SYSTEM

The volatile anesthetics have multiple and important effects on many aspects of pulmonary physiology, including respiratory rate and tidal volume, responses to CO_2 and hypoxia, and effects on bronchiolar smooth muscle tone and mucociliary function. Less pronounced, but still important effects have been observed on pulmonary vascular resistance and pulmonary blood flow.

General Ventilatory Effects

All volatile anesthetics decrease tidal volume but have lesser effects on decreasing minute ventilation because of an offsetting response to increasing respiratory rate (Fig. 15-23).^{154,245,246,247,248,249 and 250} These effects are dose-dependent, with higher concentrations of volatile anesthetics resulting in greater decreases in tidal volume^{248,249 and 250} and greater increases in respiratory rate.^{245,246,247,248 and 249} The net effect of a gradual decrease in minute ventilation has been associated with increasing resting $Paco_2$. The relative increases in $Paco_2$ as an index of respiratory depression with volatile anesthetics evaluated at <1.24 MAC are as follows: enflurane $>$ desflurane = isoflurane $>$ sevoflurane = halothane. The respiratory depression can be partially antagonized during surgical stimulation where respiratory rate has been shown to increase, resulting in a decrease in the $Paco_2$ (Fig. 15-24).²⁵¹ In addition, resting $Paco_2$ during desflurane or sevoflurane anesthesia is significantly decreased (returned toward normal) with the addition of nitrous oxide.^{248,251} This comparison (with and without nitrous oxide) requires a lessening of the potent volatile anesthetic to maintain an equi-MAC concentration when adding nitrous oxide to the inspired gas, and this probably contributes to the return of $Paco_2$ toward normal. The degree of respiratory depression from inhaled anesthetics appears to be lessened during prolonged administration of the anesthetic.^{247,252}

Figure 15-23. Comparison of mean changes in resting PaCO_2 , tidal volume, respiratory rate, and minute ventilation in patients anesthetized with either halothane, isoflurane, enflurane, sevoflurane, desflurane, or nitrous oxide. Anesthetic-induced tachypnea compensates in part for the ventilatory depression caused by all volatile anesthetics (decrease in minute ventilation and tidal volume and concomitant increase in PaCO_2). Desflurane results in the greatest increase in PaCO_2 with corresponding reductions in tidal volume and minute ventilation. Isoflurane, like all other inhaled agents, increases respiratory rate; however, isoflurane does not result in dose-dependent tachypnea. (Adapted from Calverley RK, Smith NT, Jones CW *et al*: Ventilatory and cardiovascular effects of enflurane anesthesia during spontaneous ventilation in man. *Anesth Analg* 57:610, 1978; Lockhart SH, Rampil IJ, Yasuda N *et al*: Depression of ventilation by desflurane in humans. *Anesthesiology* 74:484, 1991; Fourcade HE, Stevens WC, Larson CPJ *et al*: The ventilatory effects of Forane, a new inhaled anesthetic. *Anesthesiology* 35:26, 1971; and Doi M, Ikeda K: Respiratory effects of sevoflurane. *Anesth Analg* 66:241, 1987.)

Figure 15-24. The effect of surgical stimulation on the ventilatory depression of inhaled anesthesia with isoflurane in the presence and absence of nitrous oxide. Surgical stimulation increased alveolar ventilation and decreased PaCO_2 at all depths of anesthesia examined. (Adapted from Eger EI II, Dolan WM, Stevens WC *et al*: Surgical stimulation antagonizes the respiratory depression produced by forane. *Anesthesiology* 36:544, 1972.)

Ventilatory Mechanics

The decrease in functional residual capacity during general anesthesia has been explained by a number of mechanisms, including a decrease in the intercostal muscle tone, alteration in diaphragm position, changes in thoracic blood volume, and the onset of phasic expiratory activity of respiratory muscles.^{253,254,255} and ²⁵⁶ About 40% of the muscular work of breathing is *via* intercostal muscles and about 60% is from the diaphragm. The diaphragmatic muscle function is relatively spared when contrasted to the parasternal intercostal muscles.^{253,254} However, inspiratory rib cage expansion is reasonably well maintained during anesthesia because of preserved activity of the scalene muscles.²⁵⁴ Expiration is generally considered a passive function mediated by the elastic recoil of the lung. The process of applying a resistance or load to expiration typically results in a slowing of respiration; but under anesthesia, additional responses have been noted, including a substantial asynchrony of the thoracic movements with respiration.²⁵⁷ This suggests that in patients with pulmonary disease associated with increased expiratory resistance, the act of spontaneous ventilation during general anesthesia might be associated with increased risk.²⁵⁸

Response to Carbon Dioxide and Hypoxemia

In normal subjects not under anesthesia, increases in minute ventilation of approximately $3 \text{ l} \cdot \text{min}^{-1}$ for each 1 mm Hg increase in PaCO_2 have been demonstrated. This relatively high sensitivity to CO_2 is mediated by central chemoreceptors and has been used as an index of ventilatory drive. All of the inhaled anesthetics produce a dose-dependent depression of the ventilatory response to hypercarbia (Fig. 15-25).^{154,245,246,248,249} Early studies suggested that the addition of nitrous oxide to halothane depressed ventilation less than an equi-MAC dose of halothane alone²⁵⁹; however, this does not appear to be the case for desflurane (Fig. 15-25).²⁴⁸ During anesthesia with spontaneous ventilation, an apneic threshold can be determined which is generally 4–5 mm Hg below the prevailing resting PaCO_2 , and this threshold is not related to the slope of the CO_2 response curves or to the level of the resting PaCO_2 . The clinical relevance of this threshold may be important when assisting ventilation in an anesthetized patient who is breathing spontaneously. This only serves to lower the PaCO_2 to approach that of the apneic threshold, thus mandating more control of ventilation.

Figure 15-25. All inhaled anesthetics produce similar dose-dependent decreases in the ventilatory response to carbon dioxide. (Adapted from Eger EI II: Desflurane. *Anesth Rev* 20:87, 1993.)

Inhaled anesthetics, including nitrous oxide, also produce dose-dependent attenuation of the ventilatory response to hypoxia.^{260,261,262,263} and ²⁶⁴ This action appears to be dependent on the peripheral chemoreceptors. In fact, even subanesthetic concentrations of volatile anesthetics (0.1 MAC) have profound effects on the ventilatory drive to hypoxia (Fig. 15-26).^{265,266} Studies indicate anywhere from 15–75% depression of the response to hypoxia with 0.1 MAC of a volatile anesthetic. This has important clinical implications. The extreme sensitivity of the volatile anesthetics in terms of inhibiting hypoxic responsiveness may persist in patients during their stay in the recovery room because of residual effects. In this regard, the short-acting anesthetics (sevoflurane and desflurane) may prove advantageous because of their more rapid washout. In addition, they appear to have the least effect on hypoxic sensitivity at subanesthetic concentrations (Fig. 15-26). The effects of the volatile anesthetics on hypoxic drive may play an even more important role in patients who rely on hypoxic drive to set their level of ventilation, such as those with chronic respiratory failure. In these situations, consideration should be given to the need for more prolonged mechanical ventilation in the postoperative period until the residual effects of the volatile anesthetics have resolved.

Figure 15-26. Influence of 0.1 MAC of five volatile anesthetic agents on the ventilatory response to a step decrease in end-tidal oxygen concentration. Values are mean \pm SD. Subanesthetic concentrations of the volatile anesthetics, except desflurane and sevoflurane, profoundly depress the response to hypoxia. (Adapted from Sarton E, Dahan A, Teppema L *et al*: Acute pain and central nervous system arousal do not restore impaired hypoxic ventilatory responses during sevoflurane sedation. *Anesthesiology* 85:295, 1996.)

Bronchiolar Smooth Muscle Tone

Bronchoconstriction under anesthesia occurs because of direct stimulation of the laryngeal and tracheal areas, the administration of adjuvant drugs that cause histamine release, and from noxious stimuli, especially in lightly anesthetized patients.²⁶⁷ These responses are enhanced in patients with known reactive airway disease (including those requiring bronchodilator therapy or those with chronic smoking histories). Airway smooth muscle, which extends as far distally as the terminal bronchioles, is under the influence of both parasympathetic and sympathetic nerves. The parasympathetic nerves mediate baseline airway tone and reflex bronchoconstriction, and this has been attributed to M_3 muscarinic receptors on the airway smooth muscle that promote increases in intracellular cGMP. Adrenergic receptors also are located on bronchial smooth muscle, with the β_2 receptor subtype playing an important role in promoting bronchiolar muscle relaxation through an increase in intracellular cAMP. The volatile anesthetics relax airway smooth muscle by directly depressing smooth muscle contractility, and indirectly by inhibiting the reflex neural pathways.²⁶⁸ They also may have protective effects by acting on the bronchial epithelium *via* a nonadrenergic, noncholinergic mechanism, possibly involving the nitric oxide pathway.²⁶⁹ Based upon computerized tomography (CT) scans in dogs, halothane has been shown to be a better bronchodilator than isoflurane.^{270,271} A study in patients comparing isoflurane, halothane, and sevoflurane to a control group receiving thiopental indicated that sevoflurane may be a better bronchodilator than isoflurane or halothane (Fig. 15-27).²⁷² Studies from our laboratory suggest that desflurane administration shortly after induction of anesthesia with thiopental and tracheal intubation results in a transient increase in respiratory system resistance (bronchoconstriction), and we have attributed this to a direct effect from the pungency and airway irritability of desflurane. Volatile anesthetics have been used effectively to treat status asthmaticus when other conventional treatments have failed.^{273,274,275} and ²⁷⁶ Although halothane has been successfully used in these situations, newer volatile anesthetics may be a better choice because of their absence of cardiovascular depression and reduced risk of cardiac arrhythmias compared to halothane.

Figure 15-27. Respiratory system resistance decreased (bronchodilation) in the presence of 1.1 MAC isoflurane, halothane, and sevoflurane, whereas no change occurred in patients receiving thiopental $1.25 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ plus 50% nitrous oxide. The greatest decrease in resistance occurred with sevoflurane. (Adapted from Rooke GA, Choi J-H, Bishop MJ: The effect of isoflurane, halothane, sevoflurane, and thiopental/nitrous oxide on respiratory system resistance after tracheal intubation. *Anesthesiology* 86:1294, 1997.)

Mucociliary Function

Adequate mucociliary function may be important in preventing postoperative atelectasis and hypoxemia. There are a number of factors involved in diminished mucociliary function, particularly in the mechanically ventilated patient, and anesthesia plays an as yet poorly defined role. Halothane, enflurane, and nitrous oxide with halothane have been shown to decrease, in a dose-dependent fashion, mucociliary movement.^{277,278} It also is known that smokers have impaired mucociliary function compared to nonsmokers, and the combination of a volatile anesthetic in a smoker who is mechanically ventilated sets up a scenario for inadequate clearing of secretions, mucous plugging, atelectasis, and hypoxemia.

Pulmonary Vascular Resistance

Although vascular smooth muscle is clearly affected by the volatile anesthetics, the pulmonary vasodilator action of the inhaled anesthetics, including halothane, isoflurane, enflurane, sevoflurane, and desflurane, in normal lungs is minimal.^{279,280} and ²⁸¹ In addition, any decrease in cardiac output that might occur from a volatile anesthetic tends to offset the direct vasodilator action of the anesthetic, resulting in little or no change in pulmonary artery pressures and pulmonary blood flow. Even nitrous oxide, which has little effect on cardiac output and pulmonary blood flow, has at best a small effect to increase pulmonary vascular resistance. However, the effect of nitrous oxide may be magnified in patients with resting pulmonary hypertension.^{282,283} Perhaps more important in terms of volatile anesthetics and pulmonary blood flow is their ability to modulate hypoxic pulmonary vasoconstriction (HPV). During periods of hypoxemia, HPV reduces blood flow to underventilated areas of the lung, thereby shunting blood flow to areas of the lung with greater oxygen concentrations. The net effect is to improve the \dot{V}/Q matching. Although all of the inhaled anesthetics have been shown to attenuate HPV in animal models,^{279,280} and ²⁸¹ the situation is less clear in patient studies. This may reflect the multiple effects of the volatile anesthetics on factors involved in pulmonary blood flow, including their cardiovascular, autonomic, and humoral actions. In patients undergoing one-lung ventilation during thoracic surgery, minimal effects on PaO_2 and intrapulmonary shunt fraction (Q_s/Q_t) have been noted when changing from two-lung to one-lung ventilation during halothane, isoflurane, enflurane, and desflurane anesthesia (Fig. 15-28).^{284,285} and ²⁸⁶ Isoflurane appears to be less inhibitory on HPV than halothane and, although this effect is subtle,²⁸⁶ it might be attributed to the greater maintenance of cardiac output known to occur with isoflurane.

Figure 15-28. Arterial oxygenation (PaO_2) and intrapulmonary shunt (Q_s/Q_t) in patients ventilated with both lungs (2-LV) or with one lung (1-LV). Patients received either an inhalational agent, halothane or isoflurane, or a continuous intravenous anesthetic, thiopental. Note the minimal effect on PaO_2 and shunt that occurs on changing from a volatile anesthetic to an iv agent. (Adapted from Benumof JL, Augustine SD, Gibbons JA: Halothane and isoflurane only slightly impair arterial oxygenation during one-lung ventilation in patients undergoing thoracotomy. *Anesthesiology* 67:910, 1987.)

HEPATIC EFFECTS

Although postoperative liver dysfunction has been associated with most of the volatile anesthetics in current use, the most focused attention has been directed to halothane. There appear to be two distinct mechanisms by which halothane can cause hepatitis. One is more common but relatively mild, does not require a previous exposure, and has a low morbidity. The other, which is associated with repeat exposure and probably represents an immune reaction to oxidatively derived metabolites of halothane, has been implicated in severe liver damage and fulminant hepatic failure.

The liver has two blood supplies. One is the well-oxygenated blood from the hepatic artery and the other is the poorly oxygenated blood supply from the portal vein. Hepatocyte hypoxia is a significant contributor to postoperative hepatic injury. A pleasant attribute of the ether-based anesthetics (isoflurane, sevoflurane, and desflurane) is their ability to maintain or increase hepatic artery blood flow while decreasing (or not changing) portal vein blood flow.^{163,287} This contrasts with halothane where decreases in portal vein blood flow are not compensated by increases in hepatic artery blood flow (Fig. 15-29).²⁸⁸ Rather, halothane causes selective hepatic artery vasoconstriction.²⁸⁹ According to animal model estimates, there is a 65% reduction in oxygen availability during halothane anesthesia while the reduction in availability is just 35% during isoflurane anesthesia.²⁹⁰

Figure 15-29. Changes (% mean \pm SE) in hepatic blood flow during administration of isoflurane or halothane. Decreases in portal vein blood flow produced by 2 MAC isoflurane are offset by increases in hepatic artery blood flow (autoregulation). Halothane resulted in decreases in both portal vein and hepatic artery blood flow, thereby significantly compromising total hepatic artery blood flow. (Adapted from Gelman S, Fowler KC, Smith LR: Liver circulation and function during isoflurane and halothane anesthesia. *Anesthesiology* 61:726, 1984.)

Situations that decrease hepatic blood flow or increase hepatic oxygen demand make patients vulnerable to the unwanted effects of halothane on hepatic blood flow. For example, surgery in the area of the liver (or elsewhere in the abdominal cavity) that might compromise hepatic blood flow puts patients at risk for hepatic cell injury. In addition, enzyme induction, which increases oxygen demand, enhances the vulnerability of patients to the effects of halothane. Furthermore, patients who are critically dependent upon oxygen supply for survival of remaining liver tissue, such as the cirrhotic patient, are at higher risk for further hepatic injury than noncirrhotic individuals.²⁹¹ Whether this injury is attributable to a direct effect of halothane during hypoxic conditions or to reductive metabolism of halothane that is enhanced under hypoxic conditions is not entirely clear.²⁹²

Changes in liver function tests have been used as an index of hepatic injury during anesthesia. Transient increases in plasma alanine aminotransferase (ALT) activity followed the administration of enflurane, but not desflurane, isoflurane, or sevoflurane in human volunteers (Fig. 15-30).^{287,293,294} Although changes in the ALT or aspartate aminotransferase (AST) are accepted indices of liver cell damage, these measures may not accurately reflect the extent of hepatic injury and are not uniquely specific to the liver. Most cases of halothane hepatitis demonstrate lesions in the centrilobular area of the liver, and, not coincidentally, this area is most susceptible to hypoxia. Therefore, a more sensitive measure of injury may be glutathione-S-transferase (GST), which is distributed primarily in the centrilobular hepatocytes.²⁹⁵ In patient studies comparing halothane anesthesia to isoflurane and enflurane,^{296,297} significant increases in GST occurred after halothane (24–50%) and enflurane (20%), but not after isoflurane. There were two peaks in the GST responses; the first was 3–6 hours after halothane and the second was approximately 24 hours after halothane. It has been suggested that the early peak reflects direct damage or impaired liver blood flow and the second peak may be caused by metabolites or an immune response. (The immune mechanism of hepatitis is considered later in this chapter; see [Anesthetic Metabolism](#).)

Figure 15-30. Plasma alanine aminotransferase (ALT) levels do not change significantly when sevoflurane, enflurane, desflurane, or isoflurane are administered to healthy volunteers (mean \pm SEM). (Adapted from Weiskopf RB, Eger EI II, Ionescu P *et al*: Desflurane does not produce hepatic or renal injury in human volunteers. *Anesth Analg* 74:570, 1992; Frink EJ Jr, Malan TP Jr, Isner RJ *et al*: Renal concentrating function with prolonged sevoflurane or enflurane anesthesia in volunteers. *Anesthesiology* 80:1019, 1994; Eger EI II, Calverley RK, Smith NT: Changes in blood chemistries following prolonged enflurane anesthesia. *Anesth Analg* 55:547, 1976; and Stevens WC, Eger EI II, Joas TA *et al*: Comparative toxicity of isoflurane, halothane, fluroxene and diethyl ether in human volunteers. *Can J Anaesth* 20:357, 1973.)

NEUROMUSCULAR SYSTEM AND MALIGNANT HYPERTHERMIA

Compared to the alkane halothane, the ether-derived fluorinated volatile anesthetics produce about twofold greater skeletal muscle relaxation. Nitrous oxide does not relax skeletal muscles; in fact, in doses greater than 1 MAC, it may produce skeletal muscle rigidity.²⁹⁸ Interestingly, the inhaled anesthetics, in addition to the direct effects of relaxing skeletal muscle, also potentiate the action of neuromuscular blocking drugs. Although the mechanism of this potentiation is not entirely clear, it appears that it is largely due to a postsynaptic effect at the neuromuscular junction (see [Chapter 17](#)).

All of the potent volatile anesthetics serve as triggers for malignant hyperthermia in genetically susceptible patients.^{299,300,301} and [302](#) In contrast, nitrous oxide is a weak trigger for malignant hyperthermia.³⁰² Studies evaluating caffeine-induced contractures indicate that augmentation of the contractures by nitrous oxide is 1.3, whereas for isoflurane it is 3-fold, for enflurane 4-fold, and for halothane 11-fold.³⁰² Thus, halothane is the most potent trigger of the volatile anesthetics for malignant

hyperthermia.

GENETIC EFFECTS

In tests employed to identify chemicals that cause a mutagenic or carcinogenic response, all of the volatile anesthetics, including nitrous oxide, have proven to be negative. The Ames test, which identifies chemicals that act as mutagens and carcinogens, has been shown to be negative for enflurane, isoflurane, desflurane, sevoflurane, and nitrous oxide.^{236,291,303} Although halothane results in a negative Ames test, metabolites may be positive.³⁰⁴

Virtually every volatile anesthetic agent has been shown to be teratogenic in animal studies, but none has been shown to be teratogenic in humans. Animal studies have indicated that nitrous oxide exposure in the early periods of gestation may result in adverse effects, including an increased incidence of fetal resorption.^{305,306} The same vulnerability does not exist during the administration of the potent volatile anesthetics.³⁰⁷ However, learning function may be impaired in newborn animals exposed *in utero* to inhaled anesthetics.^{308,309}

There has been an ongoing concern about the incidence of spontaneous abortions in operating room personnel chronically exposed to trace concentrations of inhaled anesthetics, especially nitrous oxide.³⁰⁶ Animal studies using intermittent exposure to trace concentrations of nitrous oxide, halothane, enflurane, and isoflurane have not revealed harmful reproductive effects.³¹⁰ Methionine synthetase and thymidylate synthetase are vitamin B₁₂-dependent enzymes that have been shown to decrease in activity during nitrous oxide exposure. The mechanism appears to be an irreversible oxidation of the cobalt atom of vitamin B₁₂ by nitrous oxide. The half-time for inactivation of methionine synthetase is 46 min when 70% nitrous oxide is administered to patients (Fig. 15-31).³¹¹ Methionine synthetase and thymidylate synthetase are involved in the formation of myelin and the formation of DNA, respectively. Thus, the concern that these changes might have an effect on a rapidly developing embryo/fetus seems appropriate. Inhibition of these enzymes could also manifest as depression of bone marrow function and neurologic disturbances. Animals exposed to 15% nitrous oxide for up to 15 days developed a neuropathy presented as ataxia and spinal cord and peripheral nerve degeneration. A sensory motor polyneuropathy that is often combined with signs of posterior lateral spinal cord degeneration resembling pernicious anemia has been described in humans who chronically inhale nitrous oxide for recreational use.³¹² These effects have been attributed to reduced activity of the vitamin B₁₂-dependent enzymes.

Figure 15-31. Time course of inactivation of hepatic methionine synthase (synthetase) activity during administration of 50% nitrous oxide to rats or 70% nitrous oxide to humans. The half-life was substantially less in rats. (Adapted from Royston BD, Nunn JF, Weinbren HK *et al*: Rate of inactivation of human and rodent hepatic methionine synthase by nitrous oxide. *Anesthesiology* 68:213, 1988.)

Despite the unproved influence of trace concentrations of the volatile anesthetics on congenital development and spontaneous abortions, these concerns have resulted in the use of scavenging systems to remove anesthetic gases from the operating room and the establishment of OSHA standards for waste gas exposure. The NIOSH (National Institute for Occupational Safety and Health) recommended exposure level for nitrous oxide is 25 parts per million (ppm) as a time-weighted average over the time of exposure. The exposure limit for halogenated anesthetics (without nitrous oxide exposure) is 2 ppm.³¹³

BONE MARROW FUNCTION

Long administration of nitrous oxide has been associated with megaloblastic changes and agranulocytosis in bone marrow, presumably due to interference with DNA synthesis. Much of the concern about the volatile anesthetics in terms of bone marrow (and fetal development) is in relation to the effects on DNA synthesis and myelin formation in rapidly dividing cells. Nunn reported megaloblastic bone marrow changes in a seriously ill patient after 105 min of nitrous oxide anesthesia. These changes appeared to be prevented by administering 30 mg of folinic acid before the nitrous oxide. Megaloblastic changes in bone marrow are consistently observed in patients exposed to nitrous oxide for 24 hours,³¹¹ and four days of exposure to nitrous oxide has resulted in agranulocytosis. Two considerations related to these effects have proved irrelevant. First, in patients undergoing bone marrow transplantation, exposure to nitrous oxide has not altered viability of the bone marrow. Second, the use of nitrous oxide to treat leukemia has proved only that the potentially beneficial suppressive effects of nitrous oxide on cell synthesis are transient.³¹⁴

OBSTETRIC EFFECTS

As with vascular smooth muscle, the volatile anesthetics produce a dose-dependent decrease in uterine smooth muscle contractility and blood flow, and the effects appear to be similar with most of the volatile anesthetics.^{294,315,316} Because of the dose dependency, a common technique to provide general anesthesia for urgent cesarean sections is to use them in low concentrations, such as 0.5 MAC, combined with nitrous oxide. This decreases the likelihood of uterine atony and blood loss, especially after delivery when uterine contraction is essential. Uterine relaxation becomes substantial at concentrations of volatile anesthesia greater than 1 MAC, and this is not altered by the use of nitrous oxide. In some situations, uterine relaxation may be desirable, as in removal of a retained placenta. In this case, a brief high concentration of a volatile anesthetic may prove advantageous. In terms of neonatal effects, APGAR scores and acid-base balance are not affected by anesthetic technique (*e.g.*, spinal vs. general). More sensitive measures of neurologic and behavioral function, such as the Scanlon early neonatal neurobehavioral scale (ENNS) and the neurologic and adaptive capacities score (NACS), indicate some transient depression of scores following general anesthesia that did not persist at 24-hour post-delivery measurements.^{317,318} Fetal loss seems to increase following surgery in the first or second trimester, but the majority of these findings have been in patients following acute abdomen or trauma in emergency settings. Generally, elective surgeries are delayed until at least six weeks post-partum, or until the late second or early third trimester. Perhaps the most important factor in promoting good fetal outcome is maintaining good uterine blood flow during anesthesia and surgery.

ANESTHETIC DEGRADATION BY CARBON DIOXIDE ABSORBERS

Most adult general anesthesia is given through closed or semi-closed breathing circuits. This mandates the use of a carbon dioxide absorbent in the circuit. One of the problems with the CO₂ absorbents in use today is their content, which consists of monovalent hydroxide bases. These strong bases result in breakdown or degradation of all potent anesthetics (halothane, sevoflurane, enflurane, desflurane, and isoflurane).³¹⁹ The initial step in this degradation is removal of a labile proton. Currently, CO₂ absorbents contain the alkali bases—potassium and sodium hydroxide. Degradation of the anesthetics is slightly greater with potassium hydroxide.³²⁰ Barium hydroxide lime, which contains potassium but not sodium hydroxide, degrades the anesthetics more so than soda lime (which contains less potassium hydroxide and some sodium hydroxide).³²¹ In the case of halothane and sevoflurane, the reaction with carbon dioxide absorbents results in degradation of these anesthetics to haloalkenes.^{5,322,323} Halothane degrades to form trace amounts of BCDFE (2-bromo-2-chloro-1,1-difluoroethene) and sevoflurane degrades to form trace amounts of compound A [2,2-difluoro-1-(trifluoromethyl)vinyl ether]. These haloalkenes have been shown to be nephrotoxic in rats,^{324,325} although clinically significant renal effects of haloalkene formation in surgical patients have not been reported. In the case of desflurane, enflurane, and isoflurane, degradation occurs only in dehydrated carbon dioxide absorbents and results in carbon monoxide formation.^{320,326}

Special mention of a novel carbon dioxide absorbent that does not contain sodium or potassium hydroxide is warranted prior to delving into the controversial discussion of compound A and carbon monoxide. This new absorbent, called Amsorb, consists of calcium hydroxide with a compatible humectant, calcium chloride. Hardness and porosity have been established with two setting agents, calcium sulfate and polyvinyl pyrrolidone. This new material is chemically unreactive with sevoflurane, enflurane, isoflurane, and desflurane, and thus prevents the degradation of these compounds to carbon monoxide and compound A.³²⁷

Compound A

Sevoflurane undergoes base-catalyzed degradation in carbon dioxide absorbents to form a vinyl ether called compound A. The production of compound A is enhanced in low-flow or closed-circuit breathing systems (Fig. 15-32) and by warm or very dry CO₂ absorbents.^{328,329} and ³³⁰ Barium hydroxide lime produces more compound A than does soda lime, and this can be attributed to slightly higher absorbent temperature during CO₂ extraction.³²¹

Figure 15-32. Inhaled compound A concentrations during administration of sevoflurane at fresh gas flow rates of 1, 3, or 6 L · min⁻¹ in humans (**P* < 0.05 versus 3 L · min⁻¹; ***P* < 0.05 versus 6 L · min⁻¹). (Adapted from Bito H, Ikeda K: Effect of total flow rate on the concentration of degradation products generated by reaction between sevoflurane and soda lime. *Br J Anaesth* 74:667, 1995.)

Studies in rats where compound A has been administered in the inspired gas have identified a threshold for renal tubular necrosis between 290 and 340 ppm · h (50 ppm × 6 hr = 300 ppm · hr) (Fig. 15-33).^{331,332,333} and ³³⁴ The histology of the nephrotoxicity is characterized by cell necrosis of the cortical medullary tubules located in the proximal tubules.^{325,331,332} The biochemical markers of this necrosis include elevations of serum BUN and creatinine, glucosuria, and proteinuria.^{325,333} In addition, several enzymes from the tubule cells have been used as markers of cell injury including increases in urinary excretion of *n*-acetyl-b-D-glucosaminidase (NAG) and α-glutathione-S-transferase (αGST).^{325,333}

Figure 15-33. Renal biopsy results from rats inhaling different concentrations of compound A for 3 hours. The derived threshold to cause renal necrosis is about 100 ppm (300 ppm · h). The typical human exposure during the administration of sevoflurane in a semi-closed circuit is between 10 and 35 ppm of compound A, which falls well below the threshold to cause renal injury in rats. (Adapted from Kharasch ED, Hoffman GM, Thorning D *et al*: Role of the renal cysteine conjugate β-lyase pathway in inhaled compound A nephrotoxicity in rats. *Anesthesiology* 88:1624, 1998.)

There are species differences in the threshold for compound A-induced nephrotoxicity. The threshold is approximately 300 ppm · hr in 250-g rats,^{331,332} and ³³³ greater than 612 ppm · hr in pigs,³³⁵ and 600–800 ppm · hr in monkeys.³³⁶ In patients and volunteers receiving sevoflurane in low-flow delivery systems, inspired compound A concentrations averaged 8–24 and 20–32 ppm with soda lime and barium hydroxide lime, respectively.^{337,338,339,340,341} and ³⁴² Total exposures as high as 320–400 ppm · hr have had no clear effect on clinical markers of renal function.^{343,344} and ³⁴⁵ In randomized and prospective studies, the effects of low-flow (1 l · min⁻¹) or closed-circuit sevoflurane anesthesia on renal function in humans have been examined using both standard clinical markers of renal function (serum creatinine and BUN concentrations) and experimental markers of renal function and structural integrity (proteinuria, glucosuria, and enzymuria).^{337,339,340} and ^{341,344,346} In only one study to date has the administration of sevoflurane (to volunteers at a fresh gas flow of 2 l · min⁻¹ for 8 hr) been associated with significant increases in urinary excretion rates of glucose, protein, and enzyme markers.³⁴⁵ These increases were transient, resolving after several days, were not associated with significant changes in BUN and creatinine, and have not been reproduced by independent investigations employing volunteers in identical protocols.^{344,346} In addition, recent evidence from patients undergoing elective surgery indicates that transient proteinuria, glucosuria, and enzymuria also occur after desflurane and isoflurane anesthesia, without changes in serum BUN and creatinine.^{341,342} Proteinuria also has been documented to occur after surgery employing only epidural anesthesia.³⁴⁷ Thus, it is unclear if renal injury can be inferred from transient changes in urinary glucose or protein. This has fueled the argument that the only clinically accepted and relevant outcome markers of renal injury or renal functional impairment are serum BUN and creatinine.³⁴⁸

Aside from the high probability that the absence of renal injury in patients is due to low compound A levels during the clinical use of sevoflurane in a low-flow system, another probable explanation must be considered. Compound A is not itself toxic to organs. Rather, it is the biodegradation of compound A to cysteine conjugates and the further action of a renal enzyme called β-lyase on the conjugates that can result in formation of a potentially toxic thiol (Fig. 15-34).^{334,349,350} There is clear evidence for species differences in the biotransformation of compound A to cysteine-s conjugates.³⁵¹ Recent evidence suggests that the cysteine conjugates can be handled in one (or both) of two ways.³⁵² They can be acetylated to mercapturic acid through a detoxification pathway, which results in no organ toxicity; or they can be acted upon by an enzyme in the kidneys, renal β-lyase, to form reactive intermediates (toxification pathway). These reactive intermediates are responsible for the renal cell necrosis seen in rats. The β-lyase-dependent metabolism pathway in humans is far less extensive than the β-lyase pathway in rats (8–30 times less active).³⁵¹ Thus, compared with rats, humans receive markedly lower doses of compound A and metabolize a lower fraction *via* the renal β-lyase pathway. This may account for the safety of sevoflurane in both human volunteers and patients when compared to rat models. Because there has been limited experience with the use of sevoflurane in patients with renal impairment, caution is still advised when sevoflurane is applied to this patient population. An ongoing, multicenter phase IV study of sevoflurane versus isoflurane in patients with renal insufficiency is underway and new information should soon be available to the clinician.

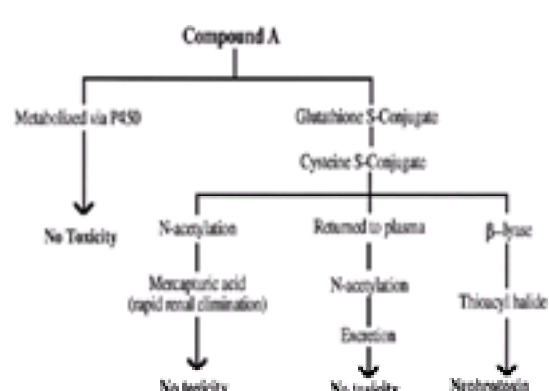

Figure 15-34. Known pathways for metabolism and elimination of compound A in humans. A potential toxin only results from the action of renal β-lyase on cysteine S-conjugates. The activity of this enzyme in humans is 8–30-fold less than in rats. Considerable handling of the cysteine S-conjugates in humans is *via* N-acetylation to

mercapturic acid. (Adapted from Kharasch ED, Jubert C: Compound A uptake and metabolism to mercapturic acids and 3,3,3-trifluoro-2-fluoromethoxy-propanoic acid during low-flow sevoflurane anesthesia. *Anesthesiology* 91:1267, 1999.)

Carbon Monoxide

CO₂ absorbents degrade desflurane, enflurane, and isoflurane to carbon monoxide when the normal water content of the absorbent (13–15%) is markedly decreased.^{320,326,353} The degradation has resulted in occasional patient exposure to toxic CO concentrations.^{354,355,356,357} and ³⁵⁸ The instances of CO poisoning have been reported in situations where the CO₂ absorbent has presumably been dried (desiccated) because an anesthetic machine has been left on with a high fresh gas flow passing through the CO₂ absorbent over an extended period of time. The anesthetic molecular structure and the presence of a strong base in the carbon dioxide absorbent are involved in the formation of CO.³²⁰ Desflurane, enflurane, and isoflurane contain an essential difluoromethoxy moiety, not found in the sevoflurane or halothane molecules, which is essential for the formation of CO. In addition, high absorbent temperatures increase CO formation.

As discussed in a recent editorial, the availability of a new CO₂ absorbent that does not degrade anesthetics (to either compound A or carbon monoxide) should change the way the clinicians deliver inhaled anesthetic, both domestically and worldwide: “From a patient safety perspective, widespread adoption of a nondestructive CO₂ absorbent should be axiomatic.”³¹⁹ Although the cost of this new CO₂ absorbent has not been established, it is likely to be somewhat greater than the cost of the currently employed CO₂ absorbents; however, the benefit may be substantial. The use of a nondestructive absorbent eliminates all the potential complications related to anesthetic breakdown and therefore minimizes the possibility of additional costs from complications including additional lab tests, hospital days, and medical/legal expenses from any serious outcome.

ANESTHETIC METABOLISM

Fluoride-Induced Nephrotoxicity

Nephrotoxicity due to metabolism (biotransformation) of halogenated anesthetics to free inorganic fluoride is now an accepted fact for methoxyflurane.³⁵⁹ The metabolism of methoxyflurane and, to a lesser extent, enflurane has resulted in a well described injury to renal collecting tubules.^{360,361} and ³⁶² The nephrotoxicity associated with these anesthetics is a high output renal insufficiency, characterized by dilute polyuria, dehydration, serum hypernatremia, hyperosmolality, and elevated BUN and creatinine, that is unresponsive to vasopressin. An association between increased plasma fluoride concentrations that occur as a result of metabolism of these anesthetics was noted early on and detailed by Mazze and colleagues.^{360,363} This work led to a “fluoride hypothesis.” Nephrotoxicity is caused by metabolism of the volatile anesthetics to fluoride, and the inorganic fluoride is the ultimate substance producing the renal injury. This traditional hypothesis has been reexamined recently, in part because sevoflurane, a newer potent volatile anesthetic, also undergoes metabolism, resulting in transient increases in serum fluoride concentrations, but has not been associated with a renal concentrating defect.^{345,362} The traditional hypothesis stated that both the duration of the high systemic fluoride concentrations (area under the fluoride–time curve) and the peak fluoride concentration (peaks above 50mM appear to represent the toxic threshold) were important in determining nephrotoxicity (Fig. 15-35).^{360,361,363} One theory for the safety of sevoflurane and relative safety of enflurane with regard to fluoride concentrations has been the more rapid elimination of these less soluble anesthetics compared to methoxyflurane. This provides a rapid decline in the plasma fluoride concentrations and less availability of the anesthetic for metabolism.³⁶⁴

Figure 15-35. Plasma inorganic fluoride concentrations (mean \pm SE) before and after 2–4 hours of methoxyflurane, enflurane, sevoflurane, isoflurane, and desflurane anesthesia. (Adapted from Kharasch ED, Armstrong AS, Gunn K *et al*: Clinical sevoflurane metabolism and disposition. II. The role of cytochrome P450 2E1 in fluoride and hexafluoroisopropanol formation. *Anesthesiology* 82:1379, 1995; Mazze RI: Metabolism of the inhaled anaesthetics: Implications of enzyme induction. *Br J Anaesth* 56(suppl):27S, 1984; and Sutton TS, Koblin DD, Gruenke LD *et al*: Fluoride metabolites after prolonged exposure of volunteers and patients to desflurane. *Anesth Analg* 73:180, 1991.)

Another report further clarifies this issue and has led to a modification of the traditional fluoride hypothesis for renal toxicity.³⁶⁵ This modification is based upon the likely contribution of intrarenal metabolism of anesthetics to fluoride to the resulting toxicity. It is well known that the human kidneys can metabolize volatile anesthetics, and recent work indicates that metabolism of methoxyflurane to fluoride in the kidney is significantly greater than that of sevoflurane and enflurane. This may be related to the multiple cytochrome P450 enzymes in the kidney responsible for metabolism of methoxyflurane (P450-2A6, P450-3A, P450-2E1).³⁶⁵ In contrast, sevoflurane and enflurane are primarily metabolized by the cytochrome P450-2E1. The theory now holds that the intrarenal fluoride generated from methoxyflurane metabolism and/or the multiple P450 isoenzymes involved in methoxyflurane metabolism account for the nephrotoxicity from this anesthetic. Despite the potential for relatively high plasma levels of fluoride following long exposure to newer anesthetics, the minimal amount of sevoflurane and enflurane renal defluorination may explain the relative absence of renal concentrating defects with these anesthetics (Fig. 15-36).^{345,362,365}

Figure 15-36. Maximal urinary osmolalities (mean \pm SE) in adult male volunteers after administration of desmopressin before and after prolonged administration (>9 MAC hours) of enflurane or sevoflurane. (Adapted from Frink EJ Jr, Malan TP Jr, Isner RJ *et al*: Renal concentrating function with prolonged sevoflurane or enflurane anesthesia in volunteers. *Anesthesiology* 80:1019, 1994.)

Factors such as total dose of anesthetic, enzyme induction, and obesity have been proved to enhance biotransformation. The activity of hepatic cytochrome P450 enzymes is increased by a variety of drugs, including phenobarbital, phenytoin, and isoniazid.^{236,366} Obesity causes increased metabolism (defluorination) in halothane,

enflurane, and isoflurane.^{367,368} and ³⁶⁹ However, the effects of obesity on the defluorination of sevoflurane are less clear.^{370,371}

Hepatic Injury from Metabolism: Halothane Hepatitis

Although postoperative liver dysfunction has been associated with most of the volatile anesthetics in current use, the most focused attention has been directed to halothane. This is due, in part, to the relatively recent demonstration of binding of an oxidatively derived metabolite of halothane to liver cytochromes that could then act as a hapten and induce an immune reaction. This hypersensitivity reaction has been associated with severe liver damage and fulminant hepatic failure. There are many causes of postoperative jaundice and abnormal liver function tests, including viral hepatitis, coexisting liver disease (such as Gilbert's disease), blood transfusions, septicemia, drug reactions, intra- and postoperative hypoxia and hypotension, and direct tissue trauma as a result of the surgical procedure.²⁹² The diagnosis of halothane hepatitis is generally made based on "incomplete exclusion," defined as the appearance of liver damage within 28 days of halothane exposure in a person in whom other known causes of liver disease have been excluded.

Halothane was introduced into clinical practice in 1956, and case reports of unexplained jaundice following anesthesia with halothane began to appear in 1958. By 1963, at least 350 putative cases of "halothane hepatitis" had been reported. The common thinking in the early 1950s was that inhaled anesthetics (except trichloroethylene) were metabolically unaltered by the body's biochemical machinery. However, in 1967, it was determined that approximately 18% of halothane was metabolized in humans.³⁷² The metabolites were oxidatively derived. It is now known that oxidative metabolism of halothane produces an intermediate that binds to liver tissue and can produce an immune response in certain individuals. However, halothane-associated hepatitis can present as one of two clinical syndromes, and it is likely that only one syndrome can be explained by an immune mechanism.^{292,373,374} Each may develop after an uneventful anesthesia and surgery with no apparent time-to-dose relationship. The most common syndrome, which occurs in close to 20% of the adult patients receiving halothane, is a mild, self-limited postoperative toxicity that has been ascribed to reductive metabolism of halothane; this route of metabolism is enhanced under low-oxygen or hypoxic conditions. Reductive metabolism of isoflurane, desflurane, sevoflurane, and enflurane does not occur. The typical presentation of hepatitis from reductive metabolism is a rapid (1–3 days) but mild, unprogressing pattern of liver injury characterized by nausea, lethargy, fever, moderately increased concentrations of liver transaminases, and, rarely, transient jaundice. It does not require a repeat exposure, as does the immune mechanism of hepatitis; it can occur on the first exposure to halothane.

Historically, an immune-mediated mechanism for halothane hepatitis seemed unlikely. Halothane is a small molecule, and thus seemed unlikely to be immunoreactive, although reductive metabolites have been shown to bind to rat liver microsomes, which contain the cytochrome P450 system. Several more recent observations suggest that reductive metabolism is not an important mechanism in the evolution of the immune-mediated halothane hepatitis.²⁹² The possibility still existed that binding of a metabolite of halothane to the liver cytochromes could act as a hapten and induce a hypersensitivity response.³⁷⁵ Supporting this possibility were the clinical manifestations of hepatitis, including eosinophilia, fever, rash, and arthralgia, and prior exposure to halothane. The possibility of a genetic susceptibility factor is suggested by case reports of halothane hepatitis in closely related patients.³⁷³ The most compelling evidence for an immune-mediated mechanism is the presence of circulating immunoglobulin G antibodies in up to 70% of patients with diagnosis of halothane hepatitis.^{292,375} This antibody is not directed against the reductive metabolite of halothane, but against an oxidative compound, trifluoroacetyl halide, which is incorporated onto the surface of the hepatocyte (Fig. 15-37).^{376,377} Trifluoroacetyl proteins (TFA) have been identified from the liver of rats after halothane exposure with enzyme-linked immunosorbent assays and immunoblotting techniques. These altered proteins can be seen by the immune system as non-self (*i.e.*, neoantigen), resulting in production of antibodies. These can now be identified from serum samples of humans by identifying anti-TFA albumin activity on an ELISA screening evaluation and by using a competitive, direct ELISA to test the ability of trifluoroacetylated lysine to block antibody binding to TFI-albumin.^{378,379}

Figure 15-37. Halothane is metabolized to a trifluoroacetylated (TFA) adduct that binds to liver proteins. In susceptible patients, this adduct (altered protein) is seen as non-self (neoantigen), generating an immune response (production of antibodies). Subsequent exposure to halothane may result in hepatotoxicity. A similar process may occur in genetically susceptible individuals after anesthetic exposure to other fluorinated volatile anesthetics (enflurane, isoflurane, desflurane) that also generate a TFA adduct. (Adapted from Njoku D, Laster MJ, Gong DH *et al*: Biotransformation of halothane, enflurane, isoflurane, and desflurane to trifluoroacetylated liver proteins: Association between protein acylation and hepatic injury. *Anesth Analg* 84:173, 1997.)

This metabolic pathway involving the cytochrome P450 system during halothane exposure is identical to the metabolic pathway noted with enflurane, isoflurane, and desflurane (Fig. 15-38). However, the expression of the neoantigens should be related to the amount of metabolism of each agent. This would suggest that, in terms of antigenic load, halothane > enflurane > isoflurane > desflurane. Indeed, case reports have appeared in the literature linking each of these anesthetics with immune-mediated hepatitis.^{374,379,380,381,382} and ³⁸³ If the incidence of fulminant hepatic failure after halothane is 1 in 35,000,³⁸⁴ hepatic failure caused by isoflurane may occur in only 1 per 3,500,000 isoflurane anesthetics, and a lower incidence would be expected with desflurane. Desflurane is the least metabolized of the volatile anesthetics, resulting in very small amounts of adduct, and only one case report of hepatotoxicity from desflurane has been described.³⁷⁹ Sensitization of this patient by two exposures to halothane (18 years and 12 years previously), precipitated massive hepatotoxicity. Anti-TFA antibodies were identified in the serum.

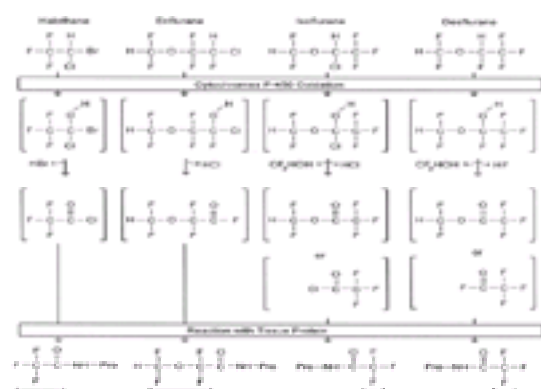

Figure 15-38. Pathways for the oxidative metabolism of fluorinated volatile anesthetics by cytochrome P450 enzymes to form acetylated protein adducts. In genetically susceptible individuals, the resulting trifluoroacetylates are thought to produce an immune response manifesting clinically as drug-induced hepatitis. (Adapted from Martin JL, Plevak DJ, Flannery KD *et al*: Hepatotoxicity after desflurane anesthesia. *Anesthesiology* 83:1125, 1995.)

Immunologic memory resulting in hepatitis has been reported 28 years after an initial halothane exposure.³⁸⁵ In addition, cross-sensitivity has been reported in which exposure to one anesthetic can sensitize patients to a second, but different anesthetic.^{379,386} There are no reports of fulminant hepatic necrosis associated with sevoflurane in humans. Sevoflurane is not metabolized to a trifluoroacetyl halide; rather, it is metabolized to hexafluoroisopropanol that does not serve as a neoantigen (Fig. 15-39).²⁸⁷

Figure 15-39. Pathway for oxidative metabolism of sevoflurane (UDPGA, uridine diphosphate glucuronic acid). Trifluoroacetylated (TFA) adducts are not formed from the metabolism of sevoflurane. (Adapted from Frink EJ Jr, Ghantous H, Malan TP *et al*: Plasma inorganic fluoride with sevoflurane anesthesia: Correlation with indices of hepatic and renal function. *Anesth Analg* 74:231, 1992.)

It is worth recalling that, despite case reports of hepatic damage associated with halothane that appeared in the literature within two years of its introduction, it has taken some 35 years of research and debate to reach the current consensus on the mechanism of halothane-associated hepatitis and fulminant hepatic failure. It is the opinion of these authors that halothane should not be used in adult surgical cases and should be strongly discouraged in the pediatric population. Although the incidence of hepatitis appears to be much lower in the pediatric population, our concern is related to immunologic memory resulting in hepatitis later in life during a repeat exposure to anesthesia. The new volatile anesthetics have an extremely low potential for hepatotoxicity, and the possibility of avoiding even one case of fulminant hepatic failure from a volatile anesthetic is sufficiently compelling to discourage use of the older, more metabolized anesthetics including halothane and enflurane.

CLINICAL UTILITY OF VOLATILE ANESTHETICS

For Induction of Anesthesia

Although current practices for establishing the anesthetic state consist of initial administration of an iv sedative/hypnotic, there is increasing interest in the use of volatile anesthetics *via* the facemask. Facemask use is commonplace in pediatric anesthesia but relatively rare in adult anesthesia. Historically, in the days of ether and cyclopropane, the standard induction technique was a mask induction. The renewed interest in this technique is primarily attributable to the advent of the newer potent and poorly soluble anesthetic sevoflurane, which is nonpungent and hence easily inhaled.³⁸⁷ An important attribute of the gaseous induction technique is the ability to take the patient “deep” in a rapid fashion, thereby avoiding some of the unwanted side effects of stage 2 anesthesia (excitation, salivation, coughing, movement). The classic stages of anesthesia (stages 1–4) were described with the use of ether anesthesia. This volatile agent was far more soluble than sevoflurane, and therefore resulted in a slow and sometimes stormy induction of anesthesia. These older anesthetic agents were replaced by halothane in the 1950s, and the success of halothane was based primarily on its nonflammability and potency. Induction of anesthesia with halothane in the pediatric population is quite common. Interestingly, induction of anesthesia with halothane in adults was also practiced, but was not exceptionally popular. Ruffe and colleagues^{388,389} described a single-breath induction with 4% halothane in adults that achieved loss of consciousness in most patients within two minutes. However, the development of the barbiturates (described in the 1930s) and iv technology and the importance of iv fluid administration were advanced through the middle of the 20th century. These factors, along with the speed of iv induction with thiopental, promoted the popularity of iv over inhaled inductions in adults. The resurgence of interest in mask induction in the adult population centers on the potential safety and utility of this technique when using sevoflurane.^{390,391,392} and ³⁹³ The safety issues center primarily on the fact that spontaneous ventilation is preserved with a gas induction, and patients essentially regulate their own depth of anesthesia, as excessive sevoflurane would, in fact, suppress ventilation. Safety would be compromised if stage 2 excitation were a problem; however, clinical studies indicate that this is not the case. It is likely that the low blood:gas solubility of sevoflurane makes for a rapid induction, and typical times to loss of consciousness average ~1 minute when delivering sevoflurane *via* the facemask. Sevoflurane also has been used in the approach to the difficult adult airway because of the preservation of spontaneous ventilation, the lack of excitation, and absence of salivation with this technique.³⁹⁴ The traditional “awake look” in the suspected difficult airway (where iv drugs are titrated to a level that allows direct laryngoscopy in the awake patient) has been modified to consist of spontaneous ventilation of high concentrations of sevoflurane until laryngoscopic evaluation is tolerated. Laryngeal mask placement can be successfully achieved two minutes after administering 7% sevoflurane *via* the facemask. Although the addition of nitrous oxide to the inspired gas mixture does not add significantly to the induction sequence, most practitioners favor high concentrations of sevoflurane with oxygen. The gas induction technique is promoted by pretreatment with benzodiazepines but complicated by apnea with opioid pretreatment.³⁹² Of course, the utility of this technique is that clinicians simply need to pay attention to the airway during the induction sequence, rather than reaching for drugs and injecting them through an iv port. End-tidal gas concentrations can be reasonably obtained (although not precisely obtained because of mixing in the face-mask during the induction sequence) and pupil responses and ventilation can be evaluated. Importantly, patient acceptance of this technique has been relatively high, exceeding 90% of the cases.³⁹³ There have been a number of techniques described to use sevoflurane for induction of anesthesia *via* facemask. These include: priming the circuit (emptying the rebreathing bag, opening the “pop-off” valve, dialing the vaporizer to 8% while using a fresh gas flow of $8\text{ l} \cdot \text{min}^{-1}$, and maintaining this for 60 seconds prior to applying the facemask to the patient); a single-breath induction from end-expiratory volume to maximum inspired volume; and simply deep breathing. All seem to have the successful end result of loss of consciousness, generally within one minute.

For Maintenance of Anesthesia

The volatile anesthetics are clearly the most popular drugs used to maintain anesthesia. They are easily administered *via* inhalation, they are readily titrated, they have a high safety ratio in terms of preventing recall, and the depth of anesthesia can be quickly adjusted in a predictable way while monitoring tissue levels *via* end-tidal concentrations. They are effective regardless of age or body habitus, and are associated with clinical signs that give an indication of anesthetic depth, irrespective of end-tidal gas monitoring. Moreover, they have some properties that prove beneficial in the operating room, including relaxation of skeletal muscle, in most cases preservation of cardiac output and cerebral blood flow, and relatively predictable recovery profiles. Some of the drawbacks to the use of the current volatile anesthetics are the absence of analgesic effects and their association with postoperative nausea and vomiting. In addition, as mentioned earlier, various inhaled anesthetics have been associated with cellular toxicity in animal models, although in patients in a clinical setting these issues have not resulted in any discernible effect on outcome. The exceptions are halothane and desflurane. Halothane has a well-described immunologic effect in producing hepatitis, it sensitizes the myocardium to epinephrine-induced arrhythmias, and it has been associated with bradycardia and bradyarrhythmias (coronary steal). Desflurane has been associated with tachycardia, hypertension, and, in select cases, myocardial ischemia when used in high concentrations or rapidly increasing the inspired concentrations (without using opioid adjuvants to prevent such a response).

PHARMACOECONOMICS AND VALUE-BASED DECISIONS

In the current environment of cost containment, clinicians are constantly being pressured to use less expensive anesthetic agents, including neuromuscular blocking drugs and volatile anesthetics. In succumbing to these pressures, the clinician must focus on providing value-based anesthesia—that is, obtaining the best results at the most practical cost. Factors involved in the value-based decision include the efficacy of the drug, its side effects, its direct costs, and its indirect effects. In terms of efficacy, all of the volatile anesthetics are reasonably similar: each can be used to establish state of anesthesia for surgical interventions and can be reversed easily.

In terms of side effects, the things to consider are serious side effects or toxicities versus manageable side effects, and to what extent these manageable side effects increase the cost. With respect to serious side effects, halothane is the least expensive of the volatile anesthetics, but it has definite life-threatening potential in terms of sensitization of the heart to arrhythmias and the development of an immune response that can cause fulminant hepatic necrosis. One can make a strong argument that halothane does not belong in the operating room. Other side effects of the volatile anesthetics are nausea and vomiting. The need for rescue medications to treat nausea and vomiting after volatile anesthesia must be weighed into any legitimate cost analysis.

Direct costs are not simply the cents per milliliter of liquid or dollars per bottle of anesthetic. Rather, they reflect the combination of the potency of the drug to establish a MAC level, the fresh gas flow, and the cost of the anesthetic. At $2\text{ l} \cdot \text{min}^{-1}$ fresh gas flow, delivering 1 MAC, both desflurane and sevoflurane cost about \$10.00 per hour. This contrasts to isoflurane, which costs \$2.00–\$3.00 per MAC-hour when delivered at $2\text{ l} \cdot \text{min}^{-1}$ because of generic price pressures.³⁹⁵

The indirect costs are probably the most difficult to pinpoint, but may be the most important to evaluating the cost of using the new volatile anesthetics. Examples of indirect costs include costs associated with OR time, time in the PACU versus bypassing the PACU to a step-down unit, labor costs, and outcome-related costs, such as litigation to defend a bad outcome from an anesthetic drug.

One of the arguments for using the newer, more expensive volatile anesthetics, sevoflurane and desflurane, has been their relative speed in terms of emergence from anesthesia. It seems that this speed matches the ambulatory anesthesia environment in which we practice and the “move ‘em in/move ‘em out” approach to surgical patients. This argument has been tempered somewhat by the basic knowledge that one of the skills of the clinician is the titration of the volatile anesthetics. Even the more soluble drugs can be titrated based on clinical experience or with the aid of processed EEG monitors (such as the bispectral index system), permitting fast wakeups regardless of the choice of anesthetic agent. However, there is solid evidence to support the use of the less soluble drugs in the longest surgical cases, even though these agents have the highest direct costs (Fig. 15-40).^{33,396} In these cases the improved recovery profile of the less soluble drugs over the more soluble drugs includes a more rapid time to emergence and a more rapid discharge from the recovery room. This discharge advantage with new agents has been difficult to show after shorter surgical procedures. Clearly, the use of the most expensive drugs in the longest procedures adds to the direct cost of managing that case, but may provide substantial cost savings in terms of side effects and indirect costs.

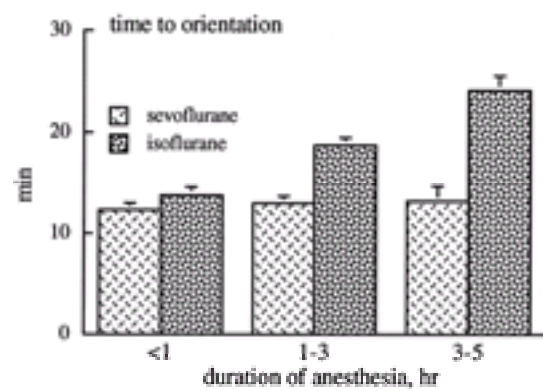

Figure 15-40. The recovery times to orientation after anesthesia of varying durations. With the less soluble anesthetic sevoflurane, the time to orientation was independent of the anesthetic duration. In contrast, long anesthetics with isoflurane were associated with delayed times to orientation. (Adapted from Ebert TJ, Robinson BJ, Uhrich TD *et al*: Recovery from sevoflurane anesthesia. *Anesthesiology* 89:1524, 1998.)

PHYSIOLOGY AND PHARMACOLOGY

Structure

The cell bodies of motor neurons supplying skeletal muscle lie in the spinal cord. They receive and integrate information from the central nervous system. This information is carried *via* an elongated structure, the axon, to distant parts of the body. Each nerve cell supplies many muscle cells (or fibers) a short distance after branching into nerve terminals. The terminal portion of the axon is a specialized structure, the synapse, designed for the production and release of acetylcholine (ACh). The synapse is separated from the endplate of the muscle fiber by a narrow gap, called the synaptic cleft, which is approximately 50 nm in width (0.05 μm).¹ The nerve terminal is surrounded by a Schwann cell, and the synaptic cleft has a basement membrane and contains filaments that anchor the nerve terminal to the muscle.

The endplate is a specialized portion of the membrane of the muscle fiber where nicotinic ACh receptors are concentrated. During development, multiple connections are made between nerve terminals and a single muscle fiber. The presence of these connections promotes clustering of receptors. As maturation continues, most of these connections atrophy and disappear, usually leaving only one connection per muscle fiber. This endplate continues to differentiate from the rest of the muscle fiber. As the nerve terminal enlarges and folds appear, the density of ACh receptors increases at the endplate and decreases to almost zero in extrajunctional areas.² Mammalian endplates usually have an oval shape with the short axis perpendicular to the fiber. The width of the endplate is sometimes as large as the diameter of the fiber, but is usually smaller. However, its length is only a small fraction of that of the fiber.³

Nerve Stimulation

Under resting conditions, the electrical potential of the inside of a nerve cell is negative with respect to the outside (typically -90 mV). If this potential is made less negative (depolarization), sodium channels open and allow sodium to enter the cell. This influx of positive ions makes the potential inside the membrane positive with respect to the outside. This potential change in turn causes depolarization of the next segment of membrane, causing more sodium channels to open, and an electrical impulse, or action potential, propagates. The duration of the action potential is brief (<1 msec), because inactivation of sodium channels occurs within a short period of time and because potassium channels, which produce outward movement of potassium ions, open and make the inside potential more negative. An action potential also triggers the opening of calcium channels, allowing calcium to penetrate the cell, and this entry of calcium has special importance at the nerve terminal.

Sodium channels are made up of three protein subunits. The ion channel *per se* is surrounded by the α subunit, a funnel-shaped protein that crosses the membrane completely. The wider end of the protein lies inside the membrane. The two smaller subunits (β_1 and β_2) lie on opposite sides of the α subunit. They do not cross the membrane entirely and face outward.⁴ When a nerve stimulator is used, an action potential may be generated if enough current is applied to depolarize the axon above a certain threshold. The magnitude of the depolarization depends both on the current applied and the duration of the stimulus.

A peripheral nerve is made up of a large number of axons of different thresholds, different sizes, and different distances from the stimulating electrode. Although each axon responds in an all-or-none fashion to the stimulus applied, not all axons may respond to a given stimulus. Thus, in the absence of neuromuscular blockers, the relationship between the amplitude of the muscle contraction and current applied is sigmoid.⁵ At low currents, the depolarization is insufficient in all axons. As current increases, more and more axons are depolarized to threshold and the strength of the muscle contraction increases. When the stimulating current reaches a certain level, all axons are depolarized to threshold and propagate an action potential. Increasing current beyond this point does not increase the amplitude of muscle contraction: the stimulation is supramaximal ([Fig. 16-1](#)).

Figure 16-1. Example of increasing stimulating current in one patient. Current pulses, 0.2-msec duration, were delivered to the ulnar nerve at the wrist every 10 sec. The force of contraction of the adductor pollicis was measured and appears as spikes. No twitch was seen if the current was <28 mA. At current strengths of ≥ 40 mA,

the current became supramaximal; increasing the current produced little change in force.

After firing once, a nerve axon cannot respond to further stimulation for a short time (usually 0.5–1 msec) known as the refractory period. If the duration of stimulation is longer than the refractory period, repetitive stimulation of the axon may result.¹ For this reason, the current pulse applied must be brief, <0.5 msec. Most commercially available stimulators deliver impulses lasting 0.1–0.2 msec.

Release of Acetylcholine

Acetylcholine is synthesized from choline and acetate. It is then packaged into 45-nm vesicles, which tend to concentrate in the area of the nerve terminal closest to the endplate. Some of these vesicles cluster near the cell membrane opposite the crests of the junctional folds of the endplate, in areas called active zones (Fig. 16-2).⁶ Each vesicle contains about 5000–10,000 ACh molecules.

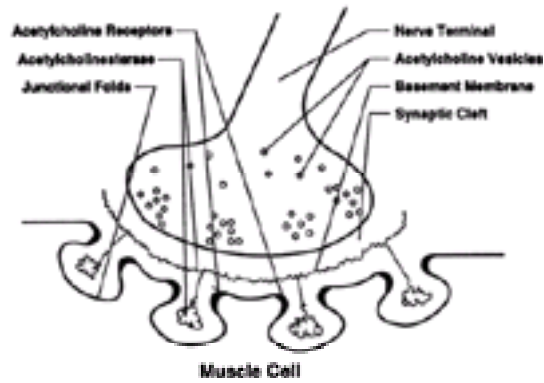

Figure 16-2. Diagram of neuromuscular junction.

Although there have been doubts regarding the vesicular hypothesis, it is now widely accepted that ACh is released in packets, or quanta, and that a quantum represents the contents of one vesicle, which amounts to 5000–10,000 molecules.⁷ In the absence of nerve stimulation, quanta are released spontaneously, at random, and this is seen as small depolarizations of the endplate (miniature endplate potential; MEPP). When an action potential invades the nerve terminal, ~200–400 quanta are released simultaneously, unloading ~1–4 million ACh molecules into the synaptic cleft.^{1,7} Calcium, which enters the nerve terminal through channels that open in response to depolarization, is required for vesicle fusion and release. Calcium channels are located near docking proteins, and this special geometric arrangement provides high intracellular concentrations of calcium to allow binding of specialized proteins on the ACh vesicular membrane with docking proteins. Binding produces fusion of the membranes and release of ACh ensues.⁸ After release, vesicles are most likely recycled, and there is evidence that these newly re-formed vesicles are released preferentially.⁷ When the calcium concentration is decreased, or if the action of calcium is antagonized by magnesium, the release process is inhibited and transmission failure may occur. Other proteins regulate storage and mobilization of ACh vesicles. Recent research on the identification of the numerous proteins regulating movement of vesicles at the nerve terminal and the study of their function has corroborated the concepts of a small, immediately releasable pool and a much larger reserve pool. Each impulse releases 0.2–0.5% of the 75,000–100,000 vesicles in the nerve terminal.⁷ With repetitive stimulation, the amount of ACh released decreases rapidly because only a small fraction of the vesicles is in a position to be released immediately. To sustain release during high-frequency stimulation, vesicles must be released from the reserve pool, and this process requires calcium.⁷

Postsynaptic Events

The 1–10 million receptors located at the endplate are made up of five glycoprotein subunits arranged in the form of a rosette and lying across the whole cell membrane (Fig. 16-3). Two of these noncontiguous subunits, designated α , are similar and each must bind simultaneously to an ACh molecule to induce a conformational change in the receptor structure such that an opening is made in the center of the rosette, allowing small ions to pass through the channel.^{1,9} Sodium ions move inside along their concentration and electrical gradients, making the inside less negative, thus depolarizing the cell membrane. There is a high density of sodium channels in the folds of synaptic clefts and in the perijunctional area.¹⁰ These channels open when the membrane is depolarized beyond a critical point, allowing more sodium to enter the cell, and producing further depolarization. The high density of sodium channels in the junctional and perijunctional areas contributes to the generation of an action potential, which propagates by activation of sodium channels along the whole length of the muscle fiber.

Figure 16-3. The nicotinic acetylcholine receptor consists of five glycoprotein subunits arranged to form an ion channel. The α subunits carry a recognition site for agonists and antagonists. (Reprinted with permission from Taylor P: Are neuromuscular blocking agents more efficacious in pairs? *Anesthesiology* 63:1, 1985.)

There are two categories of nicotinic ACh receptors. The type normally present at the endplate has an ϵ subunit. Fetal receptors and those present on the muscle outside the endplate, also called extrajunctional receptors, have a γ subunit instead of an ϵ subunit. Both types of receptor differ by their sensitivity to agonist and antagonist drugs. However, in both types, each subunit has four transmembrane domains; that is, each is a string of amino acids that crosses the membrane four times. The binding site for acetylcholine is before the first membrane domain of the α subunit on the outside of the membrane.^{9,11}

Depolarization above threshold in a muscle fiber is followed by two distinct but related phenomena: an electrical event, the action potential; and a mechanical event, muscle contraction. The activity of a whole muscle is the sum of the responses of the individual fibers and can be measured either in terms of its electrical activity (by electromyography, EMG) or its contractile force (by mechanomyography, MMG). The EMG response of the muscles of the hand is 5–10 msec in duration, but the MMG lasts ~150 msec (Fig 16-4). Thus, for frequencies up to 100 Hz, the EMG response can be distinguished for each stimulus. However, summation of individual twitch responses occurs for frequencies >7–10 Hz, and a tetanic response, greater in intensity than a muscle twitch, can be observed.

Figure 16-4. Typical electromyographic (EMG) and mechanomyographic (MMG) tracings of the adductor pollicis after single stimulation of the ulnar nerve. Note the longer duration and latency of the MMG response.

The main action of nondepolarizing neuromuscular blocking drugs is to block the postsynaptic ACh receptor by binding to at least one of the two α subunits, thus preventing access by ACh. Under normal circumstances, only a small fraction of available receptors must bind to ACh to produce sufficient depolarization to trigger a muscle contraction. In other words, there is a wide “margin of safety”. This implies that neuromuscular blocking drugs must be bound to a large number of receptors before any blockade is detectable. Animal studies suggest that 75% of receptors must be occupied before twitch height decreases in the presence of α -tubocurarine, and blockade is complete when 92% of receptors are occupied.¹² The actual number depends on species and type of muscle, and humans might have a reduced margin of safety.¹³ However, the general concept is applicable to clinical practice; that is, detectable blockade occurs over a narrow range of receptor occupancy.

ACh is hydrolyzed rapidly by the enzyme acetylcholinesterase, which is present in the folds of the endplate as well as embedded in the basement membrane of the synaptic cleft. The presence of the enzyme in the synaptic cleft suggests that not all the ACh released reaches the endplate; some is hydrolyzed en route.⁷

Presynaptic Events

The release of ACh normally decreases during high-frequency stimulation because the pool of readily releasable ACh becomes depleted faster than it can be replenished. However, the reduced amount released is well above what is required to produce muscle contraction because of the high margin of safety at the neuromuscular junction. However, during partial nondepolarizing blockade this decrease in transmitter output produces fade—a progressive decrease in muscle response with each stimulus. Nondepolarizing neuromuscular blocking drugs probably accentuate the fade by blocking presynaptic nicotinic receptors, which differ structurally from postsynaptic receptors.¹⁴ The function of the presynaptic receptors is to sustain ACh mobilization in the face of continuing stimulation. One possible mechanism of action could be to break the link between a vesicular protein and a cytoplasmic filament, which prevents mobilization of the vesicle.¹⁵ The affinity of agonists and antagonists is not the same for presynaptic receptors. Only small doses of nondepolarizing relaxants are needed to block presynaptic receptors.¹⁶ Whatever the exact mechanism of fade, it remains a key property of nondepolarizing neuromuscular blocking drugs and is useful for monitoring purposes.

NEUROMUSCULAR PHARMACOLOGY

Neuromuscular blocking drugs interact with the ACh receptor either by depolarizing the endplate or by competing with ACh for binding sites. The former mechanism is characteristic of depolarizing drugs and the latter of nondepolarizing agents. The only depolarizing agent still in use is succinylcholine. All others are of the nondepolarizing type.

The effect of all neuromuscular blocking drugs is measured as the depression of adductor muscle contraction (twitch) following electrical stimulation of the ulnar nerve. Potency of each drug is determined by constructing dose–response curves, which describe the relationship between twitch depression and dose. Then, the effective dose 95, or ED₉₅, which is the median dose corresponding to 95% twitch depression, is obtained. In addition to potency data, it is necessary to describe the time course of blockade by specifying onset (time to maximum blockade) and duration of action (time from injection to 25% recovery of twitch height). Both onset and duration depend on dose, so $2 \times \text{ED}_{95}$ has been retained for comparison purposes. Recently, categories were proposed for neuromuscular blocking drugs, which may be defined according to their onset and duration of action at the adductor pollicis to $2 \times \text{ED}_{95}$ doses (Table 16-1).¹⁷ Muscles other than the adductor pollicis may have very different onset, ED₉₅, and duration of action.

| Onset to Maximum Block (min) | | | |
|--------------------------------|--------------------------|---|---|
| Ultra-rapid (1-3) | Rapid (3-2) | Intermediate (2-10) | Long (1-10) |
| Succinylcholine | Rapacurium Rocuronium | Atracurium Mivacurium Vecuronium 2-Substituted Gallamine Mincurium Pancuronium Pipracurium | Decamethonium Doxacurium |
| Duration to 25% Recovery (min) | | | |
| Ultra-short (1-3) | Short (3-30) | Intermediate (30-100) | Long (1-100) |
| Succinylcholine | Mivacurium Rapacurium | Atracurium Cisatracurium Rocuronium Vecuronium | Decamethonium α -Tubocurarine Gallamine Mincurium Pancuronium Pipracurium |

The definition of categories according to Boland RE. From the PDN. Anesthesiology 82:35A, 1995. Drugs are listed that best fit the categories under optimal circumstances. It must be noted that onset and duration depend on potency, dose, and method of measurement. Also, systematic differences may exist within categories. For example, onset of rapacurium and rocuronium are in the 1-3-min category; but rapacurium is close to 1 min and rocuronium is close to 2 min.

Table 16-1. DEFINITION OF NEUROMUSCULAR BLOCKING DRUGS ACCORDING TO ONSET AND DURATION OF BLOCK AT ADDUCTOR POLLICIS

Depolarizing Blocking Drugs: Succinylcholine

Among drugs that depolarize the endplate, only succinylcholine and decamethonium were introduced into clinical practice in North America. Decamethonium, a drug with a slow onset and intermediate duration, has been replaced by nondepolarizing alternatives. However, succinylcholine still enjoys some popularity, despite a long list of undesired effects, because it is the only ultra-rapid onset, ultra-short duration neuromuscular blocking drug (NMBD) available. Although successful tracheal intubation can be achieved by a combination of propofol and remifentanyl¹⁸ or alfentanil,¹⁹ intubation conditions are improved by the addition of NMBDs.

Neuromuscular Effects

The effects of succinylcholine at the neuromuscular junction are not completely understood. The drug binds to presynaptic, postsynaptic, and extrajunctional receptors. When it first reaches any of these receptors, succinylcholine exhibits ACh-like activity; that is, depolarization is produced.²⁰ However, when the receptor is in contact with any agonist, including ACh, for a prolonged time, it ceases to respond to the agonist. Normally, the rapid breakdown of ACh (<1 msec) does not allow this desensitization process to take place. However, succinylcholine remains at the endplate for much longer, and desensitization can develop. Another possible mechanism is the inactivation of sodium channels in the junctional and perijunctional area, which occurs when the membrane remains depolarized. This inactivation prevents the propagation of the action potential. These two possible mechanisms are probably not mutually exclusive.

Succinylcholine-induced fasciculations are probably due to depolarization of the nerve terminal produced by activation of presynaptic receptors. This is observed clinically as disorganized muscular activity following the injection of succinylcholine. The effectiveness of small doses of nondepolarizing drugs in reducing the incidence of fasciculations suggests that the presynaptic receptors are relatively sensitive to these drugs.²¹

Succinylcholine has yet another neuromuscular effect. In some muscles, like the masseter and to a lesser extent the adductor pollicis, a sustained increase in tension that may last for several minutes can be observed.^{22,23} The mechanism of action of this tension change is uncertain but is most likely mediated by ACh receptors because it is blocked by large amounts of nondepolarizing drugs.²⁴ The increase in masseteric tone, which is probably always present to some degree, may lead to

imperfect intubating conditions and is the probable reason for the poor conditions seen in 5% of pediatric patients as described by Hanallah and Kaplan.²⁵ More subtle measurements of the force on the laryngoscope blade necessary to achieve the best view of the vocal cords suggest that experienced anesthetists use more force after succinylcholine than after vecuronium.²⁶ Masseter spasm, which has been associated with malignant hyperthermia (MH), may be an exaggerated form of this response.

Characteristics of Depolarizing Blockade

After injection of succinylcholine, single-twitch height is decreased. However, the response to high-frequency stimulation is sustained: train-of-four fade and tetanic fade are not observed. The block is antagonized by nondepolarizing agents so that the intubating dose of succinylcholine must be increased from 1.0 to 1.5 or 2 mg · kg⁻¹ after precurarization with a nondepolarizing NMB. Isobolographic analysis has shown that mixture of succinylcholine with either mivacurium or atracurium is antagonistic.²⁷ Succinylcholine is potentiated by inhibitors of acetylcholinesterase, such as neostigmine and edrophonium.²⁸

Phase II Block

After prolonged exposure to succinylcholine, the characteristics of the block change, and features of nondepolarizing blockade appear. Train-of-four and tetanic fade become apparent after the administration of 7–10 mg · kg⁻¹, which corresponds to 30–60 min of paralysis. Neostigmine or edrophonium can antagonize this block, which has been termed “nondepolarizing,” “dual,” or “Phase II block.” The last term is preferable because it does not imply any specific mechanism of action. The onset of Phase II block coincides with tachyphylaxis, as more succinylcholine is required for the same effect.²⁹

Pharmacology of Succinylcholine

Succinylcholine is rapidly hydrolyzed by plasma cholinesterase to choline and succinylmonocholine,³⁰ with an elimination half-life of <1 min in patients. Because of the rapid disappearance of succinylcholine from plasma, the maximum effect is reached quickly. Subparalyzing doses (up to 0.3–0.5 mg · kg⁻¹) reach their maximal effect within ~1.5–2 min at the adductor pollicis,³¹ and within 1 min at more central muscles, such as the masseter and the larynx (Fig. 16-5).³² With larger doses (1–2 mg · kg⁻¹), abolition of twitch response can be reached even more rapidly.

Figure 16-5. Onset and intensity of succinylcholine neuromuscular block at the adductor pollicis and laryngeal adductor muscles. (Reproduced with permission from Meistelman C, Plaud B, Donati, F: Neuromuscular effects of succinylcholine on the vocal cords and adductor pollicis muscles. *Anesth Analg* 73:278, 1991.)

The mean dose producing 50% blockade (ED₅₀) at the adductor pollicis is 0.15–0.2 mg · kg⁻¹ with opioid–nitrous oxide anesthesia,³³ and the ED₉₅ is in the range of 0.30–0.35 mg · kg⁻¹. In the absence of nitrous oxide, the ED₅₀ and ED₉₅ are increased to 0.3 and 0.5 mg · kg⁻¹, respectively.³¹ These values are doubled if *d*-tubocurarine, 0.05 mg · kg⁻¹, is given as a defasciculating agent.³¹ The time until full recovery of MMG is 10–12 min after a dose of 1 mg · kg⁻¹ (Fig. 16-6).³⁴

Figure 16-6. Approximate onset and recovery profiles for an ultra-short-acting drug, succinylcholine 1.0 mg · kg⁻¹; a short-acting drug, mivacurium 0.2 mg · kg⁻¹; an intermediate-acting drug, vecuronium, 0.1 mg · kg⁻¹; and a long-acting drug, pancuronium, 0.15 mg · kg⁻¹. Doses given are 2–2.5 × ED₉₅ for all four drugs.

Side Effects

Cardiovascular. Because of its structural similarity to ACh, succinylcholine is expected to have some parasympathetic activity. Sinus bradycardia with nodal or ventricular escape beats (or both) may occur, especially in children, and asystole has been described after a second dose of succinylcholine in adults. However, parasympathetic effects are infrequent and can be attenuated with atropine or glycopyrrolate.³⁵ Succinylcholine increases catecholamine release, and this effect may explain, in part, the low incidence of bradycardia. The exact nature of the interaction of succinylcholine with muscarinic receptors is, however, poorly understood, and the mechanism for the enhanced bradycardic effect of a second dose is not known.

Anaphylaxis. Succinylcholine has been incriminated as the trigger of allergic reactions more often than any other intravenous (iv) drug used in anesthesia. However, the prevalence is uncertain and the number of reported cases is low, given the widespread use of the drug. Anaphylactic reactions to succinylcholine and rocuronium have been described in two members of the same family with intradermal testing, as has sensitivity to pancuronium, atracurium, and mivacurium.³⁶ However, the sensitivity and specificity of skin testing are not known.

Fasciculations. The prevalence of fasciculations is high after the rapid injection of succinylcholine, especially in muscular adults. Although this is a benign side effect of the drug, most clinicians prefer to prevent fasciculations. In this respect, a small dose of a nondepolarizing neuromuscular blocking drug given 3–5 min before succinylcholine is effective. *d*-Tubocurarine 0.05 mg · kg⁻¹, gallamine 0.2 mg · kg⁻¹, atracurium 0.03 mg · kg⁻¹, or rocuronium 0.06 mg · kg⁻¹ may be given for this purpose, of which *d*-tubocurarine and rocuronium are the most effective^{37,38} if an interval of 3–5 min is allowed before administration of succinylcholine.³⁹ Pancuronium, 0.01 mg · kg⁻¹, and vecuronium, 0.007 mg · kg⁻¹, are probably less effective as defasciculants. After these nondepolarizing drugs, the dose of succinylcholine must be increased from 1 mg · kg⁻¹ to 1.5–2 mg · kg⁻¹ because of the antagonism between depolarizing and nondepolarizing drugs.³¹ Care must be taken not to exceed these doses of nondepolarizing agents to avoid partial neuromuscular blockade in awake patients. The most common symptoms are blurred vision, heavy eyelids, and, occasionally, difficulty in swallowing or breathing. Other drugs, such as diazepam, lidocaine, fentanyl, calcium, vitamin C, magnesium, and dantrolene have all been used to prevent fasciculations. The results are no better than with nondepolarizing relaxants, and they may have undesirable effects of their own. “Self-taming,” the administration of small (10-mg) doses of succinylcholine 1 min before the intubating dose, is an effective tactic but has largely been abandoned owing to the considerable blockade that may be produced by the “taming” dose.¹

Muscle Pains. Generalized aches and pains, similar to the myalgias that follow violent exercise, are common 24–48 hr after succinylcholine administration. The

relationship between muscle pains and fasciculations is not firmly established. Although many studies have failed to confirm that precurarization with a nondepolarizing neuromuscular blocking drug is of any value in the prevention of myalgias, the available evidence suggests that there is a protective effect.⁴⁰

Intragastric Pressure. Succinylcholine increases intragastric pressure, and this effect is blocked by precurarization. However, succinylcholine causes even greater increases in lower esophageal sphincter pressure.⁴¹ Thus, succinylcholine does not appear to increase the risk of aspiration of gastric contents unless the esophageal sphincter is incompetent.

Intraocular Pressure. Intraocular pressure increases by 5–15 mm Hg after injection of succinylcholine. The mechanism is unknown but occurs after detachment of extraocular muscle, suggesting an intraocular etiology.⁴² Precurarization with a nondepolarizing blocker has little or no effect on this increase, so that large doses of nondepolarizing neuromuscular blocking drugs are recommended in the presence of open eye injuries. However, it must be appreciated that other factors, such as inadequate anesthesia, elevated systemic blood pressure, and insufficient neuromuscular blockade during laryngoscopy and tracheal intubation, might increase intraocular pressure more than succinylcholine.⁴³

Intracranial Pressure. Succinylcholine may increase intracranial pressure (ICP), and this response is probably diminished by precurarization.⁴⁴ Most of this change may be due to an increase in PCO₂ produced by fasciculations.⁴⁵ Again, laryngoscopy and tracheal intubation with inadequate anesthesia or muscle relaxation are likely to increase ICP even more than succinylcholine. Any direct effect of succinylcholine on ICP is small; no changes in ICP, cerebral blood flow velocity, or EEG were observed when succinylcholine was given to patients with neurologic injury receiving mechanical ventilation.⁴⁶

Hyperkalemia. Serum potassium increases by 0.5–1.0 mEq · l⁻¹ after injection of succinylcholine. This increase is not prevented completely by precurarization. In fact, only large doses of nondepolarizing blockers abolish this effect.⁴⁷ Subjects with pre-existing hyperkalemia, such as patients in renal failure, do not have a greater increase in potassium levels, but the absolute level might reach the toxic range. However, severe hyperkalemia, occasionally leading to cardiac arrest, has been described in patients after major denervation injuries, spinal cord transection, peripheral denervation, stroke, trauma, extensive burns, and prolonged immobility with disease,^{1,48} and may be related to potassium loss via a proliferation of extrajunctional receptors. Severe hyperkalemia after succinylcholine resulting in cardiac arrest has also been observed in acidotic hypovolemic patients.⁴⁹ It is likely that acidosis encourages the intracellular to extracellular shift of potassium that is exacerbated by succinylcholine. The source of potassium in this situation is likely to be liver and not the muscles.⁵⁰

Abnormal Plasma Cholinesterase. Plasma cholinesterase activity can be reduced by a number of endogenous and exogenous causes, such as pregnancy, liver disease, uremia, malnutrition, burns, plasmapheresis, and oral contraceptives. These conditions usually lead to a slight, clinically unimportant increase in the duration of action of succinylcholine.⁵¹ Plasma cholinesterase activity is reduced by some anticholinesterases (e.g., neostigmine) so that the duration of succinylcholine given after neostigmine, but not after edrophonium, is increased from 10 to 24 min.⁵² In the absence of plasma cholinesterase, the onset of action of succinylcholine is prolonged.⁵³

A small proportion of patients (1:1500 to 1:2000 in the general population) have a genetically determined inability to metabolize succinylcholine. Either plasma cholinesterase is absent or an abnormal form of the enzyme is present. Only patients homozygous for the condition have prolonged paralysis (3–6 hr) after usual doses of succinylcholine (1–1.5 mg · kg⁻¹). In heterozygous patients, the duration of action is only slightly prolonged. Traditional methods for identifying plasma cholinesterase phenotype by measurement of enzyme activity with a variety of substrates, such as benzoyl choline and ACh, and their inhibition with dibucaine, fluoride, and so forth are only capable of identifying some enzyme variants. The complete amino acid sequence of plasma cholinesterase has now been determined using molecular genetics techniques.⁵⁴ The cholinesterase gene is located on chromosome 3 at q26,⁵⁵ and 20 mutations in the coding region of the plasma cholinergic gene have been identified. It now seems likely that the failure to identify abnormal phenotypes using conventional techniques (prolonged reaction to succinylcholine but homozygous for normal plasma cholinesterase) will be corrected as more mutations are discovered.⁵⁶ Although whole blood or fresh frozen plasma can be given to accelerate succinylcholine metabolism in patients with low or absent plasma cholinesterase, the best course of action is probably mechanical ventilation of the lungs until full recovery of neuromuscular function can be demonstrated. Neostigmine and edrophonium are unpredictable in the reversal of abnormally prolonged succinylcholine blockade⁵⁷ and are best avoided.

Clinical Uses

The main indication for succinylcholine is to facilitate tracheal intubation. The dose required is ~1.0 mg · kg⁻¹, and must be increased to 1.5–2.0 mg · kg⁻¹ if a precurarizing dose of nondepolarizing blocker has been used. Intubating conditions are optimal within 1–1.5 min.

Succinylcholine has also been used for maintenance of relaxation for up to 3 h. However, because of the availability of short and intermediate nondepolarizing drugs for this purpose, succinylcholine infusions are seldom used to maintain relaxation. Infusion rates for 90–95% blockade are ~50–100 mg · kg⁻¹ · min⁻¹ and need to be adjusted upward after 30–60 min, because of tachyphylaxis.²⁹

Children are slightly more resistant to succinylcholine than adults²³ and doses of 1–2 mg · kg⁻¹ are required to facilitate intubation. In infants, 2–3 mg · kg⁻¹ may be required. Precurarization is not necessary in patients younger than 10 years because fasciculations are uncommon in this age group. Bradycardia is common in children unless atropine or glycopyrrolate is given.³⁵ Succinylcholine may also be given intramuscularly in a dose of 4 mg · kg⁻¹ in children with difficult intravenous access, and provides adequate conditions for tracheal intubation in about 4 min.⁵⁸

Nondepolarizing Drugs

Effects at the Neuromuscular Junction

Nondepolarizing neuromuscular blocking drugs bind to the postsynaptic receptor in a competitive fashion. An excess of ACh can tilt the balance in favor of neuromuscular transmission. To exert their effect, the nondepolarizing neuromuscular blocking drugs must bind to only one of the α subunits of the receptor, because two ACh molecules must be present on the same receptor to activate it.²

Neuromuscular blockade in a given muscle is not apparent until a large proportion of receptors are occupied.¹² To reach 100% blockade, a greater fraction of receptors must be occupied. For example, in the cat tibialis anterior, it has been estimated that blockade takes place in the range of 75–92% receptor occupancy. This means that neurotransmission fails in some fibers when receptors are 75% occupied, but the most resistant fibers in the same muscle require as much as 92% occupancy to block. In other words, partial neuromuscular blockade (between 0% and 100%) is not due to reduced contraction in all fibers, but to total blockade at some endplates.

The margin of safety is reduced when high-frequency stimulation is used owing to a decrease in ACh release. Thus, fade following either train-of-four or tetanic stimulation will be detected at lower levels of receptor occupancy than that with depression of single-twitch response. For example, in the cat tibialis anterior, train-of-four fade occurs at 70% receptor occupancy.⁵⁹ The actual number, however, depends on species and varies from muscle to muscle within the same individual. So, although the principle of decreased margin of safety for high-frequency stimulation should be retained, it is futile to correlate receptor occupancy data obtained in cats with certain clinical tests in humans, such as hand grip and head lift, which involve different muscle groups.

Characteristics of Nondepolarizing Blockade

The fade observed in response to high-frequency stimulation (>0.1–0.15 Hz) is characteristic of nondepolarizing blockade. When EMG recordings are made in humans, fade reaches a maximum at 2 Hz and stays constant for frequencies up to 50 Hz.⁶⁰ With mechanical recordings, fusion of several individual responses occurs when the stimulation frequency exceeds the duration of the twitch. Thus, the initial peak is made up of the first few responses, the first being the strongest, and fade follows.

Tetanic stimulation is followed by post-tetanic facilitation, which is due to an increase in ACh release when the stimulation occurs soon after the tetanus. Thus, the response to nerve stimulation is increased. The intensity and duration of this effect depend on the frequency and duration of the tetanic stimulation. With a 50-Hz tetanus of 5-sec duration, twitch responses have been found to fall within 10% of their pretetanic values in 1–2 min, and in most cases in 1 min (Fig. 16-7).⁶¹

Figure 16-7. Characteristics of nondepolarizing blockade. Train-of-four responses are equal before the administration of vecuronium (arrow). For a given first-twitch depression, fade is less during onset (*top*) than during recovery (*bottom*). Fade also occurs with a 5-sec, 50-Hz tetanus (*bar*). Facilitation is apparent after the tetanus; *i.e.*, first-twitch height and train-of-four ratio are increased, but only for the first two trains.

Finally, nondepolarizing blockade can be antagonized with anticholinesterase agents such as edrophonium, neostigmine, or pyridostigmine. It is also antagonized by depolarizing agents, such as succinylcholine, provided that the nondepolarizing blockade is intense and that the succinylcholine dose is too small to produce a block of its own.

Pharmacokinetics

Plasma concentrations have been measured for all the nondepolarizing agents used clinically. The pharmacokinetic variables derived from these experiments depend on the dose given, the sampling schedule used, the accuracy of the assay, and the model chosen. As is the case for other drugs used in anesthesia, the elimination half-life of neuromuscular blocking agents does not always correlate with duration of action because termination of action sometimes depends on redistribution instead of elimination. However, knowledge of the kinetics of the drug helps us understand the behavior of the drug in special situations (prolonged administration, disease of the organs of elimination, and so on).

Several mechanisms can explain the various categories of durations of action listed in [Table 16-1](#):

1. Long-acting drugs all have a long (1–2 hr) elimination half-life and depend on liver and/or kidney function for termination of action.
2. Intermediate-duration drugs either have an intermediate elimination half-life (atracurium and cisatracurium); or they have long elimination half-lives (1–2 hr) but depend on redistribution rather than elimination for termination of effect (vecuronium and rocuronium) ([Fig. 16-8](#)).

Figure 16-8. Plasma concentrations versus time for four representative muscle relaxants. Concentrations are expressed as a function of each drug's concentration corresponding to 25% and 75% block. Succinylcholine is broken down rapidly in the plasma: it is a short-acting drug. Pancuronium is a long-acting drug because of its long elimination time. Atracurium is an intermediate-duration drug and has an intermediate half-life. Vecuronium has an elimination half-life comparable to that of pancuronium. However, redistribution of the drug is important and the duration of action is comparable to that of atracurium.

3. Short-duration drugs have either short elimination half-lives (the active isomers of mivacurium)⁶² or long elimination half-life but extensive redistribution (rapacuronium).⁶³
4. Ultra-short-duration drugs have a very short elimination half-life (succinylcholine).

Nevertheless, pharmacokinetic analysis illustrates some of the common properties of these drugs ([Table 16-2](#)). Each has a volume of distribution that is approximately equal to extracellular fluid (ECF) volume ($0.2\text{--}0.4 \text{ l} \cdot \text{kg}^{-1}$). In infants, in whom the ECF volume, as a proportion of body weight, is increased, the volume of distribution of *d*-tubocurarine parallels ECF volume closely.⁶⁴

| Relaxant | V_d (L · kg ⁻¹) | C_p (ml · kg ⁻¹ · min ⁻¹) | $T_{1/2}$ (min) |
|------------------------|-------------------------------|--|-----------------|
| <i>d</i> -Tubocurarine | | | |
| adults 20–60 yr | 0.3–0.6 | 1–3 | 90–200 |
| elderly 70–87 yr | 0.3 | 0.8 | 270 |
| neonates | 0.5 | 1.1 | 310 |
| infants 5–12 mo | 0.5 | 1.0 | 305 |
| children 1–12 yr | 0.3 | 1.5 | 170 |
| Atracurium | 0.2 | 5.5 | 30 |
| Decacurium | 0.2 | 2.5 | 95 |
| Mivacurium | 0.4 | 1.3 | 220 |
| Mivacurium | | | |
| <i>cis</i> -isomer | 0.3 | 105 | 1.8 |
| <i>trans</i> -isomer | 0.2 | 60 | 1.9 |
| <i>cis-cis</i> | 0.3 | 4.5 | 33 |
| Pancuronium | 0.3 | 1–2 | 100–230 |
| Rapacuronium | 0.2 | 75 | 88 |
| Rocuronium | 0.3 | 4.0 | 170 |
| Vecuronium | 0.1 | 4.5 | 110 |

Table 16-2. TYPICAL PHARMACOKINETIC DATA FOR NONDEPOLARIZING BLOCKERS IN ADULTS, EXCEPT WHERE STATED

Onset and Duration of Action

The duration of action of nondepolarizing drugs is determined by the time required for plasma concentrations to decrease below a critical level. However, onset is not determined by plasma concentrations. Peak plasma concentrations are obtained less than 1 min after injection of the drug, but maximum blockade is reached after only 2–7 min if subparalyzing doses are given. This discrepancy between concentration and block has been modeled mathematically by introducing the concept of a compartment, in which the drug concentration is directly related to its effect. The access to this “effect compartment” is controlled by a rate constant (k_{e0}).⁶⁵ This rate constant corresponds to half-times of 5–10 min for most nondepolarizing drugs.⁶⁶

The delay between peak plasma concentrations and blockade, represented by k_{e0} , is determined by all the factors that modify access of the drug to, and its removal from, the neuromuscular junction. These include cardiac output, distance of the muscle from the heart, and muscle blood flow.⁶⁶ Thus, onset times are not the same in all muscles because of different blood flows. If metabolism or redistribution is very rapid, the onset time is accelerated. This probably plays a role only for succinylcholine and mivacurium. Finally, there is growing evidence that potent drugs have a slower onset of action than less potent agents ([Fig. 16-9](#)).^{67,68} and ⁶⁹ This is because spare receptors must be occupied before blockade can be observed. Blockade of these spare receptors will occur faster, and onset will be more rapid, if more drug molecules are available, *i.e.*, if potency is low.⁶⁶

Figure 16-9. Onset times of single-twitch depression of adductor pollicis after pancuronium ($0.07 \text{ mg} \cdot \text{kg}^{-1}$), *d*-tubocurarine ($0.45 \text{ mg} \cdot \text{kg}^{-1}$), and gallamine ($2.4 \text{ mg} \cdot \text{kg}^{-1}$). Although the maximum effect was identical in all three groups, the onset of blockade was fastest after gallamine. The mean time to 50% depression was 141 sec for pancuronium, 99 sec for *d*-tubocurarine, and 66 sec for gallamine. (Reprinted with permission from Kopman AF: Pancuronium, gallamine, and *d*-tubocurarine compared: Is speed of onset inversely related to drug potency? *Anesthesiology* 70:915, 1989.)

Time to maximal blockade is independent of dose if maximum block attained is less than 100%. For most drugs, this value is 5–7 min.⁶⁶ For doxacurium, the most potent drug tested in humans, 10–15 min is required.⁷⁰ For rapacuronium, the least potent drug available, this delay is 2–3 min. Once 100% block has been achieved, the time to disappearance of the twitch decreases with increasing dose. Onset and recovery times for nondepolarizing relaxants are shown in [Table 16-3](#).

| Relaxant | ED ₉₅ (μg · kg ⁻¹) | Onset (min) | RI (min) | T ₉₀ (min) |
|------------------------|---|-------------|----------|-----------------------|
| <i>d</i> -Tubocurarine | 50 | 6 | 25–35 | 70–90 |
| Atracurium | 200 | 5–6 | 10–15 | 20–25 |
| Cisatracurium | 50 | 5–6 | 10–15 | 20–25 |
| Desacurium | 25 | 10–14 | 30–50 | 80–100 |
| Mivacurium | 200 | 5 | 30–40 | 80–90 |
| Miscarurium | 80–150 | 2–3 | 10–15 | 20 |
| Pancuronium | 60 | 4–5 | 25 | 60 |

Table 16-3. TYPICAL NEUROMUSCULAR ACTIVITY OF NONDEPOLARIZING BLOCKING DRUGS: POTENCY (ED₉₅), ONSET TO MAXIMUM EFFECT, 25–75% RECOVERY INDEX (RI), AND TIME TO 90% T₁ RECOVERY (T₉₀) AFTER AN ED₉₅ DOSE IN ADULTS

Individual Nondepolarizing Relaxants

Since 1942, nearly 50 nondepolarizing relaxants have been introduced into clinical anesthesia. This section covers only those drugs currently available in North America and Europe. The first relaxant to undergo clinical investigation was Intocostin, the purified and standardized product of curare obtained from the plant *Chondodendrum tomentosum*. The pharmacologic action of *d*-tubocurarine is discussed first as the prototypical muscle relaxant.

***d*-Tubocurarine.** *d*-Tubocurarine is a monoquaternary ammonium compound. However, at body pH, the second nitrogen atom becomes protonated so that it possesses two positively charged centers. The molecule undergoes minimal metabolism so that 24 hr after its administration about 10% of the compound is found in the urine and 45% in the bile. It is 30–50% protein-bound, but altered plasma protein concentration does not appear to modify the pharmacokinetic or pharmacodynamic behavior.⁷¹

The development of a sensitive radioimmunoassay allowed the relationship between plasma concentration of *d*-tubocurarine and recovery from neuromuscular block to be demonstrated ([Fig. 16-10](#)).⁷² As for most nondepolarizing relaxants, excretion is impaired in renal failure with an increase in elimination half-life (T_{1/2}b).⁷³

Figure 16-10. Relationship between twitch height and plasma *d*-tubocurarine concentration. (Reprinted with permission from Matteo RS, Spector S, Horowitz PE: Relation of serum *d*-tubocurarine concentration to neuromuscular blockade. *Anesthesiology* 41:441, 1974.)

CARDIOVASCULAR EFFECTS. Hypotension frequently accompanies the administration of *d*-tubocurarine. In cats, autonomic ganglionic blockade occurs at doses similar to those that produce neuromuscular blockade.⁷⁴ In addition, *d*-tubocurarine causes vagal and sympathetic blockade, although, clinically, bradycardia is more common than tachycardia.

In humans, *d*-tubocurarine causes dose-related histamine release,⁷⁵ and skin flushing is frequently observed. The hypotension can be reduced by pretreatment with the antihistamine promethazine or by administering *d*-tubocurarine slowly over 3 min. Thus, in humans, histamine release is probably more important than ganglionic blockade in the production of hypotension. Alternatively, a bolus injection of *d*-tubocurarine may induce the release of prostacyclin, which acts *via* H₁ receptors to produce hypotension.⁷⁶

AGE. The potency of *d*-tubocurarine on a $\text{mg} \cdot \text{kg}^{-1}$ basis is similar at all ages. However, the increased sensitivity of the neuromuscular junction in infants is concealed by the increased volume of distribution (see [Table 16-2](#)).^{64,77} The onset of action is more rapid in the young as a result of a more rapid circulation time. However, the decreased glomerular filtration rate (GFR) in the very young and the very old results in an increase in T_{1/2}b and prolonged duration of action.⁷⁸

BURNS. Patients with massive burns demonstrate resistance to *d*-tubocurarine and other nondepolarizing drugs that is dependent upon the size of the burn and the time since injury.⁷⁹ The pharmacokinetic behavior of atracurium is unaffected in burn patients. Resistance is associated with higher concentrations of the free drug to produce a given degree of twitch depression compared with nonthermally injured patients. As in denervation injury, there is an increase in the number of acetylcholine receptors in the diaphragm of the rat after burn injury to 45% of the body surface area.⁸⁰ Circulatory mediators such as catecholamines and prostaglandins may play a

role in producing these effects, which are at a distance from the burn areas.⁸¹

CLINICAL USE. The slow onset and long duration of *d*-tubocurarine have restricted its use, in doses of 15–30 mg · 70 kg⁻¹, to the maintenance of relaxation during surgery. However, the dose-related cardiovascular effects were a stimulus for the production of alternative agents. Initially, this led to the introduction of pancuronium, which replaced the hypotension of *d*-tubocurarine with hypertension and tachycardia. More recently, drugs of intermediate duration (atracurium, vecuronium, and rocuronium) have almost eliminated the use of *d*-tubocurarine because they have minimal cardiovascular activity. Its use is mainly confined to small doses of *d*-tubocurarine (3 mg · 70 kg⁻¹) before succinylcholine (“precurarization”) to reduce the incidence of fasciculations and muscle pains.

Atracurium. Atracurium is a bisquaternary ammonium benzylisoquinoline compound that was developed in an attempt to produce a short-acting muscle relaxant that was independent of the liver and the kidney for termination of its action.⁸² Its ED₉₅ is 0.2–0.25 mg · kg⁻¹. In humans, atracurium is metabolized both by the Hofmann reaction (nonenzymatic degradation at body temperature and pH) and ester hydrolysis to several compounds (Fig. 16-11). It has been estimated that two thirds of atracurium is degraded by ester hydrolysis and one third by Hofmann reaction.⁸³

Figure 16-11. Atracurium and its major metabolites.

The metabolites of atracurium may be toxic. The quaternary monoacrylate, quaternary alcohol, and monoquaternary analogs produce neuromuscular blockade in high doses. Also, the quaternary monoacrylate, laudanidine, the quaternary alcohol, metholaudanosine, and the monoquaternary analog decrease blood pressure but at concentrations higher than those found in clinical practice.⁸⁴

Laudanosine has been suspected of causing cerebral excitation. It has been shown to increase the MAC of halothane in rabbits.⁸⁵ At doses of 2–8 mg · kg⁻¹ it produced waking from halothane anesthesia, and at 14–22 mg · kg⁻¹ seizure activity was observed in dogs.⁸⁶ However, such doses are not used in humans. The clinical effects of laudanidine have been sought extensively but unsuccessfully. There is also interest in the potential toxic effects of the highly reactive acrylates.⁸⁷

PHARMACOKINETICS. The plasma concentration of atracurium decreases rapidly following iv administration (see Fig. 16-8). The conventional pharmacokinetic model that is used for other nondepolarizing relaxants may not be suitable for atracurium because it undergoes nonenzymatic degradation in the tissues as well as in plasma.

The *onset of action* of equipotent doses is similar for atracurium, pancuronium, *d*-tubocurarine, and vecuronium. It is slower than succinylcholine but can be reduced if the dose is increased.⁸⁹ However, such acceleration is limited by hypotension and histamine release after large doses. The duration of action is also dose-related. The time to 25% recovery of T₁ after 0.4 mg · kg⁻¹ is rapid: »30 min (see Table 16-3).

CARDIOVASCULAR EFFECTS. Atracurium is associated with few cardiovascular effects unless large doses (2 × ED₉₅) are administered. The most common cardiovascular abnormality following smaller doses is the bradycardia that is most likely due to concomitant administration of opioids⁹⁰ or to vagal traction. Hypotension and tachycardia may accompany doses exceeding 0.4 mg · kg⁻¹ (Fig. 16-12); these effects occur as a result of dose-related histamine release.⁹¹ Similar changes occur after the use of *d*-tubocurarine or metocurine but at much lower doses (Table 16-4). The most obvious clinical manifestation of histamine release is skin flushing, but this is seldom associated with hypotension or bronchospasm. These responses can be avoided by slow injection over 1–3 min or by pretreatment with H₁ and H₂ receptor blockade.⁹² Profound bronchospasm has been described following administration of even small doses of atracurium to patients with a history of bronchial asthma.⁹³ Anaphylactoid reactions to atracurium have been described, but no more frequently than after other neuromuscular blocking drugs.⁹⁴

Table 16-4. DOSES OF DRUGS ASSOCIATED WITH CARDIOVASCULAR CHANGES

AGE. The potency of atracurium is similar in adults and children. When atracurium is given by infusion to the elderly, the reduction in dose requirement and the slower recovery time observed with vecuronium are not seen,⁹⁵ presumably reflecting the organ independence of atracurium's elimination.

OBESITY. The dose of atracurium, as for all NMDs, should be reduced on a mg · kg⁻¹ basis to reflect lean body mass,⁹⁶ although reversal from similar degrees of block

is similar to that in nonobese subjects⁹⁷

CLINICAL USES. The short duration of action, rapid recovery, and absence of severe cardiovascular and cumulative drug effects have encouraged the use of atracurium as a continuous infusion ($5\text{--}10\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) or as intermittent injections in several situations including ambulatory surgery, cardiopulmonary bypass surgery, pheochromocytoma resection, and renal and hepatic disease. Large doses ($0.5\text{--}0.6\ \text{mg} \cdot \text{kg}^{-1}$) must be given if atracurium is used to produce rapid paralysis to facilitate tracheal intubation when conditions will also be influenced by the depth of anesthesia, airway reactivity, and strength of the patient.

Cisatracurium. Cisatracurium is a potent ($\text{ED}_{95}\ 0.05\ \text{mg} \cdot \text{kg}^{-1}$), long-onset, intermediate-duration benzylisoquinolinium neuromuscular blocking drug.⁹⁸ It is one of the ten isomers of atracurium that is devoid of cardiovascular effects. It is more potent than atracurium, and thus has a slower onset of maximum block. Otherwise this drug resembles atracurium in duration of action and rate of recovery. After $0.1\ \text{mg} \cdot \text{kg}^{-1}$, the mean onset is 3.1 min (versus 2.3 min after $0.5\ \text{mg} \cdot \text{kg}^{-1}$ for atracurium)⁹⁹ with spontaneous recovery to TOF 0.8 of 74 min, which is reduced to 48 and 50 min after reversal with neostigmine at 10% and 25% spontaneous recovery, respectively.¹⁰⁰ The potency is increased and the duration prolonged in the presence of volatile anesthetics.¹⁰¹ In children it is slightly more potent ($\text{ED}_{95}\ 0.04\ \text{mg} \cdot \text{kg}^{-1}$), has a slightly quicker onset (2.5 min), and shorter recovery (TOF > 0.7 at 53 min).¹⁰² Clearance, by Hofmann elimination, is greater than that of atracurium (77% versus 39%)¹⁰³ (see Table 16-2). Mixtures of cisatracurium and rocuronium are highly synergistic.¹⁰⁴ Unlike atracurium, cisatracurium does not undergo significant hydrolysis by nonspecific plasma esterases. The metabolites of cisatracurium include laudanosine and a monoquaternary acrylate. The peak plasma concentration of laudanosine following the administration of $2 \times \text{ED}_{95}$ of cisatracurium is about 5-fold less than was present following a similar dose of atracurium. Presumably, the greater potency of cisatracurium compared with atracurium results in fewer molecules being administered, and hence in lower plasma concentrations of metabolites.

In contrast to atracurium, cisatracurium is devoid of histamine-releasing properties even at high doses ($8 \times \text{ED}_{95}$), although anaphylactic reactions have been described.¹⁰⁵ Also, it lacks cardiovascular effects.¹⁰⁶ Neuromuscular blockade is easily maintained at a stable level by continuous intravenous infusion of cisatracurium at a constant rate and does not change with time, suggesting the lack of a significant cumulative drug effect and lack of dependence on renal and/or hepatic clearance mechanisms. The rate of recovery is independent of the dose of cisatracurium and the duration of the administration. Recovery from drug-induced neuromuscular blockade can be facilitated by administration of an anticholinesterase drug.

Doxacurium. Doxacurium is a long-acting bisquaternary ammonium compound that is devoid of histamine-releasing or cardiovascular side effects. The pharmacokinetic behavior of doxacurium resembles that of pancuronium with respect to $T_{1/2b}$ and dependence on renal clearance for elimination from the circulation (see Table 16-2).¹⁰⁷ In the elderly, elimination half-life is prolonged and plasma clearance reduced without any change in volume of distribution.¹⁰⁸ Doxacurium is also a weak substrate for plasma cholinesterase. The ED_{95} for doxacurium is $25\ \mu\text{g} \cdot \text{kg}^{-1}$ (see Table 16-3).¹⁰⁹ Volatile anesthetics decrease doxacurium dose requirements by 20–40% compared with doses needed during N_2O –fentanyl anesthesia.¹¹⁰ Doxacurium has a limited place in clinical practice because of its very slow onset and long duration of action. Nevertheless, it may be useful in patients with ischemic heart disease who are undergoing prolonged anesthesia or long-term mechanical ventilation of the lungs. The slow onset time, prolonged duration of action, and slow recovery make doxacurium unsuitable for facilitating tracheal intubation or for providing skeletal muscle relaxation during brief surgical procedures. When infused for more than 4 days to patients in the ICU, recovery after stopping the infusion exceeded 10 h.¹¹¹

Metocurine. Metocurine, produced by methylation of two hydroxy groups of *d*-tubocurarine, is twice as potent as the parent compound and produces less histamine release. Like *d*-tubocurarine, it undergoes minimal metabolism. Within 48 hr of administration, approximately half appears in the urine and another 2% appears in the bile.¹¹² Because metocurine is more dependent on renal function for excretion than is *d*-tubocurarine, clearance is disturbed to a greater degree in renal failure and in the elderly.

CARDIOVASCULAR EFFECTS. In animals the separation between autonomic and neuromuscular effects of metocurine is greater than for *d*-tubocurarine⁷⁴ and metocurine causes less histamine release than does *d*-tubocurarine.¹¹³ Consequently, changes in blood pressure and heart rate are not seen until doses greater than the ED_{95} are administered.

BURNS. Patients with burn injuries are resistant to all nondepolarizing relaxants, and the resistance to metocurine may be extensive. For example, an 8-year-old boy with a 35% surface burn required 12 times the normal dose of metocurine and 8 times the plasma concentration during the acute phase of the burn to produce complete neuromuscular block.¹¹⁴

CLINICAL USE. Because of its lack of cardiovascular effects, metocurine enjoyed a brief period of popularity before the introduction of atracurium and vecuronium. The combination of metocurine and pancuronium augmented neuromuscular block with opposing cardiovascular effects and was recommended for use in patients with severe cardiovascular disease.¹¹⁵ However, the introduction of intermediate- and long-acting relaxants without cardiovascular effects has made metocurine obsolete.

Mivacurium. Mivacurium is an intermediate-onset, short-duration, nondepolarizing neuromuscular blocking drug that is hydrolyzed by plasma cholinesterase.¹¹⁶ The drug is presented as a mixture of three isomers. Two, the *cis*–*trans* and *trans*–*trans*, have short half-lives, but the *cis*–*cis* isomer has a much longer half-life (2 versus 53 min, respectively). The *cis*–*cis* isomer accounts for 10% of the mixture, has less than one tenth the potency of the other isomers, and thus contributes little if anything to neuromuscular block during anesthesia.⁶² Under steady-state conditions, the ED_{95} of mivacurium is $0.08\ \text{mg} \cdot \text{kg}^{-1}$, the time to onset of action is 3.3 min, and spontaneous recovery to 95% twitch height occurs in about 25 min (see Table 16-3). At $2 \times \text{ED}_{95}$ the onset time is 2.5 min and recovery to 95% twitch height occurs in about 31 min. In infants and children the ED_{95} is greater than in adults, $120\text{--}150\ \mu\text{g} \cdot \text{kg}^{-1}$, and the onset of block is more rapid.^{117,118} The recovery time after discontinuing an infusion of mivacurium is about half that for atracurium or vecuronium infusions and is similar to that for succinylcholine.^{119,120} The effect of anticholinesterase drugs is additive to the rapid rate of spontaneous recovery from mivacurium-induced neuromuscular blockade. Therefore, mivacurium is more rapidly reversed than are the longer-acting nondepolarizing neuromuscular blocking drugs.¹²¹ However, reversal of intense neuromuscular block with neostigmine has been shown to delay recovery,¹²² presumably as a result of plasma cholinesterase inhibition by neostigmine.¹²³ Spontaneous recovery is so rapid that it has been suggested that reversal is unnecessary and that its avoidance may reduce the incidence of postoperative nausea and vomiting.¹²⁴ However, this may result in residual block on arrival in the PACU, particularly if large doses of mivacurium are used up to the end of anesthesia.¹²⁵ In addition, careful meta-analysis has shown that avoidance of reversal of mivacurium has only a marginal effect in reducing PONV at the risk of residual weakness.¹²⁶

PLASMA CHOLINESTERASE. Mivacurium is metabolized by plasma cholinesterase more slowly than succinylcholine. Duration of action is correlated with plasma cholinesterase activity, and hence is prolonged when plasma cholinesterase concentrations are decreased (e.g., in pediatric¹²⁷ and obstetric patients¹²⁸). Reversal can be accelerated with human plasma cholinesterase.¹²⁹ Patients homozygous for atypical plasma cholinesterase may show very prolonged block. After a “test-dose” of $0.14\ \text{mg} \cdot \text{kg}^{-1}$, full recovery took 7 hours.¹³⁰ Inhibition of enzymatic degradation of mivacurium by plasma cholinesterase also results in slower onset.⁵³

The cardiovascular response to mivacurium is minimal at doses of $2\text{--}3 \times \text{ED}_{95}$, whereas administration of $3 \times \text{ED}_{95}$ over 10–15 sec evokes sufficient histamine release to decrease mean arterial blood pressure transiently by about 15%.^{116,131} Therefore, the cardiovascular effects are similar to those of atracurium.

CLINICAL USE. Mivacurium is well suited to surgical procedures requiring brief muscle relaxation, particularly those in which rapid recovery is required, such as ambulatory and laparoscopic surgery. Because of its slow onset, conditions for tracheal intubation are unsatisfactory unless large bolus doses, at least $0.2\ \text{mg} \cdot \text{kg}^{-1}$, are given and a delay of at least 2 min is allowed before intubation is attempted.¹³² However, by using two doses of 0.15 and $0.1\ \text{mg} \cdot \text{kg}^{-1}$ separated by 30 sec, good to excellent intubation conditions have been achieved in almost 90% of patients, an onset similar to that of succinylcholine.¹³³ Small doses of mivacurium ($0.04\text{--}0.08\ \text{mg} \cdot \text{kg}^{-1}$) have been suggested to facilitate insertion of a Laryngeal Mask Airway,¹³⁴ although this is seldom necessary. The rapid recovery makes it necessary to monitor neuromuscular activity continuously during its administration, which is accomplished more easily by constant infusion ($5\text{--}10\ \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) than by intermittent bolus injection.

Pancuronium. Pancuronium is a long-acting, synthetic, nondepolarizing neuromuscular blocking drug developed from a series of bisquaternary aminosteroid compounds.¹³⁵ The two quaternary groups were attached to a rigid steroid structure to maintain a constant interonium distance. It is metabolized to a 3-OH compound, which has one half the neuromuscular blocking activity of the parent compound. Although values for protein binding varying from 20% to 87% have been described for pancuronium, the extent of binding does not appear to be important for its clinical activity. Clearance is decreased in renal and hepatic failure, demonstrating that excretion is dependent upon both organs. The onset of action is more rapid in infants and children than in adults and recovery is slower in the elderly.

CARDIOVASCULAR EFFECTS. Pancuronium is associated with increases in heart rate, blood pressure, and cardiac output, particularly after large doses ($2 \times \text{ED}_{95}$). The cause is uncertain but includes a vagolytic effect at the postganglionic nerve terminal, a sympathomimetic effect as a result of blocking of muscarinic receptors that normally exert some braking on ganglionic transmission, and an increase in catecholamine release.² Pancuronium does not release histamine.

CLINICAL USE. The slow onset of action of pancuronium limits its usefulness in facilitating tracheal intubation. Administration in divided doses (priming principle) produces a small but measurable acceleration,¹³⁶ but the intermediate- and short-acting compounds are more suitable when succinylcholine is contraindicated prior to tracheal intubation. In patients with myocardial ischemia, tachycardia should be avoided. Because these patients are often anesthetized with high doses of opioids, the use of pancuronium to provide muscle relaxation may offer some advantage over the use of cardiovascularly neutral relaxants. The continued popularity of pancuronium is dependent upon cost: generic pancuronium is cheaper than other nondepolarizing relaxants. Its use is associated with a high incidence of residual block in the PACU, at least in adults. Pancuronium neuromuscular block is more difficult to reverse than that of the intermediate NMBDs.¹³⁷

Rapacuronium. Rapacuronium is the most recently introduced aminosteroid NMBD.¹³⁸ It is less potent than rocuronium, and thus has a more rapid onset of action and faster recovery. Following $1.5 \text{ mg} \cdot \text{kg}^{-1}$, good to excellent intubation conditions are produced at 60 sec,¹³⁹ clinical duration (25% T_1 recovery) occurs in 17 min and spontaneous recovery to TOF 0.7 occurs in 35 min.¹⁴⁰ Rapacuronium is metabolized to a 17-OH derivative (ORG 9488) that has $\frac{1}{2}$ times the neuromuscular blocking activity of the parent compound and is excreted slowly *via* the kidneys.^{63,141} Thus it has been recommended that rapacuronium be used only for short procedures requiring neuromuscular blockade for 30 min or less. Repeated boluses produce increasing duration of block.¹⁴² When 0.05 or $0.07 \text{ mg} \cdot \text{kg}^{-1}$ neostigmine was given 2 or 5 min after $1.5 \text{ mg} \cdot \text{kg}^{-1}$ rapacuronium, recovery was accelerated so that TOF 0.7 was achieved in 17 min,¹⁴³ which was very much more rapid than after rocuronium ($0.45 \text{ mg} \cdot \text{kg}^{-1}$).¹⁴⁴ Although this duration is longer than that of succinylcholine, rapacuronium has the most rapid onset and recovery of any nondepolarizing NMBD. Rapacuronium produces mild dose-related tachycardia and hypotension, and these cardiovascular changes do not appear to be due to histamine release.¹⁴⁵ Increased airway pressure and bronchospasm have been reported in some patients.^{139,145}

Rocuronium. Rocuronium is an aminosteroid neuromuscular relaxant. It has one sixth the potency of vecuronium, a more rapid onset, but a similar duration of action¹⁴⁶ and similar pharmacokinetic behavior.¹⁴⁷ Bartkowski *et al* showed that, with equipotent doses, rocuronium onset at the adductor pollicis was much faster than that of atracurium and vecuronium¹⁴⁸ (Fig. 16-13). After doses of $600 \mu\text{g} \cdot \text{kg}^{-1}$ ($2 \times \text{ED}_{95}$, $4 \times \text{ED}_{50}$) maximal block occurs in ~60–90 s. In a multicenter study of 349 patients, intubating conditions at 60 s after $1.0 \text{ mg} \cdot \text{kg}^{-1}$ rocuronium were similar to those after $1 \text{ mg} \cdot \text{kg}^{-1}$ succinylcholine and superior to those after $0.6 \text{ mg} \cdot \text{kg}^{-1}$ rocuronium (92 versus 77% good–excellent).¹⁴⁹ As for other nondepolarizing relaxants the onset of action of rocuronium is more rapid at the diaphragm¹⁵⁰ and laryngeal muscle¹⁵¹ than at the adductor pollicis, and approximately twice as much is required to produce the same degree of paralysis at the diaphragm.¹⁵⁰ The potency, onset time, recovery index, and duration of action are similar in infants, children, and adults during nitrous oxide-alfentanil anesthesia¹⁵² in contrast to vecuronium, which is a long-acting relaxant in infants.¹⁵³

Figure 16-13. Onset of block of adductor after rocuronium, vecuronium, or atracurium. (Reproduced with permission from Bartkowski RR, Witkowski TA, Azad S *et al*: Rocuronium onset of action: A comparison with atracurium and vecuronium. *Anesth Analg* 77:574, 1993.)

CARDIOVASCULAR EFFECTS. No hemodynamic changes (blood pressure, heart rate, or ECG) were seen in humans, and there were no increases in plasma histamine concentrations after doses of up to $4 \times \text{ED}_{95}$,¹⁵⁴ although anaphylactic reactions have been described.³⁶ Similarly, when rocuronium $0.6 \text{ mg} \cdot \text{kg}^{-1}$ was given to patients before coronary artery bypass grafting, the slight hemodynamic changes observed were no different from those following equivalent doses of vecuronium.¹⁵⁵

CLINICAL USE. The rapid onset and intermediate duration of action makes this agent a potential replacement for succinylcholine in conditions where rapid tracheal intubation is indicated. However, large doses are required with a prolonged duration of action. A “timing principle” has been described in which $0.6 \text{ mg} \cdot \text{kg}^{-1}$ rocuronium is given *before* the induction agent, which is administered at the onset of ptosis. Used in this fashion, intubation conditions are similar to those after succinylcholine.¹⁵⁶ Rocuronium has replaced vecuronium as an intermediate-duration relaxant because of its more rapid onset and lack of active metabolites, and because it is unnecessary to reconstitute the drug from a lyophilized base. Initial doses of $0.6 \text{ mg} \cdot \text{kg}^{-1}$ iv will usually produce good intubating conditions within 90 sec. Subsequent doses of 0.075 – $0.225 \text{ mg} \cdot \text{kg}^{-1}$ will provide clinical relaxation for 10–20 min.¹⁵⁷ Alternatively, rocuronium might be given by continued infusion, titrated with the help of a nerve stimulator.

Vecuronium. Vecuronium is an intermediate-acting aminosteroid neuromuscular relaxant without cardiovascular effects. Its ED_{95} is 0.04 – $0.05 \text{ mg} \cdot \text{kg}^{-1}$. It is a monoquaternary ammonium compound produced by demethylation of the pancuronium molecule at the 2-piperidino position.¹⁵⁸ The demethylation reduces the ACh-like characteristics of the molecule and increases its lipophilicity, which encourages hepatic uptake. Vecuronium undergoes spontaneous deacetylation to produce 3-OH, 17-OH, and 3,17-(OH)₂ metabolites. The most potent, 3-OH vecuronium, has about 60% of the activity of vecuronium, is excreted by the kidney, and has been found to be responsible for prolonged paralysis in patients in the intensive care unit.¹⁵⁹ Vecuronium is less potent and has a shorter duration of action in men than in women,¹⁶⁰ probably as a result of a decrease in the volume of distribution which results in increased plasma concentrations in women.¹⁶¹

The pharmacokinetic variables of vecuronium are similar to those of pancuronium, and the reason for vecuronium's shorter duration of action is that the plasma concentration decreases through the effective range far more rapidly so that duration and recovery depend more on distribution than on elimination¹⁶² (Fig. 16-8). Recovery after long-term infusions of vecuronium (in excess of 6 h) is slower than after a bolus dose¹⁶³ because the peripheral storage sites have become saturated and a decrease in plasma concentration is then dependent upon metabolism and excretion and not upon redistribution.

Attempts have been made to reduce the time of onset of action of vecuronium, and other nondepolarizing blocking drugs, by using the priming principle.¹⁶⁴ This refers to the administration of a small, subparalyzing dose several minutes before the principal dose is given. For vecuronium, the best results have been obtained with a priming dose of $0.01 \text{ mg} \cdot \text{kg}^{-1}$ followed 3–4 min later by $0.1 \text{ mg} \cdot \text{kg}^{-1}$. The time to onset of maximal block is reduced by about 25%, but intubating conditions 2 min later are not as good as after succinylcholine.¹⁶⁵ However, the introduction of rocuronium is likely to make this practice obsolete.

CARDIOVASCULAR EFFECTS. Vecuronium usually produces no cardiovascular effects with clinical doses. It does not induce histamine release, although it may interfere with histamine metabolism.¹⁶⁶ Allergic reactions have been described, but no more frequently than after the use of other neuromuscular blocking drugs.

CLINICAL USE. The cardiovascular neutrality and intermediate duration of action make vecuronium a suitable agent for use in patients with ischemic heart disease or those undergoing short, ambulatory surgery. Care should be taken when vecuronium is administered immediately after thiopental because a precipitate of barbituric acid may be formed that may obstruct the intravenous cannula.¹⁶⁷

Large doses, 0.1 – $0.2 \text{ mg} \cdot \text{kg}^{-1}$, with or without priming, are frequently used to facilitate tracheal intubation in place of succinylcholine. For maintenance of relaxation, vecuronium may be given using intermittent boluses, 0.01 – $0.02 \text{ mg} \cdot \text{kg}^{-1}$, or by continuous infusion. Infusion rates to maintain constant neuromuscular block vary considerably, and doses of 1 – $2 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ have been necessary to maintain 90% block. However, the rate of spontaneous recovery of neuromuscular function is slower after administration by infusion than by intermittent boluses.¹⁶⁸ The wide individual variation suggests that dosing should be titrated with the help of neuromuscular monitoring. Vecuronium has now largely been replaced by the more rapid rocuronium.

DRUG INTERACTIONS

Interactions between neuromuscular blocking drugs and several anesthetic and nonanesthetic drugs have been suggested. Although some interactions have been

confirmed, many remain as isolated case reports or theoretical possibilities.

Interactions with Anesthetic Agents

Inhalational Agents

The anesthetic vapors potentiate neuromuscular blockade when administered in high concentration. At clinical doses, shifts in the dose–response curves of *d*-tubocurarine, gallamine, pancuronium, metocurine–pancuronium combinations, atracurium, and vecuronium have been demonstrated.^{169,170,171,172} and ¹⁷³ Enflurane and isoflurane are more potent than halothane in potentiating the effect of *d*-tubocurarine and pancuronium, but enflurane produces greater potentiation of vecuronium than do halothane or isoflurane.¹⁷² When atracurium was given by continuous infusion to children, the dose required to maintain constant blockade was reduced by about 30% during halothane (0.8%) or isoflurane (1.0%) administration.¹⁷⁴ Also, isoflurane¹⁶⁹ and nitrous oxide¹⁷⁵ have been shown to potentiate the effect of succinylcholine.

The influence of anesthetic vapors on the effect of initial doses of NMBDs is minimal unless equilibration of the anesthetic agent is allowed to occur before administration of the NMBD.¹⁷⁶ More pronounced effects may be seen in the presence of sevoflurane and desflurane¹⁷⁷ that equilibrate more rapidly. Nevertheless, the mivacurium infusion rate required to maintain 90% neuromuscular block continues to decrease for 45 min after the start of sevoflurane inhalation.¹²⁷

The cause of the potentiation is unknown, but the greater effect on tetanic and train-of-four responses than on single-twitch responses suggests that prejunctional mechanisms are involved.¹⁷⁸

Intravenous Anesthetics

Some slight potentiation of nondepolarizing neuromuscular blocking drugs has been demonstrated with most iv induction agents in animals,¹⁷⁹ but this is of limited clinical importance.

Local Anesthetics

Lidocaine, procaine, and other local anesthetic agents produce neuromuscular blockade in their own right as well as potentiating the effects of depolarizing and nondepolarizing neuromuscular blocking drugs.¹⁸⁰ Gentamicin and lidocaine have additive effects, and profound neuromuscular block has been observed after their combined use in a patient given *d*-tubocurarine.¹⁸¹

Neuromuscular Blocking Drugs

Nondepolarizing–Nondepolarizing Interactions

Combinations of similar drugs—e.g., pancuronium–vecuronium, *d*-tubocurarine–metocurine, and atracurium–mivacurium¹⁸²—have additive effects. Other combinations tend to show potentiation. The first such synergism was demonstrated for pancuronium–metocurine combinations, and it was suggested that the combination may be used to reduce unwanted hemodynamic effects without prejudicing neuromuscular block.¹¹⁵ Other combinations have also been shown to be synergistic (atracurium with *d*-tubocurarine, metocurine, mivacurium,¹⁸³ or pancuronium; vecuronium with atracurium or *d*-tubocurarine; *d*-tubocurarine with gallamine or vecuronium). Combinations of rocuronium and cisatracurium are also synergistic. The rapid onset of rocuronium was preserved,¹⁸⁴ while with mivacurium and pancuronium combinations the combination produced rapid recovery,¹⁸⁵ suggesting that the better features of each of the drugs might be conserved in the mixtures.

Administration of a combination of relaxants does not affect the degree of protein binding of either drug, so the potentiation is not the result of an increase in unbound drug. An alternative is that one drug of the pair has predominantly presynaptic activity and the other acts postsynaptically.¹⁸⁶ Finally, the potentiation may be entirely of postsynaptic origin as a result of asymmetric binding of different relaxants to the subunits of the ACh receptor.¹⁸⁷

Nondepolarizing–Depolarizing Interactions

Depolarizing and nondepolarizing relaxants are mutually antagonistic. When *d*-tubocurarine or other nondepolarizing agents are given before succinylcholine to prevent fasciculations and muscle pain, the succinylcholine is less potent and has a shorter duration of action¹⁸⁸ except after pancuronium administration when the duration of action is prolonged, presumably because pancuronium inhibits plasma cholinesterase.¹⁸⁹ Conversely, the potency of the nondepolarizing drugs is enhanced when they are administered after succinylcholine.¹⁹⁰ Isobolographic evaluation of mixtures of succinylcholine with mivacurium or atracurium demonstrate antagonism.¹⁹¹ Finally, the response to a small dose of succinylcholine at the end of an anesthetic in which a nondepolarizing agent has been used is difficult to predict. It may either antagonize or potentiate the blockade, depending on the degree of nondepolarizing block.¹⁹² In part, the ability of succinylcholine to reverse nondepolarizing block is a result of enhanced ACh release.¹⁹³ If anticholinesterase has been given, the effect of the succinylcholine is potentiated because of inhibition of plasma cholinesterase.

Antibiotics

Neomycin and streptomycin are the most potent of the aminoglycosides in depressing neuromuscular function.¹⁹⁴ They augment both depolarizing and nondepolarizing block and their effects are potentiated by magnesium and antagonized by calcium but only partly by anticholinesterases. Other aminoglycosides (e.g., gentamicin, netilmicin) also potentiate nondepolarizing neuromuscular blockade.

The polymixins are the most potent of all antibiotics in their action at the neuromuscular junction. Their effect appears to be predominantly postjunctional. Reversal of the block is difficult: calcium and anticholinesterases are both inconsistent.

The lincosamines clindamycin and lincomycin have prejunctional and postjunctional effects, and the block cannot be reversed with calcium or anticholinesterases.

Management of a prolonged block that is suspected to have arisen from a combination of antibiotics and neuromuscular blocking drugs is difficult. Only that portion of the block due to the neuromuscular blocking drug can be reversed with anticholinesterases. Management includes mechanical support of ventilation until spontaneous breathing resumes. It is better to avoid the syndrome by administering small doses of the most potent antibiotics, particularly when they are given by the iv, intraperitoneal, or intrapleural routes.

Anticonvulsants

Resistance to pancuronium, metocurine, vecuronium, and rocuronium, but not to atracurium or mivacurium, has been demonstrated in patients receiving chronic anticonvulsant therapy with carbamazepine or phenytoin, probably as a result of up-regulation of the receptor.^{195,196,197} and ¹⁹⁸ Acute administration of phenytoin produces augmentation of neuromuscular block.¹⁹⁹

Miscellaneous

Altered reactions to several other agents have been described.⁷⁸ These include potentiation of depolarizing and nondepolarizing blockade with β -agonist and calcium channel blockers as well as abnormal reactions in the presence of diuretics, corticosteroids, immunosuppressants, hypotensive agents, and several psychotropic drugs. Management of neuromuscular blockade in patients receiving other drugs is by titration of the dose with the help of a nerve stimulator.

ALTERED RESPONSES TO MUSCLE RELAXANTS

Muscle Relaxants in the Intensive Care Unit

There are several reports of critically ill patients who demonstrated residual weakness for unexpectedly long periods after discontinuation of a neuromuscular relaxant, which had been used to facilitate mechanical ventilation. In some, recovery took several months. A majority have occurred in asthmatics receiving high doses of methylprednisolone.²⁰⁰ Pancuronium or vecuronium has been the relaxant used most frequently, but recent descriptions of similar syndromes after atracurium²⁰¹

suggest that this reflects their popularity rather than a particular association with steroid-based relaxants.²⁰⁰ Some cases are the result of impaired organ excretion of the drug or an active metabolite, such as high concentrations of 3-hydroxyvecuronium in patients with renal failure.¹⁵⁹ Electromyographic studies have shown variable lesions from myopathy to axonal degeneration of motor and sensory fibers. The picture is complicated by the syndrome of “critical illness neuropathy,” which occurs in patients with sepsis and multiorgan failure. Symptoms include failure to wean from mechanical ventilation, limb weakness, and impaired deep tendon reflexes, but sensory function is usually not affected.²⁰² Other predisposing conditions include electrolyte abnormality,²⁰³ acid–base disturbance,²⁰⁴ aminoglycoside antibiotics,¹⁹⁴ and cyclosporine.⁷⁸ There are no controlled clinical studies to allow the several initiating factors to be identified and matched with particular syndromes.

Studies in ICU patients in whom the administration of relaxant was adjusted according to strict neuromuscular monitoring criteria have shown considerable variation in the requirement for NMBD to maintain the same effect among patients²⁰⁵ and a wide within-patient pharmacokinetic variability²⁰⁶ but failed to demonstrate prolonged block,^{207,208} suggesting that the prolonged effects were due to overdose, but this has not been confirmed. Although the most likely site of the lesion is in the motor nerve or muscle, prolonged administration of muscle relaxants may result in transmission failure from prejunctional or postjunctional mechanisms. These may include failure of synthesis and release of ACh, interference with calcium ion currents, disorganization of the postjunctional membrane, channel block, or down-regulation of the receptor.²⁰⁹ These reports suggest the need for more careful monitoring of neuromuscular block in ICU patients, although the optimal method and level of block to be achieved are uncertain.²¹⁰

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease in which circulating antibodies produce a functional reduction in the number of ACh receptors.^{1,211,212} The lesion is postsynaptic: the number of ACh quanta is normal and their content is either normal or increased.²¹³

Diagnosis

The characteristic EMG finding in myasthenia gravis is a voltage decrement to repeated stimulation. Stimuli at 3 Hz show a fade in response to the second stimulus, and myasthenia gravis is diagnosed if the response to the fifth is reduced by 10%.²¹⁴ Latent myasthenia gravis may be revealed by testing after exercise. The diagnosis can be confirmed with the regional curare test.²¹⁵ A forearm tourniquet is applied, 0.5 mg *d*-tubocurarine is given iv, and the tourniquet is released after 4–5 min. Myasthenia is characterized by pronounced fade in response to train-of-nine stimulation. Edrophonium, 2–8 mg, produces brief recovery from myasthenia gravis. Finally, the diagnosis can be made by recognizing circulating ACh antibody.²¹⁶

Response to Muscle Relaxants

Patients with myasthenia gravis are usually slightly resistant to succinylcholine,²¹⁷ but, during recovery, Phase II block develops rapidly and recovery is slow.²¹⁸ Sensitivity to nondepolarizing neuromuscular blocking drugs led to the avoidance of *d*-tubocurarine or pancuronium except for diagnosis. The dose required to produce neuromuscular block is reduced by about 75%. Dose–response curves for atracurium and vecuronium have characterized the response more clearly.^{219,220}

Anesthesia in Myasthenia Gravis

Traditionally, neuromuscular blocking drugs have been avoided in the patient with myasthenia gravis by the use of inhalational vapors with or without local anesthesia. More recently, there have been several reports of the successful use of atracurium,²²¹ mivacurium,²²² or vecuronium²²³ when these drugs are administered under neuromuscular monitoring. The use of atracurium or mivacurium and the avoidance of anticholinesterases seem to be particularly appropriate.

Two problems remain after thymectomy: postoperative anticholinesterase therapy and predicting the need for mechanical support of ventilation. In most patients, the dose of anticholinesterases is reduced for 1–2 days after surgery. The need for mechanical ventilation of the lungs can be predicted by preoperative lung function tests.²²⁴ Previous suggestions that the need correlated with long-standing disease or patients taking high doses of pyridostigmine have not been confirmed.

Myotonia

Myotonia is characterized by an abnormal delay in muscle relaxation after contraction. It exists in three forms: myotonic dystrophy (dystrophia myotonica, myotonia atrophica, Steinert's disease), myotonia congenita (Thomsen's disease), and paramyotonia congenita.

Diagnosis

Repeated nerve stimulation leads to a gradual but persistent increase in muscle tension. The EMG is pathognomonic; myotonic after-discharges are seen in peripheral muscle, consisting of rapid bursts of potential produced by tapping the muscle or moving the needle. They produce typical “dive-bomber” sounds on the loudspeaker.

Response to Muscle Relaxants

The characteristic abnormality is a sustained, dose-related contracture after succinylcholine that makes ventilation difficult for 2–5 min.²²⁵ The response to nondepolarizing drugs is normal, although myotonic responses have been observed after reversal with neostigmine.²²⁶

Anesthesia

Succinylcholine should be avoided and respiratory depressants used with care. Atracurium or mivacurium, without reversal, is an appropriate choice for relaxation.

Muscular Dystrophy

An increased incidence of morbidity and mortality has been described after anesthesia in the patient with Duchenne-type muscular dystrophy (DMD). In particular, there are several reports of cardiac arrest after administration of succinylcholine.^{227,228} In 1993, the number of such reports^{229,230} encouraged Burroughs Wellcome, the manufacturer of Anectine (succinylcholine), to state that “succinylcholine [is] contraindicated in children and adolescents except when used for emergency tracheal intubation.” After further discussion the recommendation was modified to a warning. Nevertheless, it is recognized that in these patients succinylcholine-induced hyperkalemic cardiac arrest is difficult to treat²³¹ and carries a high mortality.

Response to Muscle Relaxants

The response to depolarizing and nondepolarizing relaxants seems to be normal, although the regional curare test demonstrates a normal blockade that lasts for longer than normal²³² and increased sensitivity to, and delayed recovery from, vecuronium has been reported.²³³ Patients with the rare syndrome, ocular muscular dystrophy, exhibited extreme sensitivity to *d*-tubocurarine, but showed little response to anticholinesterases.²³⁴ There is considerable controversy over whether DMD patients are susceptible to MH.^{235,236}

Anesthesia

Succinylcholine should be avoided in patients with DMD. The possibility of latent or unrecognized DMD in young males (less than 10 years old) may be a reason to avoid succinylcholine in this patient population.

Upper Motor Neuron Lesions

Response to Muscle Relaxants

Patients with hemiplegia or quadriplegia as a result of central nervous system lesions show an abnormal response to depolarizing and nondepolarizing relaxants. Hyperkalemia and cardiac arrest have been described after succinylcholine, probably as a result of extrajunctional receptor spread. Hyperkalemia is usually seen from 1 week to 6 months after the lesion, so that recommendations for the avoidance of succinylcholine²³⁷ may not be indicated in the patient with chronic weakness.²³⁸

Hemiplegic patients are resistant to nondepolarizing neuromuscular blocking drugs. Monitoring of the affected side shows that the block is less intense and recovery is more rapid than on the unaffected side. However, the apparently normal side also demonstrates some weakness.²³⁹

Miscellaneous

Denervated muscle demonstrates potassium release after succinylcholine and resistance to nondepolarizing relaxants. Contractures in response to succinylcholine have also been observed in amyotrophic lateral sclerosis, myotonia, and multiple sclerosis.²¹⁸ Succinylcholine is usually avoided in several neurologic diseases, including Friedrich's ataxia, polyneuritis, and Parkinson's disease, because of isolated reports of hyperkalemia. Hyperkalemia and cardiac arrest have also been reported in burn patients starting 24–48 hr after injury. Resistance to nondepolarizing drugs may also develop.⁷⁹

MONITORING NEUROMUSCULAR BLOCKADE

Why Monitor?

Deep levels of paralysis are usually desired during anesthesia to facilitate tracheal intubation and to obtain an immobile surgical field. However, complete return of respiratory function must be attained before the trachea is extubated. Ventilatory depression is an important cause of anesthesia-related mortality and morbidity, and the presence of residual neuromuscular block in this setting is undoubtedly an important factor.^{240,241} Administration of neuromuscular blocking drug must be individualized because blockade occurs over a narrow range of receptor occupancy,^{12,59} and because there is considerable interindividual variability in response.²⁴² Thus, it is important for the clinician to assess the effect of neuromuscular blocking drugs without the confounding influence of volatile agents, iv anesthetics, and opioids. To test the function of the neuromuscular junction, a peripheral nerve is stimulated electrically, and the response of the muscle is assessed.

Stimulator Characteristics

The response of the nerve to electrical stimulation depends on three factors: the current applied, the duration of the current, and the position of the electrodes. Stimulators should deliver a maximum current in the range of 60–80 mA.⁵ Most stimulators available for clinical use are designed to provide constant current, irrespective of impedance changes due to drying of the electrode gel, cooling, decreased sweat gland function, and so forth. However, this constant current feature does not hold for high impedances (>5 kW). Thus, electrodes should be firmly applied to the skin. A current display monitor on the stimulator is an asset, because accidental disconnection can be identified easily by a current approaching 0 mA. The duration of the current pulse should be long enough for all axons in the nerve to depolarize but short enough to avoid the possibility of exceeding the refractory period of the nerve. In practice, pulse durations of 0.1–0.2 msec are acceptable. At least one electrode should be on the skin overlying the nerve to be stimulated. If the negative electrode is used for this purpose, the threshold to supramaximal stimulation is less than for the positive electrode.^{243,244} However, the difference is not large in practice. The position of the other electrode is not critical, but it should not be placed in the vicinity of other nerves. There is no need to use needle electrodes. Silver–silver chloride surface electrodes, used to monitor the electrocardiogram, are adequate for peripheral nerve stimulation, without the risk of bleeding, infection, and burns. In practice, applying these electrodes along the course of a nerve gives the best results.

Monitoring Modalities

Different stimulation modalities were introduced into clinical practice to take advantage of the characteristic features of nondepolarizing neuromuscular blockade: fade and post-tetanic facilitation with high-frequency stimulation. Thus, the following discussion refers mostly to nondepolarizing block.

Single Twitch

The simplest way to stimulate a nerve is to apply a single stimulus, at intervals of >10 sec. The amplitude of response is compared with a control, prerelaxant twitch height. However, because a control is required, the clinical usefulness of this mode of stimulation is limited.

Tetanus

When stimulation is applied at a frequency of ≈ 30 Hz, individual EMG responses can be discerned while the mechanical response of the muscle is fusion of individual twitch responses. During nondepolarizing blockade, the mechanical response appears as a peak, followed by a fade (see Fig. 16-7). In the absence of neuromuscular blocking drugs, no fade is present and the response is sustained. The sensitivity of tetanic stimulation in the detection of residual neuromuscular blockade is greater than that of single twitch, and this sensitivity increases with frequency.⁵⁹ However, at frequencies >100 Hz, some fade may be seen even in the absence of neuromuscular blocking drugs.¹⁷⁰ To avoid this problem, a 50-Hz, 5-sec train is used most commonly in practice. However, 100-Hz frequencies are most useful in the detection of residual block. No control prerelaxant response is required, as the degree of muscle paralysis can be assessed by the degree of fade following tetanic stimulation. However, the main disadvantage of this mode of stimulation is post-tetanic facilitation (Fig. 16-7), the extent of which depends on the frequency and duration of the tetanic stimulation. For a 50-Hz tetanus applied for 5 sec, the duration of this interval appears to be at least 1–2 min.⁶¹ If a single-twitch stimulation is performed during that time, the response is spuriously exaggerated.

Train-of-Four

With 2-Hz stimulation, the mechanical or electrical response decreases little after the fourth stimulus, and the degree of fade is similar to that found at 50 Hz.⁶⁰ Thus, applying train-of-four stimulation at 2 Hz provides approximately the same sensitivity as tetanic stimulation at 50 Hz. In addition, this relatively low frequency allows the response to be evaluated manually or visually. Moreover, the presence of a small number of impulses eliminates the problem of post-tetanic facilitation. Train-of-four stimulation can be repeated after a pause of 10 sec. There is a fairly close relationship between single-twitch depression and train-of-four response, and no control is required for the latter.²⁴⁵ With single-twitch blockade of >70–75%, four responses are not all visible. With blockade of >85–90%, only the first twitch is visible. In the range of 70–85% block, two to four twitches are visible. The train-of-four ratio, the height of the fourth twitch to that of the first twitch, is linearly related to first twitch height when blockade is <70%. When single-twitch height has recovered to 100%, the train-of-four ratio is $\approx 70\%$. Thus, train-of-four stimulation is a more sensitive indicator of neuromuscular blockade than single-twitch stimulation.

Post-Tetanic Count

During profound neuromuscular blockade, there is no response to single-twitch, tetanic, or train-of-four stimulation. To estimate the time required before the return of a response, one may use a technique that depends upon the principle of post-tetanic facilitation. A 50-Hz tetanus is applied for 5 sec, followed by a 3-sec pause and by stimulation at 1 Hz. The train-of-four and tetanic responses are undetectable, but facilitation produces a certain number of visible post-tetanic twitches (Fig. 16-14). For a given drug, the number of visible twitches correlates inversely with the time required for a return of single-twitch or train-of-four responses.²⁴⁶

Figure 16-14. Post-tetanic count. During profound blockade, no response can be seen after train-of-four or tetanic stimulation. However, if 1-Hz stimulation is applied after the tetanus, some twitches can be seen.

Double-Burst Stimulation

Train-of-four fade may be difficult to evaluate by visual or tactile means during recovery from neuromuscular blockade.²⁴⁷ This can be overcome, to a certain extent, by applying two short tetanic stimulations and evaluating the ratio of the second to the first response. Many patterns have been suggested, but the most promising consists of two trains of three impulses at 50 Hz, separated by 750 msec.²⁴⁸ The double-burst stimulation ratio correlates closely with the train-of-four ratio (Fig. 16-15)^{248,249} but is easier to detect manually.^{249,250} At least 12–15 sec must elapse between two consecutive double-burst stimulations.^{248,249}

Figure 16-15. Relationship between double-burst stimulation (DBS) and train-of-four stimulation (TOF). The shaded zone shows 95% confidence limits and the line is the line of identity. (Reprinted with permission from Gill S, Donati F, Bevan DR: Clinical evaluation of double burst stimulation: Its relationship to train-of-four stimulation. *Anaesthesia* 45:543, 1989.)

Recording the Response

Visual and Tactile Evaluation

When electrical stimulation is applied to a nerve, the easiest and least expensive way to assess the response is to observe or feel the response of the muscle. This method is easily adaptable to any superficial muscle. However, serious errors in assessment can be made. In the case of evaluating the response of the adductor pollicis to ulnar nerve stimulation, the train-of-four count can be made reliably during a surgical procedure,²⁵¹ but the quantitative assessment of train-of-four ratio is difficult to make during recovery. Several investigations suggest that train-of-four ratios as low as 0.3^{249,250} can remain undetected. The detection rate for tetanic fade (50 Hz) is no better.²⁵² With double-burst stimulation, fade can be detected reliably up to train-of-four ratios in the range of 0.5–0.6.^{249,250}

Measurement of Force

A force transducer can overcome the shortcomings of one's senses. If applied correctly, the device provides accurate and reliable responses, displayed as either a digital or an analog signal on a monitor, such as an electrocardiogram screen. Unfortunately, transducers are applicable to only one muscle, usually the adductor pollicis. Force measurement can be used with single-twitch, tetanus, train-of-four, double-burst, or post-tetanic stimulation. However, the availability of tetanus and double-burst stimulation is superfluous if accurate recording of the train-of-four response can be made.

Electromyography

It is possible to measure the electrical instead of the mechanical response of the muscle (see Fig. 16-4). One electrode should be positioned over the neuromuscular junction, which is usually close to the midportion of the muscle, and the other near the insertion of the muscle. A third, neutral electrode can be located anywhere else. Theoretically, any superficial muscle can be used for EMG recordings. In practice, such recordings are limited to the hypothenar eminence, the first dorsal interosseous, and the adductor pollicis muscles, which are supplied by the ulnar nerve. Most EMG recording devices compute the area under the EMG curve during a specified time window (usually 3–18 msec) after the stimulus is applied.²⁵³ This integrated EMG response is considered a better representation of the overall muscular activity than the measurement of peak response. There is usually good correlation between EMG and force of the adductor pollicis if the EMG signal is taken from the thenar eminence.²⁵⁴ The signal obtained from the hypothenar eminence is larger and less subject to movement artifacts, but it can underestimate the degree of paralysis when compared with the adductor pollicis.²⁵⁵

Accelerometry

Accelerometers respond to acceleration, which, according to Newton's law, is proportional to force if mass remains unchanged. The device is usually attached to the tip of the thumb and a digital read-out is obtained. The setup is sensitive to inadvertent displacement of the thumb and, in the absence of neuromuscular blocking drugs, train-of-four ratios > 100% can be obtained.²⁵⁶

Choice of Muscle

Muscles do not respond in a uniform fashion to neuromuscular blocking drugs. After administration of a neuromuscular blocking agent, differences can be measured with respect to onset time, maximum blockade, and duration of action. Ideally, it would be best to monitor the muscles of practical importance, such as those that must be relaxed during surgery (e.g., the abdominal muscles), or the respiratory and airway that must recover postoperatively. One approach is to choose a monitoring site that has a response similar to the muscle of interest. For example, monitoring the response of the facial nerve around the eye is a good indicator of intubating conditions, and the use of the adductor pollicis during recovery reflects upper airway muscle function. If one prefers not to change sites depending on circumstances, one has to interpret the information provided by monitoring, usually at the adductor pollicis, from knowledge of the possible differences among muscles (Fig. 16-16).

Figure 16-16. Onset and recovery after vecuronium, $0.07 \text{ mg} \cdot \text{kg}^{-1}$, at various muscles, versus time. Onset of action is more rapid at the larynx, orbicularis oculi, and diaphragm than at the adductor pollicis. Recovery occurs first at the larynx and last at the adductor pollicis. (Reprinted with permission from Donati F, Meistelman C, Plaud B: Vecuronium neuromuscular blockade at the diaphragm, the orbicularis oculi, and adductor pollicis muscles. *Anesthesiology* 73:870, 1990.)

Adductor Pollicis

The adductor pollicis, supplied by the ulnar nerve, is accessible during most surgical procedures. Its force of contraction can be measured easily, and it has become a

standard in research. After injection of a dose of muscle relaxant, the time to maximal blockade is longer than in centrally located muscles.^{257,258} The adductor pollicis is relatively sensitive to nondepolarizing neuromuscular blocking drugs, and during recovery it is blocked more than some respiratory muscles such as the diaphragm,^{257,258} laryngeal adductors,²⁵⁹ and rectus abdominis.²⁶⁰

Other Muscles of the Hand

Ulnar nerve stimulation also produces flexion and abduction of the fifth finger, which usually recovers before the adductor pollicis, the discrepancy in first twitch or train-of-four ratio being of the order of 15–20%.²⁵⁵ Relying on the response of the fifth finger might overestimate recovery from blockade. Abduction of the index finger also results from stimulation of the ulnar nerve because of contraction of the first dorsal interosseous, the sensitivity of which is comparable to that of the adductor pollicis.²⁵⁴ The hypothenar eminence (near the fifth finger) and the first dorsal interosseous are particularly well suited for EMG recordings.²⁵³

Muscles Surrounding the Eye

There seem to be major differences in the response of muscles innervated by the facial nerve and located around the eye. The response of the orbicularis oculi over the eyelid is similar to that of the adductor pollicis,²⁶¹ but recordings over the eyebrow are similar to that of the laryngeal adductors.²⁶² Onset of blockade is more rapid and recovery occurs sooner than at the adductor pollicis.²⁵⁷ Thus, facial nerve stimulation with inspection of the response of the eyebrow (which most likely represents the effect of the corrugator supercilii, not the orbicularis oculi) is indicated to predict intubating conditions and to monitor profound blockade. The facial nerve can be stimulated 2–3 cm posterior to the lateral border of the orbit.

Muscles of the Foot

The posterior tibial nerve, which can be stimulated behind the internal malleolus, produces flexion of the big toe by contraction of the flexor hallucis. The response of this muscle is comparable to that of the adductor pollicis.²⁶³ Stimulation of the external peroneal nerve produces dorsiflexion, but the sensitivity of the muscles involved has not been measured.

Clinical Applications

Monitoring Onset

The quality of intubating conditions depends chiefly on the state of relaxation of muscles of the jaw, pharynx, larynx, and respiratory system. Onset of action is faster in all these muscles than in the hand or foot because they are closer to the central circulation and they receive a greater blood flow. Among these central muscles, the diaphragm and especially the laryngeal adductors are the most resistant to nondepolarizing agents. Data on laryngeal muscles are important not only because easy passage of the tracheal tube can be performed if vocal cords are relaxed, but also because all other muscles can be presumed to be blocked if the resistant laryngeal muscles are blocked. The relationship between onset time in laryngeal and hand muscles depends on dose. At relatively low doses (e.g., rocuronium, 0.4–0.6 mg · kg⁻¹), onset time is slower at the adductor pollicis than at the laryngeal muscles. If the dose is increased (e.g., rocuronium, 0.8–1.0 mg · kg⁻¹), onset is faster at the adductor pollicis because these doses produce 100% blockade at the adductor pollicis without blocking laryngeal muscles completely.²⁶⁴ Onset time decreases considerably in any muscle if the dose given is sufficient to reach 100%. Finally, if the dose is large enough to block the laryngeal muscles completely, onset time again becomes shorter at the larynx. It is not surprising that monitoring the adductor pollicis muscle predicts intubating conditions poorly. Facial nerve stimulation with visual observation of the response over the eyebrow gives better results because the response of the corrugator supercilii is close to that of the vocal cords. Train-of-four fade takes longer to develop than single-twitch depression (see Fig. 16-7), and train-of-four stimulation does not have any advantages over single-twitch stimulation at 0.1 Hz.

Surgical Relaxation

Adequate surgical relaxation is usually obtained when fewer than two or three visible twitches are observed at the adductor pollicis. However, this criterion might prove inadequate in certain circumstances when profound relaxation is required owing to the discrepancy between the adductor pollicis and other muscles. In this case, the post-tetanic count can be used at the adductor pollicis,²⁴⁶ provided that this type of stimulation is not repeated more often than every 2–3 min. A suitable alternative is stimulation of the facial nerve with observation of the response over the eyebrow, which recovers at the same rate as such resistant muscles as the diaphragm.²⁵⁷

Monitoring Recovery

Complete return of neuromuscular function should be achieved at the conclusion of surgery unless mechanical ventilation is planned. Thus, monitoring is useful in determining whether spontaneous recovery has progressed to a degree that allows reversal agents to be given and to assess the effect of these agents.

The effectiveness of anticholinesterases depends directly on the degree of recovery present when they are administered. Preferably, reversal agents should be given only when four twitches are visible, which corresponds to a first-twitch recovery of >25%. The dose of anticholinesterase can also be adjusted according to the extent of recovery. For this assessment, using the adductor pollicis is preferable. The presence of spontaneous respiration is not a sign of adequate neuromuscular recovery. The diaphragm recovers earlier than the much more sensitive upper airway muscles. For example, the geniohyoid recovers, on average, at the same time as the adductor pollicis.²⁶⁵ To prevent upper airway obstruction after extubation, it is preferable to use the adductor pollicis to monitor recovery, instead of the more resistant muscles of the hypothenar eminence²⁵⁵ or those around the eye.²⁵⁷

Finally, the adequacy of recovery should be assessed. Traditionally, a train-of-four ratio of 0.7 was considered to be the threshold below which residual weakness of the respiratory muscles could be present.²⁶⁶ There is abundant evidence that significant weakness may occur up to train-of-four values of 0.9. Awake volunteers given mivacurium failed to perform the head-lift test when the train-of-four ratio at the adductor pollicis decreased below 0.62, but needed a train-of-four ratio of at least 0.86 to hold a tongue depressor between their teeth.²⁶⁷ This suggests that the head-lift test does not guarantee full recovery, and that the upper airway muscles used to retain a tongue depressor are very sensitive to the residual effects of neuromuscular blocking drugs. Furthermore, impairment in swallowing and laryngeal aspiration of a pharyngeal fluid was observed at train-of-four ratios as high as 0.9 in volunteers given vecuronium.²⁶⁸

Anesthetized patients appear considerably more sensitive to the ventilatory effects of neuromuscular blocking drugs than are awake patients.²⁶⁹ Whereas tidal volume is preserved in awake patients receiving relatively high doses of neuromuscular blocking drugs, anesthetized adults have a decreased tidal volume and increased PCO₂ with doses of pancuronium as low as 0.5 mg (Fig. 16-17). In conscious volunteers, administration of small doses of vecuronium to maintain train-of-four at less than 0.9 leads to severe impairment of the ventilatory response to hypoxia. The response to hypercapnia is maintained, and this indicates that the response to hypoxia is not due to respiratory muscle weakness.²⁷⁰

Figure 16-17. Minute ventilation in adults anesthetized with enflurane given the cumulative dose of pancuronium indicated. (Reprinted with permission from Nishino T, Yokokawa N, Hiraga K *et al*: Breathing pattern of anesthetized humans during pancuronium-induced partial paralysis. *J Appl Physiol* 64:78, 1988.)

Taken together, the results of these investigations indicate that normal respiratory and upper airway function does not return to normal unless the train-of-four ratio at

the adductor pollicis is 0.9 or more. However, it has become apparent that human senses fail to detect either a train-of-four or tetanic fade when the train-of-four ratio is as low as 0.3.^{247,250} With double-burst stimulation, detection failures may occur at train-of-four ratios of 0.5–0.6.^{249,250} The detection rate may be improved somewhat with train-of-four or double burst if submaximal (less than supramaximal) currents are used,²⁷¹ and/or if the movement of the first dorsal interosseus is assessed at the index finger.²⁷² Compared with the train-of-four, the ability to detect fade is not improved by using tetanic stimulation at 50 Hz for 5 sec.²⁵² However, tetanic fade can be felt manually at train-of-four ratios of 0.8–0.9 by using 100-Hz tetanic stimulation.²⁷³ Because of the presence of post-tetanic facilitation, this test should not be used more often than every 2 min. Mechanographic and EMG equipment give reliable values of train-of-four ratio, but the use of this equipment is limited by size, cost, and convenience. Accelerometers are less bulky and cheaper, but they can overestimate the value of train-of-four ratio during recovery. In any event, clinicians must be aware of the limitations of the tests they are using and complete their evaluations with clinical tests.

Factors Affecting the Monitoring of Neuromuscular Blockade

Many drugs interfere with neuromuscular function and these are dealt with elsewhere. However, certain situations make the interpretation of data on neuromuscular function difficult. For example, hypothermia decreases the response when neuromuscular blocking drugs are given. Thus, if the monitored hand is cold, the degree of paralysis will appear to be increased.²⁷⁴ Resistance to nondepolarizing neuromuscular blocking drugs occurs with nerve damage, including peripheral nerve trauma, cord transection, and stroke. In this case, monitoring of the involved limb would tend to underestimate the degree of muscle paralysis.^{275,276} A noninvolved extremity should be used. The level of paralysis should also be adjusted for the type of patient, as well as the type of surgery. For example, it is not necessary to paralyze frail individuals or patients at the extremes of age to the same extent as young muscular adults. The same applies to patients with debilitating muscular diseases.

It may be argued that neuromuscular monitoring has limited usefulness because the response of one skeletal muscle cannot be taken as representative of the whole body, and because major errors in assessment can be made. In two studies, monitoring did not influence the amount of relaxant given or the incidence of postoperative residual block.^{277,278} In at least two other investigations, monitoring and administration of neuromuscular blocking reversal drugs according to rigid criteria decreased the incidence of residual paralysis.^{279,280} It must be recognized that the effect of the neuromuscular blocking drug is the same whether or not monitoring is used. Neuromuscular monitoring can help in the diagnosis of inadequate skeletal muscle relaxation during surgery or insufficient recovery after surgery, but does not, in itself, treat these conditions.

ANTAGONISM OF NEUROMUSCULAR BLOCK

The aim in the reversal of neuromuscular blockade is to ensure that the patient leaves the operating room with unimpaired muscle strength. In some circumstances, however, this is not desirable—for example, when it has been decided to continue mechanical support of ventilation into the postoperative period. And occasionally, complete recovery is unattainable.

Assessment of Neuromuscular Blockade

The principal goal of reversal is the re-establishment of spontaneous respiration and the ability to protect the airway from aspiration. Sensitive tests of pulmonary function, such as vital capacity, maximum voluntary ventilation, and forced expiratory flow rate, are difficult to perform in everyday practice, particularly when the patient is recovering from general anesthesia. Consequently, several indirect indices, which are easier to measure, have been correlated with the more specific tests of ventilatory function. Spontaneous ventilation, adequate to prevent hypercapnia, can be maintained despite considerable measurable skeletal muscle weakness if a patent airway is ensured.

Clinical Evaluation

Several crude tests have been suggested, including head lift for 5 sec, tongue protrusion, and the ability to lift the legs off the bed. The maximum inspiratory pressure (MIP) has been correlated with tests of skeletal muscle strength (vital capacity, head lift, hand grip, leg raising) and of airway musculature (ability to swallow, approximate the vocal cords, maintain a patent airway, and to elevate the mandible) in conscious volunteers receiving subparalyzing doses of *d*-tubocurarine.²⁸¹ The MIP was reduced successively. Head lift and leg raising were affected first, typically at an MIP of –53 and –50 cm H₂O, respectively. At an MIP of –20 to –25 cm H₂O, none of the subjects could swallow or maintain a patent airway, and hand grip was abolished. Nevertheless, as long as the mandible was elevated by an observer, the vital capacity was 40% of control and PETCO₂ was normal. Thus, the ability to maintain head lift for 5 sec usually indicates sufficient strength to protect the airway and support ventilation.²⁸¹ Grip strength is more sensitive, but its assessment requires a dynamometer and preoperative control values so that it is a less useful clinical tool. In infants and neonates the ability to lift both legs off the table as a reflex response²⁸² appears to be as sensitive as the head lift in adults. Kopman has shown, in volunteers, that the most sensitive test is the ability to clamp the jaws shut and prevent removal of a wooden spatula. This correlated with a TOF of >0.86, whereas 5-sec leg lift correlated with a TOF of 0.6. All subjects complained of visual symptoms until TOF > 0.9.²⁶⁷

Evoked Responses to Nerve Stimulation

Clinical tests may be unobtainable in the patient recovering from anesthesia. Also, head lift may be impaired as a result of pain. Evoked responses to nerve stimulation are then appropriate. When the mechanical train-of-four ratio at the adductor pollicis is 0.7, most clinical tests of neuromuscular function have returned to normal,^{266,283} although, in some patients, head lift may be impaired unless train-of-four is 0.9.²⁸⁴ This assumes that such a level of train-of-four recovery can be recognized, but subjective assessment of train-of-four fade is unreliable and is usually undetected until values are less than 0.4–0.5.^{249,250} Double-burst stimulation is more sensitive, but 28–58% of cases of TOF 0.4–0.7 may be missed.^{249,250} The most sensitive test is the ability to maintain sustained contraction to 100-Hz tetanus for 5 sec.²⁷³

Detection of residual neuromuscular block is difficult unless the patient is awake and cooperative. Small degrees of paralysis will not be detected by train-of-four monitoring. However, this should not be an excuse to avoid neuromuscular monitoring. Rather, train-of-four monitoring should be done to ensure that there is no detectable fade when the patient leaves the operating room. This will not guarantee full recovery, which awaits confirmation in the PACU when the patient is awake.

Residual Paralysis

Several studies have demonstrated that residual neuromuscular blockade is frequent in patients in the recovery room after surgery. Viby-Mogensen *et al* found in 72 adult patients given *d*-tubocurarine, gallamine, or pancuronium that the train-of-four ratio was 0.7 in 30 (42%) patients, and 16 of the 68 patients who were awake were unable to sustain head lift for 5 sec.²⁸⁵ Similar results have been obtained in Sweden,²⁸⁶ Australia,²⁸⁷ Canada,²⁸⁴ and the United States.²⁸⁸ The incidence of train-of-four ratio 0.7 is about 30% following the use of the longer acting agents *d*-tubocurarine, pancuronium, alcuronium, and gallamine, but is reduced to 10% after using atracurium or vecuronium for operations lasting 2 h.^{284,289} Recovery from mivacurium is more rapid. However, if neuromuscular blockade is maintained up to the end of surgery and patients are moved rapidly to the PACU, residual block may be detected.²⁹⁰

Clinical Importance

Until recently, it was difficult to determine the importance of residual neuromuscular blockade. In a report on deaths occurring within 6 days of surgery, 11 of the 32 deaths due entirely to anesthesia were caused by postoperative ventilatory failure. The presence of neuromuscular block was considered to be contributory in 6 of those deaths.²⁹¹ Although intense residual block has been demonstrated in patients arriving in the PACU after cardiac surgery,^{292,293} the choice of intermediate or long-acting NMBD has not affected ICU or hospital length of stay.²⁹⁴ However, in 1997 Berg *et al* studied nearly 700 patients who randomly received pancuronium, vecuronium, or atracurium to produce surgical relaxation. In patients whose TOF ratio was <0.7 on arrival in the PACU and who had received pancuronium, the incidence of postoperative partial paralysis was three times greater than in patients receiving either of the two intermediate-acting drugs.²⁸⁹ Residual block is important.

Although TOF 0.7 has been taken as the gold standard for recovery of neuromuscular block, less intense blockade is associated with physiologic disturbances. Eriksson *et al* showed that, in volunteers, TOF 0.7 was associated with impaired ventilatory responses to hypoxia and disturbed esophageal motility,²⁷⁰ both of which may predispose to respiratory sequelae.

Anticholinesterase Pharmacology

The pharmacologic principle involved in the reversal of muscle relaxants is the reduction of the effect of competitive blocking drugs by increasing the concentration of ACh at the neuromuscular junction.

Mechanism of Action

Neostigmine, edrophonium, and pyridostigmine inhibit acetylcholinesterase, but this may not be the only mechanism by which blockade is antagonized.

Neostigmine and pyridostigmine are attached to the anionic and esteratic sites of the acetylcholinesterase molecule and produce longer-lasting inhibition than edrophonium. Neostigmine and pyridostigmine are inactivated by the interaction with the enzyme, whereas edrophonium is unaffected.²⁹⁵

Inhibition of acetylcholinesterase results in an increase in the amount of ACh that reaches the receptor and in the time that ACh remains in the synaptic cleft. This causes an increase in the size and duration of the endplate potentials.^{296,297} Anticholinesterases also have presynaptic effects. In the absence of neuromuscular blocking drugs, they potentiate the normal twitch response in a way similar to succinylcholine, probably as a result of the generation of action potentials that spread antidromically.¹⁶

Anticholinesterases have other effects at the junction than inhibition of acetylcholinesterase. For example, the relationship between the train-of-four ratio and T₁ depression is not the same for all agents.²⁹⁸ Also, anticholinesterases react with single ACh receptors *in vitro* to decrease channel open time.²⁹⁹

The three anticholinesterases have a ceiling effect, at least *in vitro*.³⁰⁰ Also, the effect of neostigmine may be modified by atropine³⁰¹ and by epinephrine, both of which augment the ability of neostigmine to reverse the blockade.

Neostigmine Block

Large doses of anticholinesterases, greater than those used clinically, may produce neuromuscular blockade. Fade of both EMG and MMG responses has been observed during tetanic stimulation after clinical doses of neostigmine³⁰² but not edrophonium³⁰³ were given to reverse neuromuscular blockade. Paradoxically, this neostigmine effect is antagonized with small doses of nondepolarizing relaxants. The mechanism involved is uncertain, but it appears to be of little clinical importance.

Potency

Dose–response curves have been constructed for edrophonium, neostigmine, and pyridostigmine. During a constant infusion of neuromuscular blocking drugs, the curves are obtained by plotting the peak effect versus the dose of reversal agent. In this situation, neostigmine was found to be ~12 times as potent as edrophonium.³⁰⁴ A similar relationship has been found during spontaneous recovery when the reversal agent was given at 10% T₁ recovery, and the values obtained at 10 min were used to construct the curves.³⁰⁵ Potency ratios are difficult to determine because the slopes of the edrophonium and neostigmine curves are not parallel. In addition, the slope for edrophonium is flatter for train-of-four recovery than for T₁ recovery,³⁰⁶ and the curves were shifted to the right when reversal of a more intense (99%) block was attempted³⁰⁷ (Fig. 16-18). There is no difference in the dose–response relationship of anticholinesterases if vecuronium is infused instead of pancuronium.³⁰⁸ However, there is a marked shift to the left for the curves obtained during vecuronium block if the reversal agent is given during spontaneous recovery.³⁰⁹

Figure 16-18. Dose–response curves for edrophonium and neostigmine in reversing 90% and 99% atracurium block. (Reprinted with permission from Donati F, Smith CE, Bevan DR: Dose–response relationships for edrophonium and neostigmine as antagonists of moderate and profound atracurium blockade. *Anesth Analg* 68:13, 1989.)

Pharmacokinetics

Following bolus iv injection, the plasma concentration of the anticholinesterases decreases rapidly during the first 5–10 min and then more slowly. Two-compartment analysis has demonstrated similar values for the three drugs.^{310,311} Volumes of distribution are in the range of 0.7–1.4 l · kg⁻¹ and the T_{1/2β} is 60–120 min. The drugs are water-soluble, ionized compounds so that their principal route of excretion is the kidney. Their clearances are in the range of 8–16 ml · kg⁻¹ · min⁻¹, which is much greater than the GFR because they are actively secreted into the tubular lumen.³¹² Their clearance is reduced markedly in patients in renal failure.

Pharmacodynamics

The onset of action of edrophonium (1–2 min) to peak effect is much more rapid than that of neostigmine (7–11 min) or pyridostigmine (15–20 min) (Fig. 16-19).^{304,313,314} and ³¹⁵ The reason for the differences is uncertain, but may be related to the different rates of binding to the enzyme.

Figure 16-19. Onset of action of edrophonium, neostigmine, and pyridostigmine in the reversal of 90% pancuronium block. (Data from Ferguson A, Egerszegi P, Bevan DR: Neostigmine, pyridostigmine, and edrophonium as antagonists of pancuronium. *Anesthesiology* 53:300, 1980).

The duration of action corresponds to their pharmacokinetic behavior. In practice, the recovery of neuromuscular activity after reversal has two components: slow recovery from the relaxant and rapid, augmented recovery induced by the reversal agent. No recurarization should be expected after reversal unless the duration of action of the relaxants exceeds that of the reversal agents.

Factors Affecting Reversal

Several factors modify the rate of recovery of neuromuscular activity after reversal.

Block Intensity

The more intense the block at the time of reversal, the longer the recovery of neuromuscular activity^{316,317} (Fig. 16-20). In addition, neostigmine is more effective than edrophonium or pyridostigmine in antagonizing intense (90%) blockade.³⁰⁷ When reversal is administered after spontaneous recovery to 25% T_1 has occurred, recovery is rapid and the time from reversal to TOF 0.7 is usually only a few minutes, although recovery after pancuronium may not be complete.³¹⁸ Thus, it has been recommended that reversal should not be attempted until T_1 is 25%³¹⁹ when four twitches to TOF stimulation are visible. The duration of action of atracurium (time from administration to TOF 0.7) is least when reversal is performed at TOF 0.04.³²⁰ Reversal can be attempted earlier, at least after small doses of rocuronium, vecuronium, and rapacurium, even as early as 2–5 min after administration of relaxant. However, the earlier that reversal is attempted, the longer is the time from reversal administration to TOF 0.7. In fact, the relaxant recovery time is similar when reversal is attempted at T_1 \geq 25%: shorter for rapacurium (17 min¹⁴³) than for rocuronium and vecuronium (27 min¹⁴⁴). Thus, there is little advantage in attempting early reversal except in situations where tracheal intubation and pulmonary ventilation are compromised.

Figure 16-20. Relationship between time to recovery and prereversal twitch height after reversal of alcuronium, a long-acting relaxant, or atracurium with edrophonium in children. (Reprinted with permission from Meretoja OA, Gebert R: Postoperative neuromuscular block following atracurium in children. *Can J Anaesth* 37:743, 1990.)

Anticholinesterase Dose

With more intense block a certain degree of recovery (TOF 0.7) can be obtained within a reasonable time (10 min) by increasing the dose of reversal agent. However, because of the ceiling effect, there is little benefit in administering $>0.07 \text{ mg} \cdot \text{kg}^{-1}$ neostigmine.

Attempts have been made to accelerate reversal by administering the anticholinesterase in divided doses, the priming principle. Although some acceleration can be demonstrated, the effect is small and of limited clinical importance.³²¹

Choice of Relaxant

Recovery of neuromuscular activity after reversal is dependent on the rate of spontaneous recovery as well as the acceleration induced by the reversal agent. Consequently, the overall recovery of short-acting agents (atracurium, vecuronium, mivacurium, rocuronium) following the same dose of anticholinesterase is more rapid than after pancuronium, *d*-tubocurarine, or gallamine.^{306,307,308} and ³⁰⁹ Conversely, the doses of reversal agent required to achieve the same degree of recovery are greater after the long-acting than the short-acting relaxants. For example, the dose of neostigmine required to achieve 80% twitch activity 10 min after reversal of 90% block is $\sim 40\text{--}50 \mu\text{g} \cdot \text{kg}^{-1}$ with pancuronium and *d*-tubocurarine; $20\text{--}30 \mu\text{g} \cdot \text{kg}^{-1}$ with atracurium, vecuronium,³⁰⁹ and rocuronium³²²; and $5 \mu\text{g} \cdot \text{kg}^{-1}$ with mivacurium.³²³ However, after prolonged infusions of vecuronium, spontaneous recovery becomes dependent upon elimination and metabolism rather than redistribution. Thus, the difference between vecuronium and pancuronium will be diminished because of their similar $T_{1/2}$.¹⁶²

Age

Recovery of neuromuscular activity occurs more rapidly³²⁴ with smaller doses³²⁵ of anticholinesterases in infants and children than in adults (Fig. 16-21). Thus, residual weakness in the PACU is found less frequently in children than in adults.³²⁶ Although the clearance of nondepolarizing relaxants is decreased in the elderly, the speed and extent of recovery after reversal are not affected, probably because the elimination of anticholinesterases is also reduced.

Figure 16-21. Comparison of recovery after reversal of 90% pancuronium blockade with neostigmine in adults and children. (Reprinted with permission from Meakin G, Sweet PT, Bevan JC *et al*: Neostigmine and edrophonium as antagonists of pancuronium in infants and children. *Anesthesiology* 59:316, 1983.)

Drug Interaction

Several drugs potentiate the action of neuromuscular blocking drugs, but there are few reports of impaired reversal. In the presence of enflurane and isoflurane, the reversal of pancuronium and vecuronium blockade is impaired, but only if the administration of the vapor is continued during reversal.³²⁷

Renal Failure

Anticholinesterases are actively secreted into the tubular lumen³¹² so that their clearance is reduced in renal failure.^{310,311} The rate and extent of recovery of pancuronium in renal failure after neostigmine are not impaired in renal failure, and “recurarization” does not occur.³²⁸

Acid–Base Balance, Electrolytes

The influence of acid–base disturbances on the reversal of neuromuscular blockade is poorly understood. Although it has been suggested that reversal is impaired in the ill, cachectic patient (neostigmine-resistant curarization) as a result of acidosis, this has been difficult to confirm in the laboratory.³²⁹

In addition to the prolonged block induced by magnesium sulfate, the recovery of vecuronium-induced block was prolonged in patients who had received $60 \mu\text{g} \cdot \text{kg}^{-1} \text{MgSO}_4$.³³⁰

Other Effects

Cardiovascular

Anticholinesterases provoke profound vagal stimulation. The time course of the vagal effects parallels the reversal of block: rapid for edrophonium and slower for neostigmine. However, the bradycardia and bradyarrhythmias can be prevented with anticholinergic agents. Atropine has a rapid onset of action (1 min), duration of 30–60 min, and crosses the blood–brain barrier. Its time course makes it appropriate for use in combination with edrophonium,³⁰⁴ whereas glycopyrrolate (onset 2–3 min) is more suitable with neostigmine or pyridostigmine. Because glycopyrrolate does not cross the blood–brain barrier, the incidence of memory deficits after anesthesia is less than that after atropine.³¹⁴ If atropine is given with neostigmine, the dose is approximately half that of neostigmine (atropine $20 \mu\text{g} \cdot \text{kg}^{-1}$ versus neostigmine $40 \mu\text{g} \cdot \text{kg}^{-1}$). Such a combination leads to an initial tachycardia followed by a slight bradycardia. Atropine requirements are less with edrophonium (atropine $7\text{--}10 \mu\text{g} \cdot \text{kg}^{-1}$ versus edrophonium $0.5 \text{mg} \cdot \text{kg}^{-1}$).

Other Cholinergic Effects

Anticholinesterases produce increased salivation and bowel motility. Although atropine blocks the former, it appears to have little effect on peristalsis. Some reports claim an increase in bowel anastomotic leakage after the reversal of neuromuscular blockade.³³¹ Others have held the use of anticholinesterases to be responsible for an increased incidence of vomiting after ambulatory surgery.³³²

Respiratory Effects

Anticholinesterases may cause an increase in airway resistance, but anticholinergics reduce this effect. Several other factors, such as pain, the presence of an endotracheal tube, or light anesthesia, may predispose to bronchoconstriction at the end of surgery so that it is difficult to incriminate the reversal agents.

Clinical Use

Several reversal regimens have been proposed and are effective. In general, the more intense the block, the greater the dose of anticholinesterase that is required. However, there does not seem to be any advantage in giving more than the equivalent of neostigmine $0.07 \text{mg} \cdot \text{kg}^{-1}$. Neostigmine is preferred to edrophonium for intense block, but the rapid action of edrophonium has the advantage of allowing the extent of reversal to be assessed in the operating room.

INTRODUCTION

Local anesthetics block the generation, propagation, and oscillations of electrical impulses in electrically excitable tissue. Use of local anesthetics in clinical anesthesia is varied and includes direct injection into tissues, topical application, and intravenous administration to produce clinical effects at varied locations including the central neuraxis, peripheral nerves, mucosa, skin, heart, and airway. Detailed knowledge of pertinent anatomy and pharmacology will aid in optimal therapeutic use of local anesthetics. Care should be taken to avoid potential central nervous system and cardiovascular toxicity from local anesthetics.

Cocaine was the first local anesthetic used (1884) but eventually fell into disfavor owing to its toxicity and addiction potential. The first aminoester local anesthetic, procaine, was introduced in 1905, and the first aminoamide local anesthetic, lidocaine, was introduced in 1944. Commercial release of these agents, which possessed high efficacy and low toxicity, revitalized the use of local anesthetics for regional anesthesia and other clinical applications. Many local anesthetics have been introduced since then, with ropivacaine (1996) and *levo*-bupivacaine (2000) representing the latest offerings. This chapter reviews: (1) mechanisms of action of local anesthetics for neural blockade; (2) pharmacology and pharmacodynamics of local anesthetics; (3) pharmacokinetics of local anesthetics; (4) clinical use of local anesthetics; (5) toxicity of local anesthetics; and (6) new local anesthetics and local anesthetic preparations.

MECHANISMS OF ACTION OF LOCAL ANESTHETICS

Anatomy of Nerves

Local anesthetics are often used to block nerves either peripherally or centrally. Knowledge of the anatomy of nerves will aid in understanding mechanism of action of local anesthetics. Peripheral nerves are mixed nerves containing afferent and efferent fibers that may be myelinated or unmyelinated. Each axon within the nerve fiber is surrounded by endoneurium composed of nonneural glial cells. Individual nerve fibers are gathered into fascicles and surrounded by perineurium composed of connective tissue. Finally, the entire peripheral nerve is encased by epineurium composed of dense connective tissue (Fig. 17-1). Thus, several layers of protective tissue surround individual axons, and these layers act as barriers to the penetration of local anesthetics.¹ In addition to the enveloping connective tissue, all mammalian nerves with a diameter greater than 1 μm are myelinated. Myelinated nerve fibers are segmentally enclosed by Schwann cells forming a bilayer lipid membrane that is wrapped several hundred times around each axon.² Thus, myelin accounts for over half the thickness of nerve fibers > 1 μm (Fig. 17-2). Separating the myelinated regions are the nodes of Ranvier where structural elements for neuronal excitation are concentrated (Fig. 17-3).³ The nodes are covered by interdigitations from nonmyelinating Schwann cells⁴ and by negatively charged glycoproteins. Although axonal membranes are not freely in contact with their environment at the nodes, these areas do allow passage of drugs and ions.⁵ Furthermore, the negatively charged proteins may bind basic local anesthetics and thus act as a depot. Unmyelinated nerve fibers (diameter <1 μm) are encased by a Schwann cell that covers several (5–10) fibers at once (Fig. 17-2). These fibers are continuously encased by Schwann cells and do not possess interruptions (nodes of Ranvier). The existence of multiple protective layers around both myelinated and unmyelinated nerve fibers presents a substantial barrier to the entry of clinically used local anesthetics. For example, animal models suggest that only 1.6% of an injected dose of local anesthetic penetrates into the nerve following performance of peripheral nerve blocks.⁶

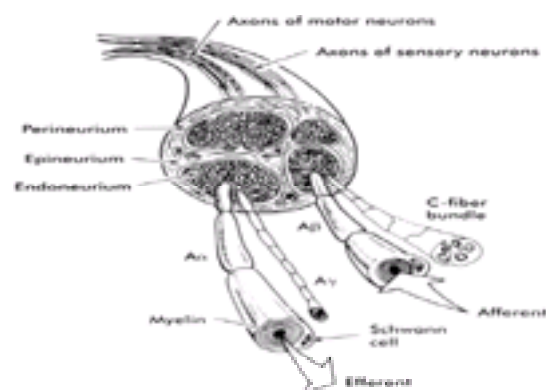

Figure 17-1. Schematic cross section of typical peripheral nerve. The epineurium, consisting of collagen fibers, is oriented along the long axis of the nerve. The perineurium is a discrete cell layer, whereas the endoneurium is a matrix of connective tissue. Both afferent and efferent axons are shown. Sympathetic axons (not shown) are also present in mixed peripheral nerves. (Adapted with permission from Strichartz GR: Neural physiology and local anesthetic action. In Cousins MJ, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain, p 35. Philadelphia, Lippincott–Raven, 1998.)

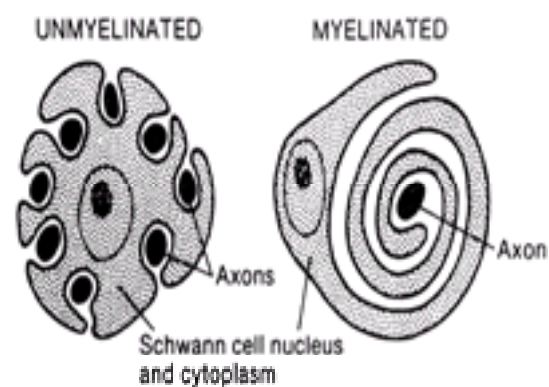

Figure 17-2. Schwann cells form myelin around one myelinated axon or encompass several unmyelinated axons. (Adapted with permission from Carpenter RL, Mackey DC: Local anesthetics. In Barash PG, Cullen BF, Stoelting RF (eds): Clinical Anesthesia, p 413. Philadelphia, Lippincott–Raven, 1996.)

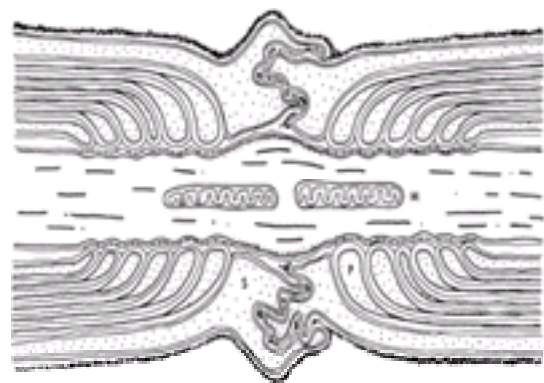

Figure 17-3. Diagram of node of Ranvier displaying mitochondria (M), tight junctions in paranodal area (P), and Schwann cell (S) surrounding node. (Adapted with permission from Strichartz GR: Mechanisms of Action of Local Anesthetic Agents. In Rogers MC, Tinker JH, Covino BG, Longnecker DE (eds): Principles and Practice of Anesthesiology, p 1197. St. Louis, Mosby–Year Book, 1993.)

Nerve fibers are commonly classified by size, conduction velocity, and function (Table 17-1). In general, increasing myelination and nerve diameter lead to increased conduction velocity. The presence of myelin accelerates conduction velocity due to increased electrical insulation of nerve fibers and saltatory conduction. Increased nerve diameter accelerates conduction velocity both by increased myelination and by improved electrical cable conduction properties of the nerve. Myelinated and unmyelinated nerves carry out both afferent and efferent functions.

| Classification | Diameter (µm) | Myelin | Conduction (m/sec) | Location | Function |
|----------------|---------------|--------|--------------------|---|---------------------------------------|
| A alpha | 4-2 | + | 35-200 | Motors to and efferent from muscle and joints | Vision and proprioception |
| A beta | 3-4 | + | 15-55 | Efferent to muscle groups | Touch |
| A gamma | 1-4 | + | 5-25 | Intrinsic sensory nerve | Touch |
| A delta | 1-4 | + | 5-25 | Intrinsic sensory nerve | Touch, Temperature |
| B | <1 | + | 3-5 | Parasympathetic efferent | Intrinsic function |
| C | 0.5-1.5 | - | 0.5-1.5 | Parasympathetic efferent, Intrinsic sensory nerve | Intrinsic function, Pain, Temperature |

Table 17-1. CLASSIFICATION OF NERVE FIBERS

Electrophysiology of Neural Conduction

Ionic disequilibria across semipermeable membranes form the basis for neuronal resting potentials and for the potential energy needed to initiate and maintain electrical impulses. The resting potential of neural membranes averages -60 to -70 mV, with the interior being negative to the exterior. This resting potential is predominantly maintained by a potassium gradient with 10 times greater concentration of potassium within the cell. This gradient is maintained by an active protein pump that transports potassium into the cell and sodium out of the cell through voltage-gated potassium channels that are open at resting potentials.⁷ Potassium equilibrium is not the only factor in resting potential, as a resting potential of approximately -90 mV is predicted by the Nernst equation if only potassium is considered. In addition to potassium channels, voltage-independent channels that allow “leak” currents of sodium, chloride, and other ions affect the resting potential.

In contrast to the dependence of resting membrane potential on potassium disequilibria, generation of action potentials is primarily due to activation of voltage-gated sodium channels.⁷ These channels are protein structures spanning the bilayer lipid membrane composed of structural elements, an aqueous pore, and voltage-sensing elements that control passage of ions through the pore (Fig. 17-4).⁸ Sodium channels exist in several conformations depending on membrane potential and time. At resting membrane potential, sodium channels predominantly exist in a resting (closed) conformation.^{7,9} During membrane depolarization, channels open within a few hundred microseconds and allow passage of 10^7 ions \cdot sec⁻¹. Sodium channels are relatively selective, but other monovalent ions can also gain passage through the channel. For example, lithium traverses about as well as sodium, whereas potassium only about one tenth as well. Following activation (opening) of the sodium channel and depolarization, the channel will spontaneously close into an inactivated state in a time-dependent fashion to allow repolarization, then revert to a resting conformation.¹⁰ Thus, a three-state kinetic scheme (Fig. 17-5) conceptualizes the changes in sodium channel conformation that account for changes in sodium conductance during depolarization and repolarization.

Figure 17-4. Diagram of bilayer lipid membrane of conductive tissue with sodium channel (cross-hatching) spanning the membrane. Tertiary amine local anesthetics exist as neutral base (N) and protonated, charged form (NH⁺) in equilibrium. The neutral base (N) is more lipid-soluble, preferentially partitions into the lipophilic membrane interior, and easily passes through the membrane. The charged form (NH⁺) is more water-soluble and binds to the sodium channel at the negatively charged membrane surface. Both forms can affect function of the sodium channel. The N form can cause membrane expansion and closure of the sodium channel. The NH⁺ form will directly inhibit the sodium channel by binding with a local anesthetic receptor. The natural “local anesthetic” tetrodotoxin (TTX) binds at the external

surface of the sodium channel and has no interaction with clinically used local anesthetics. (Adapted with permission from Strichartz GR: Neural physiology and local anesthetic action. In Cousins MJ, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain, p 35. Philadelphia, Lippincott-Raven, 1998.)

Figure 17-5. Illustration of dominant form of sodium channel during generation of an action potential. R = resting form; O = open form; I = inactive form. (A) The concurrent generation of an action potential as the membrane depolarizes from resting potential. (B) Concurrent changes in ion flux, as inward sodium current (I_{Na^+}) and outward potassium current (I_{K^+}) together yield the net ionic current across the membrane (I_i). (Adapted with permission from Strichartz GR: Neural physiology and local anesthetic action. In Cousins MJ, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain, p 35. Philadelphia, Lippincott-Raven, 1998.)

An action potential will be generated by depolarization when the impulse firing threshold of the axon is reached. That is the point at which no further depolarization is required for local processes to generate a complete action potential. This threshold is not an absolute voltage, but rather depends on the dynamics of the sodium and potassium channels. For example, a brief maximally depolarizing stimulus will not generate an action potential because there is insufficient time for sodium channels to open. Nor will a depolarizing stimulus that increases too slowly create an action potential. As the stimulus slowly increases, initially activated sodium channels will spontaneously inactivate, so there will never be enough open channels at one time to generate an action potential. Furthermore, voltage-sensitive potassium channels would begin to increase potassium conductance that would further inhibit generation of an action potential. Thus, successful generation of an action potential requires a depolarizing stimulus of correct intensity and duration.

Once an action potential is generated, propagation of the potential along the nerve fiber is required for information to be transmitted. Both impulse generation and propagation are “all or nothing” phenomena. In the case of impulse propagation, either the locally generated action potential reaches the threshold potential of adjacent segments and causes propagation along the nerve, or the local depolarization ends. Nonmyelinated fibers require achievement of threshold potential at the immediately adjacent membrane, whereas myelinated fibers require generation of threshold potential at a subsequent node of Ranvier.

Repolarization after action potential generation and propagation rapidly follows owing to increasing equilibria of internal and external sodium ions, a time-controlled decrease in sodium conductance, and a voltage-controlled increase in potassium conductance.¹¹ In addition, active internal concentration of potassium occurs via the membrane-bound enzyme Na^+ / K^+ -ATPase which extrudes three sodium ions for every two potassium ions that are absorbed. Although many mammalian nonmyelinated nerve fibers develop a period of hyperpolarization after the action potential, myelinated nerve fibers return directly to resting membrane potential.¹¹

Molecular Mechanisms of Action of Local Anesthetics

Most evidence indicates that the sodium channel is the key target of local anesthetic activity. The wide variety of compounds that exhibit local anesthetic activity combined with the different effects of neutral and charged local anesthetics suggests that local anesthetics may act on the sodium channel either by modification of the lipid membrane surrounding it or by direct interaction with its protein structure.

Previous studies have demonstrated that anesthetics can reduce sodium conductance through sodium channels by interacting with the surrounding lipid membrane.¹² Alterations in neuronal membranes by local anesthetics can occur by altering the fluidity of the membrane that causes membrane expansion and subsequent closure of the sodium channel. Furthermore, alterations in membrane composition may lower the probability of occurrence of the open sodium channel state. Such observations can account for local anesthetic actions of neutral and lipophilic local anesthetics, but do not explain the different activity of clinically used, tertiary amine local anesthetics (e.g., lidocaine).

Instead, the mechanisms of action of these local anesthetics are best explained by direct interaction with the sodium channel (modulated receptor theory).^{13,14} The commonly used tertiary amine local anesthetics exist in free equilibrium as both a lipid-soluble neutral form and a hydrophilic, charged form depending on pK_a and environmental pH. Although the neutral form may exert anesthetic actions as described above, the cationic species is clearly the more potent form (see Fig. 17-4).¹⁴ These tertiary amine local anesthetics also demonstrate greater sodium channel blockade when the neural membrane is repetitively depolarized (1-100 Hz),^{15,16} whereas neutral local anesthetics exhibit little change in activity with increased frequency of stimulation (use-dependent block). Increasing frequency of stimulation increases the probability that sodium channels will exist in the open and inactive forms as compared to the unstimulated state. Thus, differences in activity of tertiary amine local anesthetics between use-dependent (repetitive stimulation) and tonic (unstimulated) block are well explained by the existence of a single local anesthetic receptor within the sodium channel that possesses different affinities during different channel conformations (resting, open, inactive). Specifically, higher affinities occur during the open and inactive phases. In support of this theory, when the affinity of inactive channels for local anesthetics is decreased through genetic manipulation, use-dependent block is abolished.¹⁷

Molecular manipulation of the sodium channel is beginning to reveal specifics of the local anesthetic receptor. Binding sites to local anesthetics are located on the intracellular side of the sodium channel, may have different binding areas during the open and inactivated conformations of the sodium channel, and possess stereoselectivity with preference for the R isomers.^{9,18,19} The use of molecular techniques to determine exact binding sites for different actions of local anesthetics and the development of tailored agonists to these binding sites may, in future, create more effective local anesthetics that are specific for tonic or use-dependent block.

Mechanism of Blockade of Peripheral Nerves

Local anesthetics may block function of peripheral nerves through several mechanisms. As discussed above, sodium channel blockade leads to attenuation of neural action potential formation and propagation. Although it remains unknown in humans by what percent the neural action potential must be decreased before functional block occurs, recent animal studies suggest that the action potential must be decreased by at least 50% before measurable loss of function is observed.⁶ Previous studies have examined the differences in susceptibility of nerve fiber to local anesthetic blockade based on size, myelination, and length of fiber exposed to local anesthetic. Clinically, one can often discern a differential pattern of sensory block after application of local anesthetic to a peripheral nerve.²⁰ Classically, the sensation of temperature is lost, followed by sharp pain, then light touch. Thus, an initial assumption was that small, unmyelinated (C) fibers conducting temperature sensation were inherently more susceptible to local anesthetic blockade than large, myelinated (A) fibers conducting touch. However, experimental studies reveal a more complex picture. When local anesthetic block is restricted to 1 cm of the length of a nerve, A fibers exhibit a greater susceptibility to tonic block than do C fibers. In contrast, C fibers are more susceptible to use-dependent block.¹⁶ Differential block of large and small nerve fibers is also affected by choice of local anesthetic. Those with an amide group, high pK_a , and lower lipid solubility are more potent blockers of C fibers. Thus, experimental studies indicate that local anesthetic block of nerve fibers will intrinsically depend on type (size) of fiber, frequency of membrane stimulation, and choice of local anesthetic.^{15,21}

During clinical applications, it is likely that >1 cm of the peripheral nerve is exposed to local anesthetic. For example, sciatic nerve blocks in humans probably result in 5–10 cm of affected nerve length.⁶ In such a situation, the exposure length of the nerve fiber becomes an important determinant of blocking susceptibility.^{22,23} Small nerve fibers require a shorter length of fiber exposed to local anesthetic for block to occur than do large fibers. It is theorized that this observation is due to *decremental conduction*.²³ This phenomenon describes the decreased ability of successive nodes of Ranvier to propagate an impulse in the presence of local anesthetic (Fig. 17-6). As internodal distances become greater with increasing nerve fiber size,²⁴ larger nerve fibers will demonstrate increasing resistance to local anesthetic block. Thus, this theory provides an explanation for the clinical occurrence of differential sensory block.

Figure 17-6. Diagram illustrating the principle of decremental conduction block by local anesthetic at a myelinated axon. The first node of Ranvier at left contains no local anesthetic and gives rise to a normal action potential (*solid curve*). If the nodes succeeding the first are occupied by a concentration of local anesthetic high enough to block 74–84% of the sodium conductance, the action potential amplitudes decrease at successive nodes (amplitudes are indicated by interrupted bars representing three increasing concentrations of local anesthetic). Eventually, the impulse decays to below-threshold amplitude if the series of local anesthetic containing nodes is long enough. Propagation of the impulse has then been blocked by decremental conduction, even though none of the nodes is completely blocked. Concentrations of local anesthetic that block more than 84% of the sodium conductance at three successive nodes prevent any impulse propagation at all. (Adapted with permission from Fink BR: Mechanisms of differential axial blockade in epidural and spinal anesthesia. *Anesthesiology* 70:851, 1989.)

A final mechanism whereby local anesthetics may block peripheral nerve function is *via* degradation of transmitted electrical patterns. It is theorized that a large part of the sensory information transmitted *via* peripheral nerves is carried *via* coding of electrical signals in after-potentials and after-oscillations.²⁵ Evidence for this theory is found in studies demonstrating loss of sensory nerve function after incomplete local anesthetic blockade. For example, sensation of temperature of the skin can be lost despite unimpeded conduction of small fibers.²⁶ Furthermore, a surgical depth of epidural and peripheral nerve block anesthesia can be obtained with only minor changes in somatosensory-evoked potentials from the anesthetized area.^{27,28} Previous studies have demonstrated that application of sub-blocking concentrations of local anesthetic will suppress normally occurring after-potentials and after-oscillations without significantly affecting action potential conduction.²⁹ Thus, disruption of coding of electrical information by local anesthetics may be another mechanism for block of peripheral nerves.

Mechanism of Blockade of Central Neuraxis

Central neuraxial block *via* spinal or epidural administration of local anesthetics involves the same mechanisms at the level of spinal nerve roots, either intra- or extradural, as discussed above. In addition, central neuraxial administration of local anesthetics allows multiple potential actions of local anesthetics within the spinal cord at different sites. For example, within the dorsal horn, local anesthetics can exert familiar ion channel block of sodium and potassium channels in dorsal horn neurons and inhibit generation and propagation of nociceptive electrical activity.³⁰ Similar actions in the ventral horn may contribute to block of motor activity from central neuraxial administration of local anesthetics. Other spinal cord neuronal ion channels, such as calcium channels, are also important for afferent and efferent electrical activity. Administration of calcium channel blockers to spinal cord N (neuronal) calcium channels results in hyperpolarization of cell membranes, resistance to electrical stimulation from nociceptive afferents, and intense analgesia.³¹ Local anesthetics appear to have similar actions on calcium channels, which may contribute to analgesic actions of central neuraxially administered local anesthetics.³²

In addition to ion channels, multiple neurotransmitters are involved in nociceptive transmission in the dorsal horn of the spinal cord.³³ For example, substance P, the archetypal tachykinin, is an important neurotransmitter that modulates nociception from C fibers and is released from presynaptic terminals of dorsal root ganglion cells.³⁴ Administration of local anesthetics in concentrations that occur after spinal and epidural anesthesia inhibits release of substance P and may exert analgesic actions by presynaptic actions.³⁵ Other neurotransmitters that are important for nociceptive processing in the spinal cord, such as acetylcholine and γ -aminobutyric acid (GABA), are also affected by local anesthetics in the presynaptic area. Local anesthetics can affect these analgesic pathways by either directly binding to receptors or by altering local pharmacokinetics of endogenous agonists.^{36,37} and ³⁸ Finally, local anesthetics can also affect the postsynaptic effects of nociceptive neurotransmitters. Administration of clinically relevant concentrations of local anesthetics inhibits binding of substance P to its receptor in the central neuraxis in a noncompetitive fashion.³⁹ These studies suggest that antinociceptive effects of central neuraxial local anesthetic block may be mediated *via* complex interactions at neural synapses in addition to ion channel blockade.

PHARMACOLOGY AND PHARMACODYNAMICS

Chemical Properties and Relationship to Activity and Potency

The clinically used local anesthetics consist of a lipid-soluble, substituted benzene ring linked to an amine group (tertiary or quaternary depending on pK_a and pH) *via* an alkyl chain containing either an amide or ester linkage (Fig. 17-7). The type of linkage separates the local anesthetics into either *aminoamides*, metabolized in the liver, or *aminoesters*, metabolized by plasma cholinesterases. Several chemical properties of local anesthetics will affect their efficacy and potency.

All clinically used local anesthetics are weak bases that can exist as either the lipid-soluble, neutral form or as the charged, hydrophilic form. The combination of pH of the environment and pK_a , or dissociation constant, of a local anesthetic determines how much of the compound exists in each form (Table 17-2). As previously discussed, the primary site of action of local anesthetics appears to exist on the intracellular side of the sodium channel, and the charged form appears to be the predominantly active form.¹⁴ Penetration of the lipid-soluble form through the lipid neural membrane appears to be the primary form of access of local anesthetic molecules, although some access by the charged form can be gained *via* the aqueous sodium channel pore (see Fig. 17-5).⁴⁰ Thus, decreasing pK_a for a given environmental pH will increase the percentage of lipid-soluble forms in existence, hastening penetration of neural membranes and onset of action.

Table 17-2. PHYSICOCHEMICAL PROPERTIES OF CLINICALLY USED LOCAL ANESTHETICS

Lipid solubility is another important determinant of activity. Although increasing lipid solubility may hasten penetration of neural membranes, increasing solubility may also result in increased sequestration of local anesthetic in myelin and other lipid-soluble compartments. Thus, increasing lipid solubility usually slows the rate of onset of action.⁴¹ Similarly, duration of action is increased as absorption of local anesthetic molecules into myelin and surrounding neural compartments creates a depot for slow release of local anesthetics.⁴¹ Finally, increased lipid solubility increases potency of the local anesthetic.^{12,13} This observation may be explained by a correlation between lipid solubility and both sodium channel receptor affinity and ability to alter sodium channel conformation by direct effects on lipid cell membranes.

Degree of protein binding also affects activity of local anesthetics, as only the unbound form is free for pharmacologic activity. In general, increasing protein binding is associated with increased duration of action. Although the sodium channel is a protein structure, it does not appear that degree of local anesthetic protein binding correlates with binding to the local anesthetic receptor. Studies suggest that dissociation of local anesthetic molecules from the sodium channel occurs in a matter of seconds regardless of degree of protein binding of the local anesthetic.⁴² Thus, prolongation in duration of action associated with an increased degree of protein binding must involve other extracellular or membranous proteins.

A final physical property of current interest is stereoisomeric mixture of the commercially available local anesthetics. All currently available local anesthetics are racemic mixtures with the exception of lidocaine (achiral), ropivacaine (S), and *levobupivacaine* (l = S).^{43,44} Stereoisomers of local anesthetics appear to have potentially different effects on anesthetic potency, pharmacokinetics, and systemic toxicity.^{43,45} For example, R isomers appear to have greater *in vitro* potency for block of both neural and cardiac sodium channels and may thus have greater therapeutic efficacy and potential systemic toxicity.^{19,46} A complete analysis of clinical effects resulting from the potential differences in pharmacology between optical isomers has not been undertaken, nor have optimal mixtures of optical isomers been determined. Future production and commercial release of specific local anesthetic isomers may allow for precise selection of not only type of local anesthetic but also exact racemic mixtures for specific applications. (Ropivacaine and *levobupivacaine* are discussed in the section on New and Future Local Anesthetics.)

Relative *in vitro* potencies of the clinically used local anesthetics have been identified and vary depending on individual nerve fibers and frequency of stimulation (Table 17-3). As previously mentioned, increasing nerve size and increasing rate of electrical stimulation increase susceptibility to local anesthetic blockade for affected nerve length <1 cm. In general, increasing lipid solubility of local anesthetic correlates with increasing anesthetic potency (see Table 17-2).⁴⁷ However, clinical use of local anesthetics is more complex than the bathing of nerve fibers in solutions, and *in vivo* potencies often do not correlate with *in vitro* determinants.⁴⁸ Local factors affecting diffusion and spread of anesthetic will have great impact on clinical effects and will vary with different applications (e.g., peripheral nerve block vs. spinal injection). Furthermore, clinical use may not require absolute suppression of the compound action potential, but rather a disruption of information coding in the pattern of discharges. Few rigorous studies have been performed to evaluate relative clinical potencies of local anesthetics, and commonly accepted values are listed in Table 17-4.

| Local Anesthetic | Nerve Fiber | | | | | |
|------------------------|-------------|-----|-----|---------------------|------|------|
| | Tonic Block | | | Use-Dependent Block | | |
| | A | B | C | A | B | C |
| Bupivacaine | 123 | 84 | 59 | 16 | 213 | 247 |

Table 17-4. RELATIVE POTENCY OF LOCAL ANESTHETICS FOR DIFFERENT CLINICAL APPLICATIONS

Mixtures of Local Anesthetics

Combining a quick-acting local anesthetic (chlorprocaine, lidocaine, prilocaine) with one having a long duration of action (bupivacaine, etidocaine) is practiced by some clinicians. The value of such combinations is unclear, as previous studies have reported inconsistent effects on onset and duration of action that may vary with type of local anesthetic, ratio of local anesthetic mixtures, and type of neural block.^{49,50} These disparate findings may reflect the complexity of potential interactions of mixtures of local anesthetics. Actions of local anesthetic combinations could be due to additive, antagonistic, or synergistic actions at the local anesthetic receptor; to effects on permeability of component local anesthetics through tissue barriers; or to changes in uptake of component local anesthetics.⁵⁰ Thus, current evidence does not allow conclusions regarding effectiveness of mixing local anesthetics. However, systemic toxicity appears to be additive, and caution should be used to limit total doses of local anesthetic mixtures.^{51,52}

Tachyphylaxis to Local Anesthetics

Tachyphylaxis to local anesthetics is a clinical phenomenon whereby repeated injection of the same dose of local anesthetic leads to decreasing efficacy. Tachyphylaxis has been described after central neuraxial blocks, peripheral nerve blocks, and for different local anesthetics.^{53,54} An interesting clinical feature of tachyphylaxis to local anesthetics is its dependence on dosing interval. If dosing intervals are short enough such that pain does not occur, tachyphylaxis does not

develop. Conversely, longer periods of patient discomfort before redosing hastens development of tachyphylaxis.⁵³ Previous studies investigating the etiology of tachyphylaxis have found little pharmacokinetic or -dynamic change after repeated doses of local anesthetics. For example, with the development of clinical tachyphylaxis, there is no difference in local anesthetic spread within or clearance from the epidural space.⁵⁵ Changes in pH of the surrounding tissues do not affect the development of tachyphylaxis.⁵⁴ Prolonged exposure of peripheral nerve and neural cells to local anesthetic does not affect either flux through sodium channels⁵⁶ or propagation of the action potential over time.⁵⁷ The lack of an etiology, coupled with the observation that pain is important for the development of tachyphylaxis, led to speculation that there is a central, spinal mechanism for tachyphylaxis *via* spinal cord sensitization. A series of studies in 1994 lend support to this theory.⁵⁸ Rats receiving repeated sciatic nerve blocks with 2-chloroprocaine and lidocaine failed to develop tachyphylaxis in the absence of noxious stimulation. Exposure of the rats to increasingly noxious degrees of thermal stimulation increasingly hastened development of tachyphylaxis, whereas pretreatment with a NMDA antagonist (MK-801) that prevents spinal cord sensitization also prevented development of tachyphylaxis. Second-messenger effects of nitric oxide for NMDA pathways may be especially important, as administration of nitric oxide synthase inhibitors prevented development of tachyphylaxis in a dose-dependent manner in the same model.⁵⁹ The clinical relevance of these findings needs to be explored, but the development of a plausible etiology for local anesthetic tachyphylaxis may lead to useful clinical means for its prevention.

Additives to Increase Local Anesthetic Activity

Epinephrine

Epinephrine has been added to local anesthetics since the early 1890s.⁶⁰ Reported benefits of epinephrine include prolongation of local anesthetic block,⁶¹ increased intensity of block,⁶² and decreased systemic absorption of local anesthetic.⁶³ The mechanism whereby epinephrine augments local anesthetic actions remains uncertain. It is commonly theorized that vasoconstriction plays an important role,⁶⁴ as most local anesthetics, with the exception of ropivacaine,⁶⁵ produce local vasodilation.⁶⁶ Local vasoconstriction would theoretically inhibit systemic absorption of local anesthetic, thus allowing a greater amount available for blocking activity. Further analgesic effects from epinephrine may also occur *via* interaction with α_2 -adrenergic receptors in the brain and spinal cord,⁶⁷ especially since local anesthetics increase the vascular uptake of epinephrine.⁶⁸ Although most reports support the practice of adding epinephrine, reported effectiveness depends on amount of epinephrine added, local anesthetic used, and type of regional block (Table 17-5). It is unfortunate that few data are available concerning the optimal amount of epinephrine as an additive. The smallest dose should be used, as epinephrine combined with local anesthetics may have toxic effects on tissue,⁶⁹ the cardiovascular system,⁷⁰ peripheral nerves, and the spinal cord.^{33,60}

| | Increase Duration | Decrease Blood Levels (%) | Dose/Concentration of Epinephrine |
|--------------------|-------------------|---------------------------|-----------------------------------|
| NERVE BLOCK | | | |
| Bupivacaine* | ++ | 10-20 | 1:200,000 |

Table 17-5. EFFECTS OF ADDITION OF EPINEPHRINE TO LOCAL ANESTHETICS

Alkalinization of Local Anesthetic Solution

Since the late 1800s, local anesthetic solutions have been alkalinized in order to hasten onset of neural block.⁷¹ The pH of commercial preparations of local anesthetics ranges from 3.9 to 6.47 and is especially acidic if prepackaged with epinephrine.⁷² As the pK_a of commonly used local anesthetics ranges from 7.6 to 8.9 (see Table 17-2), less than 3% of the commercially prepared local anesthetic exists as the lipid-soluble neutral form. As previously discussed, the neutral form is believed to be the most important for penetration into the neural cytoplasm, whereas the charged form primarily interacts with the local anesthetic receptor within the sodium channel. Therefore, the initial rationale for alkalinization was to increase the percentage of local anesthetic existing as the lipid-soluble neutral form. However, clinically used local anesthetics cannot be alkalinized beyond a pH of 6.05–8 before precipitation occurs,⁷² and such pHs will only increase the neutral form to about 10%. Although a tripling of available local anesthetic (from 3% to 10%) will improve efficacy, recent studies have proposed several other mechanisms for the effects of alkalinization.

In general, clinical studies demonstrate increased activity of alkalinized local anesthetic only when epinephrine is present, either prepackaged or freshly added.⁷³ Although prepackaged epinephrine-containing solutions are quite acidic, fresh addition of epinephrine does not alter the pH of the more alkaline, plain local anesthetic solutions.⁷² Thus, the association between increased local anesthetic activity with alkalinization and epinephrine does not appear to be due solely to increased acidity with epinephrine. On the other hand, the vasoconstrictive effects of epinephrine are also pH-dependent. At a pH less than 5.6, little vasoconstriction is seen, and maximal vasoconstriction occurs around a pH of 7.8. Therefore, alkalinization may affect activity of local anesthetic by activation of vasoconstrictive effects of epinephrine.

A series of studies examining desheathed nerve fibers suggested multiple mechanisms of interaction between bicarbonate and local anesthetic independent of neural penetration.⁷⁴ Alkalinization of the local environment by itself inhibited neural impulse conduction. Furthermore, addition of bicarbonate potentiates local anesthetic block of impulse conduction specific to type of local anesthetic. This finding suggests a specific interaction at the local anesthetic receptor within the sodium channel. Thus, it is likely that alkalinization of local anesthetics works through multiple mechanisms to affect local anesthetic activity. Alkalinization of local anesthetics presents an easy, attractive means to alter activity of local anesthetics,⁷³ especially as toxicity is not increased.⁶⁰

Opioids

Addition of opioids to local anesthetics has gained popularity. Opioids have multiple central neuraxial and peripheral mechanisms of analgesic action (see Chapter 14). Supraspinal administration of opioids results in analgesia *via* opiate receptors in multiple sites,⁷⁵ *via* activation of descending spinal pathways,⁷⁶ and *via* activation of nonopioid analgesic pathways.⁷⁷ Spinal administration of opioids provides analgesia primarily by attenuating C fiber nociception,⁷⁸ and is independent of supraspinal mechanisms.⁷⁹ Co-administration of opioids with most local anesthetics epidurally⁸⁰ and intrathecally⁸¹ results in synergistic analgesia.⁸² An exception to this analgesic synergy is 2-chloroprocaine, which appears to decrease the effectiveness of epidural opioids when used for epidural anesthesia.⁸³ The mechanism for this action is unclear but does not appear to involve direct antagonism of opioid receptors.⁸⁴ Overall, clinical studies support the practice of central neuraxial co-administration of local anesthetics and opioids in humans for prolongation and intensification of analgesia and anesthesia⁸⁵; however, the optimal mixtures have yet to be determined.⁸⁶

The discovery of peripheral opioid receptors offers yet another circumstance in which the co-administration of local anesthetics and opioids may be useful.⁸⁷ The most promising clinical results have been from intra-articular and peri-incisional administration of local anesthetic and opioid for postoperative analgesia,^{88,89} whereas combining local anesthetics and opioids for nerve blocks appears to be ineffective.⁹⁰ There are several reasons for a predicted lack of effect of co-administration of local anesthetic and opioid for peripheral nerve blocks. Anatomically, peripheral opioid receptors are found primarily at the end terminals of afferent fibers.⁹¹ However, peripheral nerves are commonly blocked by deposition of anesthetic proximal to the end terminals of nerve fibers. In addition, common sites for peripheral nerve blocks are encased in multiple layers of connective tissue which the anesthetics must traverse before gaining access to peripheral opioid receptors. Finally, previous studies have demonstrated the importance of concomitant local tissue inflammation for analgesic effectiveness of peripheral opioid receptors.⁹² The mechanism for the underlying dependence on local inflammation is speculative and may involve up-regulation or activation of peripheral opioid receptors or “loosening” of intercellular junctions to allow passage of opioids to receptors. Nonetheless, lack of inflammation at the site of a peripheral nerve block may also reduce the effects of co-administration of local anesthetic and opioid. All of these factors combine to decrease the theoretical effectiveness of combinations of local anesthetics and opioids for peripheral nerve blocks. In summary, co-administration of opioids and local anesthetic in the central neuraxis appears to be an effective, nontoxic³³ means to improve activity of local anesthetic, whereas there is little theoretical reason to expect the mixture to enhance peripheral nerve block.

α_2 -Adrenergic Agonists

α_2 -Adrenergic agonists can be a useful adjuvant to local anesthetics. α_2 Agonists, such as clonidine, produce analgesia *via* supraspinal and spinal adrenergic receptors.⁹³ Clonidine also has direct inhibitory effects on peripheral nerve conduction (A and C nerve fibers).⁹⁴ Thus, addition of clonidine may have multiple routes of action depending on type of application. Preliminary evidence suggests that co-administration of α_2 agonist and local anesthetic results in central neuraxial and peripheral nerve analgesic synergy,⁹⁵ whereas systemic (supraspinal) effects are additive.⁹⁶ Overall, clinical trials indicate that clonidine enhances intrathecal and epidural anesthesia,^{93,97} peripheral nerve blocks,⁹⁸ and intravenous regional anesthesia⁹⁹ without evidence for neurotoxicity.³³

PHARMACOKINETICS OF LOCAL ANESTHETICS

Clearance of local anesthetic from neural tissue and from the body governs both duration of effect and potential toxicity. Clinical effects of neural block from local anesthetics are primarily dependent on local factors as discussed in the Pharmacology section. However, systemic toxicity is primarily dependent on blood levels of local anesthetics. Resultant blood levels after administration of local anesthetics for neural blockade depend on absorption, distribution, and elimination of local anesthetics.

Systemic Absorption

In general, local anesthetics with decreased systemic absorption will have a greater margin of safety in clinical use. The rate and extent of absorption will depend on numerous factors, of which the most important are the site of injection, the dose of local anesthetic, the physicochemical properties of the local anesthetic, and the addition of epinephrine.

The relative amounts of fat and vasculature surrounding the site of local anesthetic injection will interact with the physicochemical properties of the local anesthetic to affect rate of systemic uptake. In general, areas with greater vascularity will have more rapid and complete uptake as compared to those with more fat, regardless of type of local anesthetic. Thus, rates of absorption from injection of local anesthetic into various sites generally decrease in the following order: intercostal > caudal > epidural > brachial plexus > sciatic/femoral (Table 17-6).^{100,101}

| Local Anesthetic | Technique | Dose (mg) | C_{max} (mg/dL) | T_{max} (min) | Steady State Concentration (mg/dL) |
|------------------|--|-----------|-------------------|-----------------|------------------------------------|
| Ropivacaine* | Brachial plexus | 550 | 1.00 | 20 | 3 |
| | Caudal plexus | 500 | 1.50 | 17 | |
| | Epidural | 500 | 1.50 | 20 | |
| | Intercostal | 540 | 0.90 | 30 | |
| Lidocaine | Lumbar sympathetic block/brachial plexus | 400 | 1.89 | 15 | |
| | Brachial plexus | 400 | 4.00 | 25 | 8 |
| | Epidural | 400 | 4.25 | 20 | |
| | Intercostal | 400 | 4.80 | 15 | |
| Mepivacaine | Brachial plexus | 500 | 3.00 | 24 | 3 |
| | Epidural | 500 | 4.00 | 18 | |
| | Intercostal | 500 | 8.00 | 9 | |
| | Sciatic/femoral | 500 | 3.00 | 30 | |

C_{max} = peak plasma level; T_{max} = time until C_{max} .
 Data from Liu RH: Local anesthetics and analgesia. In: Ashburn MA, Rice J (eds): The Management of Pain, p 140. New York, Churchill Livingstone, 1997; and Strassler BG, Sidoroff S, Merson AJ et al: Plasma concentrations of ropivacaine and its enantiomers during continuous extrapleural intercostal nerve block. In: J Anesth 1993; 3:101.
 * C_{max} and T_{max} after bupivacaine are expected to be similar to those of the racemate.

Table 17-6. TYPICAL C_{max} AFTER REGIONAL ANESTHETICS WITH COMMONLY USED LOCAL ANESTHETICS

The greater the total dose of local anesthetic injected, the greater the systemic absorption and peak blood levels (C_{max}). This relationship is nearly linear (Fig. 17-8) and is relatively unaffected by anesthetic concentration¹⁰² and speed of injection.^{100,101}

Figure 17-8. Increasing doses of ropivacaine used for wound infiltration result in linearly increasing maximal plasma concentrations (C_{max}). (Data from Mulroy MF, Burgess FW, Emanuelsson B-M: Ropivacaine 0.25% and 0.5%, but not 0.125%, provide effective wound infiltration analgesia after outpatient hernia repair, but with sustained plasma drug levels. Reg Anesth Pain Med 24:136, 1999.)

Physicochemical properties of local anesthetics will affect systemic absorption. In general, the more potent agents with greater lipid solubility and protein binding will result in lower systemic absorption and C_{max} (Fig. 17-9).¹⁰¹ Increased binding to neural and nonneural tissue probably explains this observation.

Figure 17-9. Fraction of dose absorbed into the systemic circulation over time from epidural injection of lidocaine or bupivacaine. Bupivacaine is a more lipid-soluble, more potent agent with less systemic absorption over time. (Adapted with permission from Tucker GT, Mather LE: Properties, absorption, and disposition of local anesthetic agents. In Cousins MJ, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain, p 55. Philadelphia, Lippincott-Raven, 1998.)

Effects of epinephrine have been previously discussed. In brief, epinephrine can counteract the inherent vasodilating characteristics of most local anesthetics. The reduction in C_{max} with epinephrine is most effective for the less lipid-soluble, less potent, shorter-acting agents (see Table 17-5), as increased tissue binding rather than local blood flow may be a greater determinant of absorption for the long-acting agents.

Distribution

After systemic absorption, local anesthetics are rapidly distributed to the body. Regional distribution of local anesthetic will depend on organ blood flow, partition coefficient of local anesthetic between compartments, and plasma protein binding. The end organs of main concern for toxicity are within the cardiovascular and the central nervous systems. Both are considered members of the "vessel-rich group" and will have local anesthetic rapidly distributed to them. Despite the high blood perfusion, regional blood and tissue levels of local anesthetics within these organs will not initially correlate with systemic blood levels due to hysteresis.¹⁰³ As regional, rather than systemic, pharmacokinetics govern subsequent pharmacodynamic effects, systemic blood levels may not correlate with effects of local anesthetics on end organs.¹⁰⁴ Regional pharmacokinetics of local anesthetics for the heart and brain have not been fully delineated; thus the volume of distribution at steady state (VD_{ss}) is often used to describe local anesthetic distribution (Table 17-7). However, VD_{ss} describes the extent of total body distribution and may be inaccurate for specific organ systems.

| Local Anesthetic | VD _{ss} (l · kg ⁻¹) | CL (l · kg ⁻¹ · hr ⁻¹) | T _{1/2} (hr) |
|------------------|---|--|--------------------------|
| Bupivacaine | 1.02 | 0.41 | 3.5 |
| Isro-Bupivacaine | 0.78 | 0.32 | 2.6 |
| Chloroprocaine | 0.50 | 2.96 | 0.11 |
| Etidocaine | 1.9 | 1.05 | 2.6 |
| Lidocaine | 1.3 | 0.85 | 1.6 |

Br J Clin Pharm 38:125, 1994.

Table 17-7. PHARMACOKINETIC PARAMETERS OF CLINICALLY USED LOCAL ANESTHETICS

Elimination

Clearance (CL) of aminoester local anesthetics is primarily dependent on plasma clearance by cholinesterases,¹⁰⁵ whereas aminoamide local anesthetic clearance is dependent on clearance by the liver.¹⁰⁶ Thus, hepatic extraction, hepatic perfusion, hepatic metabolism, and protein binding (Table 17-7) will primarily determine the rate of clearance of aminoamide local anesthetics. In general, local anesthetics with higher rates of clearance will have a greater margin of safety.¹⁰¹

Clinical Pharmacokinetics

The primary benefit of a knowledge of the systemic pharmacokinetics of local anesthetics is the ability to predict C_{max} after the agents are administered, thereby avoiding the administration of toxic doses (Table 17-6, Table 17-8 and Table 17-9). However, pharmacokinetics are difficult to predict in any given circumstance as both physical and pathophysiologic characteristics will affect the individual pharmacokinetics. There is some evidence for increased systemic levels of local anesthetics in the very young and in the elderly owing to decreased clearance and increased absorption,¹⁰¹ whereas correlation of resultant systemic blood levels between dose of local anesthetic and patient weight is often inconsistent (Fig. 17-10).¹⁰⁷ Effects of gender on clinical pharmacokinetics of local anesthetics have not been well defined, although pregnancy may decrease clearance.¹⁰¹ Pathophysiologic states such as cardiac and hepatic disease will alter expected pharmacokinetic parameters (Table 17-10), and lower doses of local anesthetics should be used for these patients. As expected, renal disease has little effect on pharmacokinetic parameters of local anesthetics (Table 17-10). Finally, the skill of the anesthesiologist should be considered, as a large dose of local anesthetic placed in the correct location may have much less potential for systemic toxicity than a small dose incorrectly injected intravascularly. All of these factors should be considered when utilizing local anesthetics and minimizing systemic toxicity, the commonly accepted maximal dosages (Table 17-9) notwithstanding.

| Agent | Relative Potency for CNS Toxicity | CVS:CNS |
|------------------|-----------------------------------|---------|

CLINICAL USE OF LOCAL ANESTHETICS

Local anesthetics are used in a variety of ways in clinical anesthesia practice. Probably, the most common clinical use of local anesthetics for anesthesiologists is for regional anesthesia and analgesia. Central neuraxial anesthesia and analgesia can be accomplished by epidural or spinal injections of local anesthetics. Placement of epidural and spinal catheters can allow continuous infusion of local anesthetics and other analgesics for extended durations. Intravenous regional anesthesia and peripheral nerve blocks allow for anesthesia of the head and neck including the airway, upper extremities, trunk, and lower extremities. Newly developed catheters for continuous peripheral nerve blocks can also be placed to allow continuous infusions of local anesthetics and other analgesics for prolonged analgesia in a fashion similar to continuous epidural analgesia. Topical application of local anesthetics to the airway, eye, and skin provides sufficient anesthesia for painless performance of minor anesthetic and surgical procedures such as tracheal intubation, intravenous catheter placement, or spinal puncture.¹⁰⁸ Typical applications for each local anesthetic are listed in [Table 17-9](#).⁴⁹

Other common clinical uses for local anesthetics include administration of lidocaine to blunt responses to tracheal instrumentation and to suppress cardiac dysrhythmias. Intravenous or topical administration of lidocaine have been used with variable success to blunt hemodynamic response to tracheal intubation and extubation.^{109,110} In addition to hemodynamic responses, instrumentation of the airway can result in coughing, bronchoconstriction, and other airway responses. Intravenous lidocaine can be effective for decreasing airway sensitivity to instrumentation by depressing airway reflexes and decreasing calcium flux in airway smooth muscle.^{111,112} Doses of intravenous lidocaine from 2 to 2.5 mg · kg⁻¹ are needed to consistently blunt hemodynamic and airway responses to tracheal instrumentation.^{111,112} and ¹¹³ Intravenous lidocaine is also effective for attenuating increases in intraocular pressure, intracranial pressure, and intra-abdominal pressure during airway instrumentation.¹¹⁴ Attenuation of all these responses may be beneficial in selected clinical situations (*e.g.*, corneal laceration or increased intracranial pressure). Intravenous lidocaine has well recognized antidysrhythmic effects and is easy to administer as an intravenous bolus followed by infusion for treatment of ventricular dysrhythmias.¹¹⁵

Finally, intravenous lidocaine (1–5 mg · kg⁻¹) is an effective analgesic and has been used to treat postoperative¹¹⁶ and chronic neuropathic pain.¹¹⁷ The mechanism of analgesia remains unclear,¹¹⁸ but does not involve typical block of impulse conduction in peripheral nerves.^{119,120} Both peripheral inhibition of spontaneous electrical activity in injured C nerve fibers, Ad nerve fibers,¹²⁰ and dorsal root ganglia¹¹⁹ and central inhibition of activity of hippocampal and thalamic neurons^{121,122} probably contribute to systemic analgesic effects of local anesthetics. The ability of local anesthetics to provide systemic analgesic effects at central and peripheral sites may in part explain the ability of a single neural block to provide long-lasting analgesia from neuropathic pain.^{118,123} In addition, orally administered tocainide and mexiletine (Class I anti-arrhythmic agents that are similar to lidocaine) have been successfully used to treat chronic pain conditions such as peripheral neuropathies^{124,125} and central spinal cord pain.¹²⁶

TOXICITY OF LOCAL ANESTHETICS

Systemic Toxicity of Local Anesthetics

Central Nervous System (CNS) Toxicity

Local anesthetics readily cross the blood–brain barrier, and generalized central nervous system toxicity may occur from systemic absorption or direct vascular injection. Signs of generalized CNS toxicity due to local anesthetics are dose–dependent ([Table 17-11](#)). Low doses produce CNS depression, and higher doses result in CNS excitation and seizures.¹²⁷ The rate of intravenous administration of local anesthetic will also affect signs of CNS toxicity, as higher rates of infusion of the same dose will lessen the appearance of CNS depression while leaving excitation intact.¹²⁸ This dichotomous reaction to local anesthetics may be due to a greater sensitivity of cortical inhibitory neurons to the impulse blocking effects of local anesthetics.¹²⁹ As expected, incidences of seizures vary after regional anesthetic techniques owing to differences in systemic absorption and the likelihood of unintentional vascular injection ([Table 17-12](#)).^{130,131}

| Plasma Concentration (µg · ml ⁻¹) | Effect |
|---|---|
| 1–5 | Analgesia |
| 5–10 | Lightheadedness Tinnitus Numbness of tongue |
| 10–15 | Seizures Unconsciousness |
| 15–25 | Coma Respiratory arrest |
| >25 | Cardiovascular depression |

Table 17-11. DOSE-DEPENDENT SYSTEMIC EFFECTS OF LIDOCAINE

| Anesthesia | Total Number of Procedures | Total Number of Seizures | Incidence of Seizures |
|-------------------------|----------------------------|--------------------------|-----------------------|
| Peripheral nerve block* | 25,800 | 31 | 11/10,000 |
| Epidural† | 45,578 | 15 | 3/10,000 |
| Intravenous regional | 11,200 | 3 | 3/10,000 |

*Increased incidence of seizures with bupivacaine vs. lidocaine.

Results of a prospective survey in France. *Anesthesiology* 87:479, 1997; and Brown DL, Ransom DM, Hall JA et al: Regional anesthesia and local anesthetic-induced systemic toxicity: Seizure frequency and accompanying cardiovascular changes. *Anesth Analg* 81:521, 1995.

Table 17-12. INCIDENCE OF SEIZURES AFTER REGIONAL ANESTHESIA IN THE UNITED STATES AND EUROPE

Local anesthetic potency for generalized CNS toxicity approximately parallels action potential blocking potency (Table 17-4 and Table 17-8). In general, decreased local anesthetic protein binding and clearance will increase potential CNS toxicity.⁶³ External factors can increase potency for CNS toxicity, such as acidosis and increased PCO₂, perhaps *via* increased cerebral perfusion or decreased protein binding of local anesthetic.¹²⁷ There are also external factors that can decrease local anesthetic potency for generalized CNS toxicity. For example, seizure thresholds of local anesthetics are increased by administration of barbiturates and benzodiazepines.¹³²

Addition of vasoconstrictors such as epinephrine may reduce or promote the potential for generalized local anesthetic CNS toxicity. Addition of epinephrine to local anesthetics will decrease systemic absorption and peak blood levels and increase the safety margin. On the other hand, the convulsive threshold for intravenous administration of lidocaine in the rat is decreased by about 42% when epinephrine (1:100,000), norepinephrine, or phenylephrine is added to the plain solution.¹³³ The mechanisms of increased toxicity with addition of epinephrine are unclear, but appear to depend on the development of hypertension from vasoconstriction. A hyperdynamic circulatory system may enhance the toxic effects of local anesthetics by causing increased cerebral blood flow and delivery of lidocaine to the brain^{134,135} or through disruption of the blood–brain barrier.¹³⁶ In addition to enhancing distribution of local anesthetic to the brain, hyperdynamic circulatory changes can also decrease clearance of local anesthetic from the body due to changes in distribution of blood flow away from the liver. Changes in total body clearance from hyperdynamic circulatory changes induced by local anesthetic seizures have been studied in dogs.¹³⁷ Seizures significantly increased heart rate, blood pressure, and cardiac output while significantly decreasing total body clearance (29–68%) of lidocaine, mepivacaine, bupivacaine, and etidocaine.

Cardiovascular (CV) Toxicity of Local Anesthetics

In general, much greater doses of local anesthetics are required to produce CV toxicity than CNS toxicity. Similar to CNS toxicity, potency for CV toxicity reflects the anesthetic potency of the agent (Table 17-4 and Table 17-8). Recent attention has focused on the apparently exceptional cardiotoxicity of the more potent, more lipid-soluble agents (bupivacaine, *levo*-bupivacaine, etidocaine, ropivacaine).^{43,138} These agents appear to have a different sequence of CV toxicity than less potent agents. For example, increasing doses of lidocaine lead to hypotension, bradycardia, and hypoxia, whereas bupivacaine often results in sudden cardiovascular collapse due to ventricular dysrhythmias that are resistant to resuscitation.¹³⁹ Subsequent studies have identified multiple mechanisms in the CNS and CV system for increased cardiotoxicity from potent local anesthetics.

Cardiovascular Toxicity Mediated at the CNS. It has been demonstrated that the central and peripheral nervous systems may be involved in the increased cardiotoxicity with bupivacaine. The nucleus tractus solitarius in the medulla is an important region for autonomic control of the cardiovascular system.¹⁴⁰ Neural activity in the nucleus tractus solitarius of rats is markedly diminished by intravenous doses of bupivacaine immediately prior to development of hypotension.¹⁴⁰ Furthermore, direct intracerebral injection of bupivacaine can elicit sudden dysrhythmias and cardiovascular collapse.¹⁴¹

Peripheral effects of bupivacaine on the autonomic and vasomotor systems may also augment its CV toxicity. Bupivacaine possesses a potent peripheral inhibitory effect on sympathetic reflexes¹⁴² that have been observed even at blood concentrations similar to those measured after uncomplicated regional anesthesia.¹⁴³ Finally, bupivacaine also has potent direct vasodilating properties which may exacerbate cardiovascular collapse.^{66,144}

Cardiovascular Toxicity Mediated at the Heart. The more potent local anesthetics appear to possess greater potential for direct cardiac electrophysiologic toxicity. A previous study examining lidocaine, bupivacaine, and ropivacaine in rats has demonstrated equivalent peak effects on myocardial contractility but much greater effects on electrophysiology (prolongation of QRS) from bupivacaine and ropivacaine than lidocaine (Fig. 17-11).¹⁴⁵ Although all local anesthetics block the cardiac conduction system *via* a dose-dependent block of sodium channels, two features of bupivacaine's sodium channel blocking abilities may enhance its cardiotoxicity. First, bupivacaine exhibits a much stronger binding affinity to resting and inactivated sodium channels than lidocaine.¹⁴⁶ Second, local anesthetics bind to sodium channels during systole and dissociate during diastole (Fig. 17-12). Bupivacaine dissociates from sodium channels during cardiac diastole much more slowly than lidocaine. Indeed, bupivacaine dissociates so slowly that the duration of diastole at physiologic heart rates (60–180 bpm) does not allow enough time for complete recovery of sodium channels and bupivacaine conduction block accumulates. In contrast, lidocaine fully dissociates from sodium channels during diastole and little accumulation of conduction block occurs (Fig. 17-13).^{146,147} Thus, enhanced electrophysiologic effects of more potent local anesthetics on the cardiac conduction system may explain their increased potential to produce sudden cardiovascular collapse *via* cardiac dysrhythmias.

Figure 17-11. Dose-related effects of bupivacaine, lidocaine, and ropivacaine on myocardial contractility (LV dp/dt) and on QRS prolongation in rats. Relative potencies of bupivacaine:ropivacaine:lidocaine for myocardial depression are 4:1:3 and for QRS prolongation are 15:1:7. (Data from Reiz S, Haggmark S, Johansson G et al: Cardiotoxicity of ropivacaine—a new amide local anaesthetic agent. *Acta Anaesthesiol Scand* 33:93, 1989.)

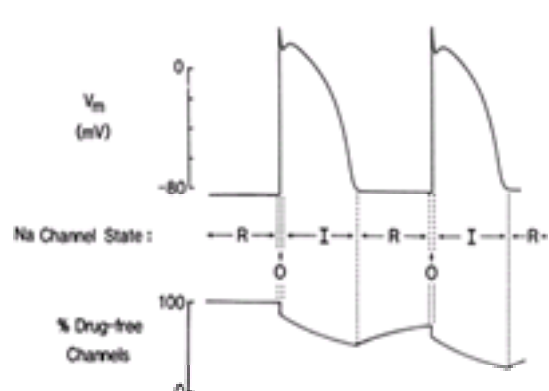

Figure 17-12. Diagram illustrating relationship between cardiac action potential (*top*), sodium channel state (*middle*), and block of sodium channels by bupivacaine (*bottom*). R = resting, O = open, and I = inactive forms of the sodium channel. Sodium channels are predominantly in the resting form during diastole, open transiently

during the action potential upstroke, and are in the inactive form during the action potential plateau. Block of sodium channels by bupivacaine accumulates during the action potential (systole) with recovery occurring during diastole. Recovery of sodium channels is from dissociation of bupivacaine and is time-dependent. Recovery during each diastolic interval is incomplete and results in accumulation of sodium channel block with successive heart beats. (Adapted with permission from Clarkson CW, Hondegham LM: Mechanisms for bupivacaine depression of cardiac conduction: Fast block of sodium channels during the action potential with slow recovery from block during diastole. *Anesthesiology* 62:396, 1985.)

Figure 17-13. Heart rate–dependent effects of lidocaine and bupivacaine on velocity of the cardiac action potential (V_{max}). Bupivacaine progressively decreases V_{max} at heart rates above 3 bpm due to accumulation of sodium channel block, whereas lidocaine does not decrease V_{max} until heart rate exceeds 150 bpm. (Adapted with permission from Clarkson CW, Hondegham LM: Mechanisms for bupivacaine depression of cardiac conduction: Fast block of sodium channels during the action potential with slow recovery from block during diastole. *Anesthesiology* 62:396, 1985.)

Increased potency for direct myocardial depression from the more potent local anesthetics is another contributing factor to increased cardiotoxicity. However, potency of myocardial depression roughly parallels anesthetic potency (Fig. 17-11);¹⁴⁵ thus, appropriate use of bupivacaine, *levo*-bupivacaine, etidocaine, and ropivacaine will not lead to excessive myocardial depression. Indeed, blood concentrations of bupivacaine and ropivacaine that typically occur from systemic absorption after regional blocks do not result in significant myocardial depression in animals or humans.^{43,148,149} Again, multiple mechanisms may account for the increased potency for myocardial depression from more potent local anesthetics. Bupivacaine, the most completely studied potent local anesthetic, possesses a high affinity for sodium and potassium channels in the cardiac myocyte.^{150,151} Furthermore, bupivacaine inhibits calcium channels,¹⁵¹ release of calcium from sarcoplasmic reticulum,¹⁵² and mitochondrial energy metabolism.¹⁵³ Thus, multiple direct effects of bupivacaine on activity of the cardiac myocyte may enhance the cardiotoxicity of bupivacaine.

The multitude of different cardiac and neural mechanisms of cardiotoxicity may in part explain the reported difficulties of resuscitation after cardiovascular collapse from bupivacaine.¹³⁸ An additional contributing factor may be bupivacaine's ability to inhibit cyclic AMP production.¹⁵⁴ Cyclic AMP is an important second messenger for the adrenergic receptor system, and thus modulates the resuscitative effects of epinephrine. Bupivacaine inhibition of cyclic AMP suggests that large doses of epinephrine may be necessary during resuscitation from overdose, as has been previously reported.¹⁵⁵ Once cardiovascular collapse occurs, maintenance of respiration and myocardial perfusion are vital, as hypercapnia, hypoxia, acidosis, hypothermia, hyperkalemia, hyponatremia, and myocardial ischemia will all sensitize the heart to bupivacaine cardiotoxicity.^{156,157}

Treatment of Systemic Toxicity from Local Anesthetics

The best method for avoiding systemic toxicity from local anesthetics is through prevention. Toxic systemic levels can occur by unintentional intravenous or intra-arterial injection or by systemic absorption of excessive doses placed in the correct area. Unintentional intravascular and intra-arterial injections can be minimized by frequent syringe aspiration for blood, use of a small test dose of local anesthetic (~3 ml) to test for subjective systemic effects from the patient (e.g., tinnitus, circumoral numbness), and either slow injection or fractionation of the rest of the dose of local anesthetic.¹³⁸ Detailed knowledge of local anesthetic pharmacokinetics will also aid in reducing the administration of excessive doses of local anesthetics. Ideally, heart rate, blood pressure, and the electrocardiogram should be monitored during administration of local anesthetics.

Treatment of systemic toxicity is primarily supportive. Injection of local anesthetic should be stopped. Oxygenation and ventilation should be maintained, as systemic toxicity of local anesthetics is enhanced by hypoxemia, hypercarbia, and acidosis.^{156,157} If needed, the patient's trachea should be intubated and positive pressure ventilation instituted. As previously discussed, signs CNS of toxicity will typically occur prior to CV events. Seizures can increase body metabolism and cause hypoxemia, hypercarbia, and acidosis. Pharmacologic treatment to terminate seizures may be needed if oxygenation and ventilation cannot be maintained. Intravenous administration of thiopental (50–100 mg), midazolam (2–5 mg), and propofol (1 mg · kg⁻¹) can terminate seizures from systemic local anesthetic toxicity.^{49,158} Succinylcholine (50 mg) can terminate muscular activity from seizures and facilitate ventilation and oxygenation. However, succinylcholine will not terminate seizure activity in the CNS, and increased cerebral metabolic demands will continue unabated.⁴⁹

Cardiovascular depression from less potent local anesthetics (e.g., lidocaine) is usually mild and caused by mild myocardial depression and vasodilation. Hypotension and bradycardia can usually be treated with ephedrine (10–30 mg) and atropine (0.4 mg). As previously discussed, potent local anesthetics (e.g., bupivacaine) can produce profound cardiovascular depression and malignant dysrhythmias that should be promptly treated. Oxygenation and ventilation must be immediately instituted, with cardiopulmonary resuscitation if needed. Ventricular dysrhythmias may be difficult to treat and may need large and multiple doses of electrical cardioversion, epinephrine, bretyllium, and magnesium.^{49,115}

Neural Toxicity of Local Anesthetics

In addition to systemic toxicity, local anesthetics can cause injury to the central and peripheral nervous system from direct exposure. Mechanisms for local anesthetic neurotoxicity remain speculative, but previous studies have demonstrated local anesthetic–induced injury to Schwann cells, inhibition of fast axonal transport, disruption of the blood–nerve barrier, and decreased neural blood flow with associated ischemia.¹⁵⁹ Although all clinically used local anesthetics can cause concentration-dependent nerve fiber damage in peripheral nerves when used in high enough concentrations, previous studies have demonstrated that local anesthetics in clinically used concentrations are generally safe for peripheral nerves.¹⁶⁰ The spinal cord and the nerve roots, on the other hand, are more prone to injury. Spinal cord or nerve root toxicity may manifest itself as neurohistopathologic, physiologic, or behavioral/clinical changes such as pain, motor and sensory deficits, and bowel and bladder dysfunction.

In 1985 Ready *et al* evaluated the neurotoxic effects of single intrathecal injections of clinically relevant concentrations of tetracaine, lidocaine, bupivacaine, or chloroprocaine in rabbits, after which spinal cord histopathology remained normal and persistent behavioral deficits were not seen.¹⁶¹ However, histopathologic changes and neurologic deficits did occur with higher concentrations of tetracaine (1%) and lidocaine (8%). Desheathed peripheral nerve models, designed to mimic unprotected nerve roots in the cauda equina, have been used to further assess electrophysiologic neurotoxicity of local anesthetics.^{162,163} and ¹⁶⁴ Lidocaine 5% and tetracaine 0.5% caused irreversible conduction block in these models, whereas lidocaine 1.5%, bupivacaine 0.75%, and tetracaine 0.06% did not. Electrophysiologic toxicity of lidocaine in isolated nerve preparations represented by incomplete recovery of neuromuscular function occurs at 40 mM (~1%) (Fig. 17-14) with irreversible ablation of the compound action potential seen at 80 mM (~2%). Although such studies do not reflect *in vivo* conditions, they suggest that lidocaine and tetracaine may be especially neurotoxic in a concentration-dependent fashion, and that neurotoxicity could theoretically occur with clinically used solutions. Local anesthetic effects on spinal cord blood flow, another possible etiology of neurotoxicity from direct drug exposure, appear benign. Spinal administration of bupivacaine, lidocaine, mepivacaine, and tetracaine cause vasodilation and increase spinal cord blood flow, whereas ropivacaine causes vasoconstriction and reduction in spinal cord blood flow in a concentration-dependent fashion.¹⁶⁵

Figure 17-14. The nonreversible effect of 40 mM lidocaine on the compound action potential (CAP) of frog sciatic nerve. Lidocaine was applied to a stable nerve preparation for 15 min and then washed with frog Ringer's solution for 2 hr. Tracings represent CAPs in response to stimulus (1-Hz stimulus = heavy line; 40-Hz stimulus = thin line). 40 mM lidocaine completely ablated the CAP when applied to the nerve. The 1-Hz CAP response began to return after 10–15 min of washing and reached a new level in 45 min, where it was stable for the subsequent 2 hr of observation. The recovered 1-Hz CAP is only 65% of the original. (Adapted with permission from Bainton C: Concentration dependence of lidocaine-induced irreversible conduction loss frog nerve. *Anesthesiology* 81:657, 1994.)

Neurohistopathologic data in humans after intrathecal exposure to local anesthetics is not available. Electrophysiologic parameters such as somatosensory-evoked potentials, monosynaptic H-reflex,¹⁶⁶ and cutaneous current perception thresholds¹⁶⁷ have been used to evaluate recovery after spinal anesthesia. These measurements have shown complete return to baseline activity after 5% lidocaine spinal anesthesia in very small study populations. Epidemiologic studies in 1999 report an incidence of 0–0.7% postoperative neurologic injury in patients undergoing spinal anesthesia.³³ Thus, despite findings that all local anesthetics have the potential for neurotoxicity in laboratory and animal models, spinally administered local anesthetics have not notably manifested their neurotoxic potential in human studies to date.

Transient Neurologic Symptoms (TNS) after Spinal Anesthesia

Prospective, randomized studies reveal a 4–40% incidence of transient neurologic symptoms (TNS), including pain or sensory abnormalities in the lower back, buttocks, or lower extremities, after lidocaine spinal anesthesia.^{33,168,169} These symptoms have been reported with other local anesthetics as well (Table 17-13). The incidence of TNS varies with the type of surgical procedure and positioning and is apparently unaffected by baricity or dose. Contemporary reports of cauda equina syndrome after single-bolus administration, as well as continuous, lidocaine spinal anesthesia, and the potential concentration-dependent neurotoxicity of lidocaine, have led several authors to label TNS as a manifestation of subclinical neurotoxicity.¹⁷⁰

| Agent | Preparation | Position | Approximate TNS Incidence |
|-------------|----------------------------|--------------------------|---------------------------|
| Lidocaine | Hyperbaric 2–3% | Lithotomy | 30–40% |
| | Hyperbaric 0.5–3% | Knee arthroscopy | 20–30% |
| | Hyperbaric 5% | Supine/unspecified | 5–10% |
| Ropivacaine | Isobaric/hyperbaric | Lithotomy/other | None |
| Tetracaine | Hyperbaric | General use | None |
| Prilocaine | Hyperbaric + phenylephrine | Lower extremity/perineal | 12% |
| | Hyperbaric 5% | Knee arthroscopy | 4% |
| Mepivacaine | Isobaric 3% | Supine/other | 1% |
| | Hyperbaric 4% | Lithotomy/other | 30–40% |
| Ropivacaine | Isobaric 1.5% | Knee arthroscopy | None |
| | Hyperbaric 0.25% | Supine volunteers | None |

Table 17-13. INCIDENCE OF TRANSIENT NEUROLOGIC SYMPTOMS (TNS) AFTER SPINAL ANESTHESIA

As previously discussed, laboratory work in both intrathecal and desheathed peripheral nerve models has proved that the concentration of lidocaine is a critical factor in neurotoxicity. As concentrations of lidocaine below 40 mM (~1.0%) are not neurotoxic to desheathed peripheral nerve, such dilute concentrations of spinal lidocaine should not cause TNS if the syndrome is due to subclinical concentration-dependent neurotoxicity. However, the dilution of lidocaine to as low as 0.5% does not decrease the incidence of TNS.¹⁶⁸ The high incidence of TNS observed with lidocaine concentrations <1% despite further dilution in cerebrospinal fluid would appear to lessen the plausibility of a concentration-dependent neurotoxic etiology. Other potential etiologies for TNS include patient positioning, early mobilization, needle trauma, neural ischemia, pooling of local anesthetics secondary to maldistribution by pencil-point needles or the addition of glucose, muscle spasm, myofascial trigger points, and irritation of dorsal ganglia.¹⁶⁸ Clearly, the etiology of TNS remains undetermined, and further studies are needed to elucidate the underlying mechanism.

In summary, local anesthetics all have the potential to be neurotoxic, particularly in concentrations and doses greater than those used clinically. In neurohistopathologic, electrophysiologic, behavioral, and *in vitro* models, lidocaine and tetracaine appear to have greater potential for neurotoxicity than bupivacaine at clinically relevant concentrations. Nonetheless, large-scale surveys of the complications of spinal anesthesia attest to the relative safety of spinally administered local anesthetics.

Allergic Reactions to Local Anesthetics

True allergic reactions to local anesthetics are rare and usually involve Type I (IgE) or Type IV (cellular immunity) reactions.^{171,172} Type I reactions are worrisome, as anaphylaxis may occur, and are more common with ester than amide local anesthetics.¹²⁷ True Type I allergy to aminoamide agents is extremely rare.¹⁷² Increased allergenic potential with esters may be due to hydrolytic metabolism to *para*-aminobenzoic acid which is a documented allergen.¹⁷³ Added preservatives such as methylparaben and metabisulfite can also provoke an allergic response.¹⁷⁴ Skin testing with intradermal injections of preservative-free local anesthetics has been advocated as a means to determine tolerance to local anesthetic.¹⁷⁴ These tests should be undertaken with caution, as potentially severe and even fatal reactions can occur in truly allergic patients.¹⁷²

NEW AND FUTURE LOCAL ANESTHETICS

Local Anesthetics with Decreased Systemic Toxicity

In 1979, an editorial drew attention to the potential for sudden cardiovascular collapse with unintentional intravascular injection of potent local anesthetics such as bupivacaine.⁴⁴ Enhanced awareness of potential cardiovascular toxicity with long-acting local anesthetics led to withdrawal of FDA approval of high concentrations of bupivacaine (0.75%) for obstetric use in the United States and to changes in clinical practice, such as the use of test doses, intermittent aspiration, and incremental injection of local anesthetic.¹³⁸ Indeed, reports suggest that current clinical use of potent local anesthetics is very safe, with an incidence of CNS toxicity with epidural injection approximating 3/10,000 and an incidence of 11/10,000 with peripheral nerve blocks (Table 17-12).^{130,131} There appears to be a higher incidence of continued unintentional intravascular injection of local anesthetic during peripheral nerve blocks, perhaps due to differences in practice or less clinical awareness. This observation is consistent with Albright's original editorial, as four out of six of the initial reports were observed during performance of peripheral nerve blocks. Thus, current concerns for systemic toxicity for local anesthetics should be focused on clinical practice involving placement of peripheral nerve blocks rather than that associated with epidural anesthesia.

The recent release of single-optical isomer (S/L) preparations of ropivacaine and impending release of *levo*-bupivacaine appear well suited to fill this niche. Both ropivacaine and *levo*-bupivacaine appear to be approximately equipotent to racemic bupivacaine for epidural and plexus anesthesia (see Table 17-4).^{175,176,177} and ¹⁷⁸ Both ropivacaine and *levo*-bupivacaine appear to have approximately 30–40% less systemic toxicity on a mg:mg basis in both animal^{44,179} (Table 17-14 and Table 17-15) and human^{180,181} volunteer studies (Fig. 17-15 and Fig. 17-16), which is likely due to reduced affinity for brain and myocardial tissue from their single isomer

preparation.^{46,182} It is hoped that, with the introduction of these new agents, the incidence of systemic local anesthetic toxicity will be reduced.

| Species | Measurement | Lidocaine | Ropivacaine | Bupivacaine |
|---------|------------------------------|-----------|-------------|-------------|
| Dog | Ventricular fibrillation (%) | 0 | 33 | 65 |
| | Resuscitate (%) | 75 | 100 | 66 |
| Sheep | Ventricular fibrillation (%) | — | 40 | 75 |
| Pig | Myocardial depression (%) | 13 | 38 | 50 |
| | Death (%) | 0 | 0 | 25 |

Extended-Duration Local Anesthetics

There are potential clinical applications for extended-duration local anesthetics that act for 2–7 days. Central neuraxial use of such extended-duration local anesthetics would probably be limited to treatment of chronic and cancer pain because of the associated extended duration of motor block. Use of extended-duration local anesthetics for infiltration anesthesia/analgesia and for peripheral nerve blocks could result in an increased use for both forms of anesthesia for treatment of acute and chronic pain. Current technology for extending the duration of action typically involves modification of the method of delivery rather than development of new local anesthetics. Such delivery systems include encapsulation of local anesthetic in liposomes, microspheres, or polymers with slow degradation and release (Fig. 17-17).¹⁸³ Animal studies with these extended-duration preparations demonstrate the ability to provide peripheral nerve block analgesia from 2 days to >2 weeks (Fig. 17-18).¹⁸⁴ In addition to extended clinical duration, these delivery systems also appear to decrease potential for both CNS and cardiovascular toxicity due to slow release of local anesthetic and altered tissue uptake (Fig. 17-19).¹⁸⁵ Commercial release of these products has the potential to markedly change the practice of anesthesia and analgesia. For example, anesthesia could be initiated in the pre-op clinic while peripheral nerve blocks and infiltration analgesia may be increasingly utilized for treatment of acute and chronic pain.

Local Anesthetics with Combined Mechanisms of Action

An increased understanding of the mechanisms of pain has led to the realization that numerous neurotransmitters are involved in the spinal cord and peripheral nervous system, and these may result in central sensitization of the CNS responses to pain.^{33,186} Local anesthetics are somewhat effective for prevention of pain and central sensitization when delivered either centrally or peripherally.^{187,188} However, targeted modulation of the multiple receptors involved in the mechanisms of pain and central sensitization could produce multimodal analgesia, with added efficacy and decreased side effects, in contrast to local anesthetics alone. Molecules that have local anesthetic activity in combination with analgesic activities *via* other mechanisms (opioid receptors, α -adrenergic receptors, etc.) could potentially provide this multimodal analgesia by either central neuraxial or peripheral delivery. Sameridine is a mixed local anesthetic and opioid agonist compound that is undergoing clinical trials as a spinal agent,¹⁸⁹ and other mixed function compounds may soon undergo testing.

Very Short-Duration Local Anesthetics

The popularity of ambulatory surgery continues to grow, with 60–70% of surgery in the United States being performed on an outpatient basis. Current popular general anesthetic agents such as propofol or desflurane have a very brief duration of action, allowing for rapid recovery and patient discharge. Regional anesthetic techniques with local anesthetics for ambulatory surgery are somewhat hampered by the lack of a similar agent with 5–10 min offset time after cessation of infusion. Unfortunately, no such rapid-acting local anesthetic is near commercial release.

INTRODUCTION

The past decade has been marked by an intense interest in better refining the optimal perioperative evaluation before surgery. The impetus for this focus is a desire to save costs and make the perioperative process more efficient. Within the general context of using the best evidence to define medical practice, preoperative testing represents a unique and complex problem of relating a diagnostic test to an intervention whose outcome would be different if the test were not performed. Except for high-risk populations, such as patients undergoing major vascular surgery or with known cardiovascular disease, extremely large sample sizes are needed to identify differences in final outcomes such as stroke, myocardial infarction, or death. In lower-risk groups, the difficulty is in linking the value of preoperative testing to the rare morbid events; therefore, the trend in the literature is toward assessing surrogate outcomes such as costs, resource utilization, and cancellation of cases. In many cases, studies are undertaken to prove that a test does not affect outcome in lower-risk populations. Most importantly, all of these studies emphasize an initial history and physical examination to define those patients who might benefit from further evaluation and diagnostic testing.

In defining the components and extent of the anesthesia evaluation of the patient prior to surgery, it is important to acknowledge that it serves multiple purposes. The Joint Commission for the Accreditation of Health Care Organizations (JCAHO) requires that all patients receive a preoperative anesthetic evaluation. The American Society of Anesthesiologists approved Basic Standards for Preanesthetic Care, which outline minimum requirements for the preoperative evaluation.¹ A preoperative evaluation is also an important component of perioperative management. In a study evaluating methods of reducing preoperative anxiety, a thorough preoperative evaluation can be as effective as an anxiolytic premedication.² Finally, the preoperative evaluation serves to establish a database upon which a risk assessment and perioperative management decisions can be made.

The concept of establishing a data base is predicated upon the assumption that information regarding the patient's medical condition can be used to modify care, and that this will result in improved outcome. Although there are no hard data in the form of randomized controlled trials to support such an assumption, there are several decision analyses regarding preoperative cardiac evaluation that highlight the potential benefits of testing and coronary revascularization.^{3,4} and ⁵

In an ideal world, the preoperative database would be complete and contain confirmatory evidence of the pertinent disease processes. It is important for anesthesiologists to determine the presence or absence of certain pathophysiologic processes in all patients, but frequently the evaluation is abbreviated and focuses on the systems of interest. For example, the patient undergoing a carotid endarterectomy may have a more extensive neurologic evaluation than a patient undergoing an elective cholecystectomy. Bleeding history may require more extensive evaluation in the patient for whom an epidural anesthetic is planned than if general anesthesia is planned. Therefore, the anesthesiologist frequently applies clinical judgment in the decision to further assess the probability of disease.

In this chapter, the clinical risk factors that raise the probability of disease and the use of tests to confirm the diagnosis are outlined. In addition, the cost–benefit issues of a more detailed database are discussed. This chapter provides an overview of the preoperative evaluation process; for more specific details, the reader is referred to chapters focusing on given organ systems.

THE EVOLVING CONCEPTS OF PREOPERATIVE SCREENING

It is now the exception rather than the rule for patients to be admitted to the hospital the day prior to surgery. Even patients undergoing coronary artery bypass grafting are being admitted the morning of surgery. In order to obtain a thorough history in these patients, preoperative screening clinics have been created. There are multiple approaches to obtaining a preoperative evaluation in such settings. In some practice settings, these centers are staffed entirely by attending anesthesiologists. This poses a significant financial burden, since it represents time away from the operating rooms. If this activity is combined with other responsibilities, the preoperative evaluations performed may be cursory. In order to balance the financial burden of utilizing attending staff with issues of appropriate medical supervision, many centers employ nurse specialists, with questions referred to anesthesiologists. Since the system to evaluate all patients would require extensive resources at high expense, alternative means of obtaining an adequate evaluation are necessary. In many practice settings, the internist or primary caregiver provides a preoperative evaluation, with the anesthesiologist performing a brief history at the time of surgery. Alternatively, the surgeon may identify healthy patients for whom a telephone interview may suffice or whose evaluation may occur the day of surgery. Managed care organizations may also restrict the number and nature of preoperative tests performed, and the anesthesiologist may not be able to evaluate the patient prior to surgery. It is important for the anesthesiologist to take an active role in the design and implementation of the preoperative screening clinic, since it is area in which they can reduce total health care expenditures by reducing unnecessary testing.

Several systems have been developed to ensure accuracy and completeness of the information from the preoperative evaluation. Multiple preoperative questionnaires have been developed and tested against traditional physician interviewing. These questionnaires are at least as accurate as, if not more accurate than, physician interviews.⁶ Computer-driven programs have also been developed, which demonstrate good success.⁷ In both cases, repetition of critical questions is essential. The precise method of obtaining the history is not as important as its completeness and its accurate ability to dictate appropriate care.

Increasingly, the systems by which a preoperative evaluation is obtained are being evaluated for their value in improving the efficiency of the perioperative process. By assuming responsibility for ordering tests, the anesthesiologist can obtain a more appropriate laboratory panel and potentially reduce cancellations the day of surgery arising from an inadequate evaluation. Additionally, laboratories can be centralized and patient and family perioperative education can occur within the confines of these centers. Fisher *et al* demonstrated the cost-effectiveness of establishing a preoperative evaluation clinic at Stanford by reducing both testing and cancellations.^{8,9} Starsnic and colleagues at Thomas Jefferson University compared a group whose testing was primarily ordered by surgeons augmented by anesthesiologists in the preoperative evaluation clinic versus a group whose testing was ordered primarily by anesthesiologists augmented by the surgeons as deemed necessary during two consecutive time periods in 1992.¹⁰ They demonstrated an average cost savings of \$20.89 per patient when the anesthesiologist was the primary physician determining testing. Importantly, there were no recorded cancellations or alterations in intraoperative management attributable to inadequate testing. Similarly, Allison and Bromley performed an analysis of the cost savings of unnecessary testing at the Department of Veterans Affairs Medical Center in South Carolina and demonstrated a potential savings of \$11,757.50 per year.¹¹ Vogt and Henson performed a retrospective chart review and estimated a potential hospital savings of

approximately \$80,000 by eliminating unindicated tests for the 5100 patients seen in the preoperative clinic annually.¹²

An alternative approach to the construction of a preoperative evaluation clinic is through the simple dissemination of guidelines. Mancuso studied the impact of new guidelines on physicians' ordering of preoperative tests at an orthopedic hospital.¹³ A simple memo was distributed to the participating surgeons after the establishment of ordering patterns by a multidisciplinary group. They demonstrated a marked reduction in the number of tests without an increase in cancellations or untoward events. A savings in charges of \$34,000 was realized. Although the compliance of the physicians was variable, this simple approach did demonstrate efficacy in reducing costs. These studies suggest that the anesthesiologist's involvement in the design of the system to determine the preoperative testing algorithm is essential for economic success.

APPROACH TO THE PATIENT: HISTORY

The approach to the patient should always begin with a thorough history. A thorough history may frequently be sufficient (without additional routine laboratory tests) prior to certain procedures. In fact, Schein *et al* studied approximately 20,000 patients undergoing cataract procedures, randomizing half of the patients to no routine testing prior to surgery.¹⁴ They found no difference in outcome between those who received testing and those who did not if the primary physician evaluated the patient within 30 days and determined that the patient's medical condition was stable.

The indication for the surgical procedure is part of the preoperative history, since it will help determine the urgency of the surgery. True emergent procedures, which are associated with an accepted higher morbidity and mortality, require a more abbreviated evaluation.¹⁵ The difficult area is with regard to urgent procedures. For example, ischemic limbs or malignant tumors require surgery soon after presentation, but can usually be delayed for 24 hours for further evaluation. The indication for the surgical procedure may also have implications on other aspects of perioperative management. For example, the presence of a small bowel obstruction has implications regarding the risk of aspiration and the need for a rapid sequence induction. The extent of a lung resection will dictate the need for further pulmonary testing and perioperative monitoring. Patients undergoing carotid endarterectomy may require a more extensive neurologic examination. Frequently, further information will be required that necessitates contacting the surgeon.

Information regarding previous anesthetics is important in order to evaluate for the presence of a difficult airway, a history of malignant hyperthermia, and the individual's response to surgical stress and specific anesthetics. A history of a previous surgical procedure performed without complications under general anesthesia reduces the probability of a major airway problem, although it does not eliminate it. The ability to review previous anesthetic records is required to confirm a previous easy intubation, assuming the patient's body habitus has not changed in the interim. The patient should be questioned regarding any previous difficulty with anesthesia or other family members' having a history of difficulty with anesthesia. Frequently, the patient will relate an "allergy" to anesthesia, which may indicate a history of malignant hyperthermia.

The history should include a complete list of medications in order to adequately define a preoperative medication regimen, anticipate potential drug interactions, and provide clues to underlying disease. A complete list of drug allergies, including previous reactions, should also be obtained. Once the general issues are completed, the preoperative history can focus on specific organ systems.

Specific Organ Systems

Cardiac Disease

Cardiovascular disease has traditionally been approached from two perspectives: multifactorial risk indices and evaluation of new preoperative testing modalities in specific patient groups. The first area was popularized by the pioneering work of Drs. Saklad and Dripps and the American Society of Anesthesiologists (Physical Status Index) (Table 18-1) and that of Dr. Lee Goldman and colleagues (Cardiac Risk Index).^{1,15} The second area involves the assessment of new, noninvasive testing modalities and has received extensive attention during the previous two decades. Specific testing modalities will be addressed later in the chapter.

| Status | Disease State |
|-------------------------|--|
| ASA Class 1 | No organic, physiologic, biochemical, or psychiatric disturbance |
| ASA Class 2 | Mild to moderate systemic disturbance that may not be related to the reason for surgery |
| ASA Class 3 | Severe systemic disturbance that may or may not be related to the reason for surgery |
| ASA Class 4 | Severe systemic disturbance that is life-threatening with or without surgery |
| ASA Class 5 | Moribund patient who has little chance of survival but is submitted to surgery as a last resort (resuscitative effort) |
| Emergency operation (E) | Any patient in whom an emergency operation is required |

From information in American Society of Anesthesiologists: New classification of physical status. *Anesthesiology* 24:111, 1963.

Table 18-1. AMERICAN SOCIETY OF ANESTHESIOLOGISTS PHYSICAL STATUS CLASSIFICATION

In interpreting studies that develop a multifactorial index of risk, three basic assumptions are made. The first is that data on all of the potentially important variables are available. For example, if angina was not included in the data base, it could not be included in the final index. Second, eliminating variables from the model must be based upon biological significance, not just on statistical significance. In the original Goldman Cardiac Risk Index, New York Heart Association (NYHA) Class IV angina was not found to be a risk factor; however, the number of patients who fit this criteria was too small to achieve statistical significance.¹⁵ Therefore, it was eliminated, probably erroneously, from the model. Third, if a factor is identified as placing the patient at significant risk, and if the anesthesiologist can use the information to modify and reduce that risk, then the factor may no longer appear to be significant. In other words, the perioperative period cannot be used as a black box. Should perioperative hemodynamic management decisions not include the hypertensive status of a patient, then lack of hypertensive management in subsequent patients may lead to increased morbidity.

Noncardiac Risk Indices

In 1977, Goldman and colleagues published their landmark article studying 1001 patients undergoing noncardiac surgical procedures, excluding transurethral resection of the prostate (TURP).¹⁵ The authors excluded this surgery because of their impression of a low morbidity rate when performed under spinal anesthesia. They identified nine risk factors and gave each factor a certain number of points (Goldman Cardiac Risk Index, or CRI). A myocardial infarction and S3 gallop were identified as the most significant risk factors. By adding up the total number of points, patients were placed in one of four classes. The patient's class could then be compared to the rates of morbidity and mortality from the original cohort.

The CRI was subsequently validated in another cohort of patients; however, it has not been found to be predictive in patients undergoing major vascular surgery.^{16,17} Multiple studies have demonstrated that major vascular surgery is associated with a higher rate of morbidity and mortality compared to nonvascular surgery.^{15,18,19} and ²⁰ In order to rectify this problem, Detsky and colleagues proposed a modification of the CRI for vascular patients.²¹

Although both of these indices were extremely useful when initially proposed, perioperative care has changed significantly in the intervening years. Goldman Class III and IV continues to represent a high-risk cohort; however, recent mortality has been lower than originally reported.²² In addition, many vascular surgery patients would be classified as low-risk, but would benefit from further risk stratification.¹⁷ Significant changes in the medical care of the patient with coronary artery disease has had profound impact on the perioperative period.

In an attempt to update the original CRI, Goldman and colleagues studied 4315 patients aged 50 years who were undergoing elective major noncardiac procedures in a tertiary-care teaching hospital.²³ Six independent predictors of complications were identified and included in a revised CRI: high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine $>2.0 \text{ mg} \cdot \text{dl}^{-1}$. Rates of major cardiac complication with 0, 1, 2, or 3 of these factors were 0.5%, 1.3%, 4%, and 9%, respectively, in the derivation cohort and 0.4%, 0.9%, 7%, and 11%, respectively, among 1422 patients in the validation cohort (Fig. 18-1).

Figure 18-1. CRI cardiac risk index. Bars represent rate of major cardiac complications in entire patient population (both derivation and validation cohorts combined) for patients in revised CRI classes according to type of procedure performed. AAA = abdominal aortic aneurysm. Note that, by definition, patients undergoing AAA, thoracic, and abdominal procedures were excluded from Class I. In all subsets except patients undergoing AAA, there was a statistically significant trend toward greater risk with higher-risk class. See text for details. (Reproduced with permission from Lee TH, Marcantonio ER, Mangione CM *et al*: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation* 100:1043, 1999.)

A primary issue with all of these indices from the anesthesiologist's perspective is that a simple estimate of risk does not help in refining perioperative management, but may provide information to assess the probability of risk. In contrast, the anesthesiologist is most concerned with defining the cardiovascular risk factors and symptoms or signs of unstable cardiac disease states, such as myocardial ischemia, congestive heart failure, valvular heart disease, and significant cardiac arrhythmias.

In patients with symptomatic coronary disease, the preoperative evaluation may lead to the recognition of a change in the frequency or pattern of anginal symptoms. Symptoms of cardiovascular disease should be carefully determined, especially the characteristics of chest pain, if present. Certain populations of patients—the elderly, for example, or women or diabetics—may present with more atypical features. The presence of unstable angina has been associated with a high perioperative risk of myocardial infarction (MI).²⁴ The perioperative period is associated with a hypercoagulable state and surges in endogenous catecholamines, both of which may exacerbate the underlying process in unstable angina, increasing the risk of acute infarction.²⁵ The preoperative evaluation can affect both a patient's short- and long-term health by instituting treatment of unstable angina.

The patient with stable angina represents a continuum from mild angina with extreme exertion to dyspnea with angina after walking up a few stairs. The patient who manifests angina only after strenuous exercise does not demonstrate signs of left ventricular dysfunction and would not be a candidate for changes in management. In contrast, a patient with dyspnea on mild exertion would be at high risk for developing perioperative ventricular dysfunction, myocardial ischemia, and possible MI. These patients have an extremely high probability of having extensive coronary artery disease, and additional monitoring or cardiovascular testing should be contemplated, depending upon the surgical procedure and institutional factors.

In virtually all studies, the presence of active congestive heart failure preoperatively has been associated with an increased incidence of perioperative cardiac morbidity.^{15,21} Stabilization of ventricular function and treatment for pulmonary congestion are prudent prior to elective surgery. Also, it is important to determine the etiology of the left heart failure. Congestive symptoms may be due to nonischemic cardiomyopathy or mitral or aortic valvular insufficiency and/or stenosis. Since the type of perioperative monitoring and treatments would be different, clarifying the cause of cardiac congestion is important.

Patients with a prior MI have coronary artery disease, although a small group of patients may sustain a MI from a nonatherosclerotic mechanism. Traditionally, risk assessment for noncardiac surgery was based upon the time interval between the MI and surgery. Multiple studies have demonstrated an increased incidence of reinfarction if the MI was within 6 months of surgery.^{26,27} and ²⁸ With improvements in perioperative care, this difference has decreased. Therefore, the importance of the intervening time interval may no longer be valid in the current era of thrombolytics, angioplasty, and risk stratification after an acute MI. Although many patients with an MI may continue to have myocardium at risk for subsequent ischemia and infarction, other patients may have their critical coronary stenosis either totally occluded or widely patent. For example, the use of percutaneous transluminal coronary angioplasty, thrombolysis, and early coronary artery bypass grafting has changed the natural history of the disease.^{29,30} Therefore, patients should be evaluated from the perspective of their risk for ongoing ischemia. The American Heart Association/American College of Cardiology Task Force on Perioperative Evaluation of the Cardiac Patient Undergoing Noncardiac Surgery has defined three risk groups—major, intermediate, and minor³¹ (Table 18-2). They indicate that recent MI (MI < 30 days) places patients in the group at highest risk; after that period, a prior MI places the patient at intermediate risk.³¹

Major

- Unstable coronary syndromes
- Recent myocardial infarction with evidence of important ischemia
- Recent myocardial infarction with evidence of important ischemia
- Evidence of unstable angina or previous MI with ST-segment depression
- Myocardial infarction with evidence of important ischemia

Intermediate

- High-grade electrocardiographic abnormalities
- High-grade electrocardiographic abnormalities in the presence of unstable angina
- High-grade electrocardiographic abnormalities in the presence of unstable angina
- High-grade electrocardiographic abnormalities in the presence of unstable angina

Minor

- Mild angina (previous MI/Coronary Class I or II)
- Mild angina (previous MI/Coronary Class I or II)
- Mild angina (previous MI/Coronary Class I or II)
- Mild angina (previous MI/Coronary Class I or II)

Advanced age

- Age > 70 years
- Age > 70 years
- Age > 70 years
- Age > 70 years

Other

Table 18-2. CLINICAL PREDICTORS OF INCREASED PERIOPERATIVE CARDIOVASCULAR RISK (MYOCARDIAL INFARCTION, CONGESTIVE HEART FAILURE, DEATH)

Patients at Risk for Coronary Artery Disease (CAD)

For those patients without overt symptoms or history, the probability of CAD varies with the type and number of atherosclerotic risk factors present. Peripheral arterial disease has been shown to be associated with CAD in multiple studies. Hertzler and colleagues studied 1000 consecutive patients scheduled for major vascular surgery and found that approximately 60% of patients had at least one coronary artery with a critical stenosis.³²

Diabetes mellitus is common in the elderly and represents a disease that affects multiple organ systems. Complications of diabetes mellitus are frequently the cause of urgent or emergent surgery, especially in the elderly. Diabetes accelerates the progression of atherosclerosis, which can frequently be silent. Diabetics have a higher probability of CAD than nondiabetics do. There is a high incidence of both silent myocardial infarction and myocardial ischemia.³³ Eagle *et al* demonstrated that diabetes is an independent risk factor for perioperative cardiac morbidity.³⁴ In attempting to determine the degree of this increased probability, the length of the disease and other associated end-organ dysfunction should be taken into account. Autonomic neuropathy has been found to be the best predictor of silent coronary artery disease.³⁵ Since these patients are at very high risk for silent MI, the electrocardiogram should be obtained to examine for the presence of Q waves.

Hypertension has also been associated with an increased incidence of silent myocardial ischemia and infarction.³³ Hypertensive patients who have left ventricular hypertrophy and are undergoing noncardiac surgery are at a higher perioperative risk than nonhypertensive patients.³⁶ Investigators have suggested that the presence of a strain pattern on ECG suggests a chronic ischemic state.³⁷ Therefore, these patients should also be considered to have an increased probability of CAD and developing cardiovascular morbidity.

There is a great deal of debate regarding a trigger to delay or cancel a surgical procedure in a patient with poorly or untreated hypertension. Hypertension has been divided into three stages, with Stage 3 denoting that which might be used as a cut-off (Table 18-3).³⁸ Aggressive treatment of blood pressure is associated with increasing reduction in long-term risk, although the effect diminishes in all but diabetic patients as diastolic blood pressure is reduced below 90 mm Hg.³⁹ Although there has been a suggestion in the literature that a case should be delayed if the diastolic pressure is greater than 110 mm Hg, the study often quoted as the basis for this determination demonstrated no major morbidity in this small cohort of individuals in their study.⁴⁰ In fact, the authors actually suggested that proceeding with

elective surgery is safe with a diastolic blood pressure up to 110 mm Hg, and that the sample size was too small to make comments above this level. In the absence of end-organ changes, such as renal insufficiency or left ventricular hypertrophy with strain, it would seem appropriate to proceed with surgery. In contrast, a patient with a markedly elevated blood pressure and new onset of a headache should have surgery delayed for further treatment.

| Category | Systolic | | Diastolic |
|--------------|----------|-----|-----------|
| Optimal | <120 | and | <80 |
| Normal | <130 | and | <85 |
| High-normal | 130-139 | or | 85-89 |
| Hypertension | | | |
| Stage 1 | 140-159 | or | 90-99 |
| Stage 2 | 160-179 | or | 100-109 |
| Stage 3 | ≥180 | or | ≥110 |

Reproduced with permission from Sixth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Arch Intern Med 157:2413, 1997.

Table 18-3. BLOOD PRESSURE (mm Hg)

Several other risk factors have been used to suggest an increased probability of CAD. These include the atherosclerotic processes associated with tobacco use and hypercholesterolemia. Although these risk factors increase the probability of developing coronary artery disease, they have not been shown to increase perioperative risk. When attempting to determine the overall probability of disease, the number and severity of the risk factors are important.

Importance of Surgical Procedure

The surgical procedure influences the extent of the preoperative evaluation required by determining the potential range of changes in perioperative management. For example, a pulmonary artery catheter or transesophageal echocardiography may be appropriate for a patient undergoing major abdominal or vascular surgery, but would not be considered appropriate for ambulatory surgery. Similarly, coronary revascularization may be beneficial for procedures associated with a high incidence of morbidity and mortality, but not those associated with a low incidence, as described below. There are few hard data to define the surgery-specific incidence of complications. It is known that peripheral procedures, such as those included in a study of ambulatory surgery completed at the Mayo Clinic, are associated with an extremely low incidence of morbidity and mortality.⁴¹ Similarly, major vascular procedures are associated with the highest incidence of complications, with a similar incidence documented for infra-inguinal and aortic surgery.⁴² Eagle *et al* published data on the incidence of perioperative myocardial infarction and mortality by procedure for patients enrolled in the Coronary Artery Surgery Study (CASS).⁴³ They determined the overall risk of perioperative morbidity in patients with known coronary artery disease on medical treatment and the potential reduced rate of perioperative morbidity in those patients who had a prior coronary artery bypass grafting. High-risk procedures include major vascular, abdominal, thoracic, and orthopedic surgery. The American Heart Association/American College of Cardiology Guidelines defined three tiers of surgical stress, which are shown in [Table 18-4](#).³¹

| | |
|---------------------|---|
| HIGH | (Reported cardiac risk often >5%) • Emergent major operations, particularly in the elderly • Aortic and other major vascular • Peripheral vascular • Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss |
| INTERMEDIATE | (Reported cardiac risk generally <5%) • Carotid endarterectomy • Head and neck • Intra-aortic and intrathoracic • Orthopedic • Prostate |
| LOW | (Reported cardiac risk generally <1%) • Endoscopic procedures • Superficial procedures • Cataract • Breast |

* Combined incidence of cardiac death and nonfatal myocardial infarction.

Table 18-4. CARDIAC RISK* STRATIFICATION FOR NONCARDIAC SURGICAL PROCEDURES

Importance of Exercise Tolerance

Exercise tolerance is one of the most important determinants of perioperative risk and the need for invasive monitoring.⁴⁴ An excellent exercise tolerance, even in patients with stable angina, suggests that the myocardium can be stressed without becoming dysfunctional. If a patient can walk a mile without becoming short of breath, the probability of extensive coronary artery disease is small. Alternatively, if patients experience dyspnea associated with chest pain during minimal exertion, the probability of extensive coronary artery disease is high. A greater degree of coronary artery disease has been associated with a higher perioperative risk.⁴⁵ Additionally, these patients are at risk for developing hypotension with ischemia, and therefore may benefit from more extensive monitoring or coronary revascularization. Exercise tolerance can be assessed with formal treadmill testing or with a questionnaire that assesses activities of daily living ([Table 18-5](#)).³¹

| | | | |
|--------|--|----------|---|
| 1 MET | Can you take care of yourself? Bat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2-3 mph or 32-48 km/hr? Do light work around the house like dusting or washing dishes? | 4 METs | Walk on level ground at 4 mph or 6.4 km/hr? Run a short distance Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or softball? |
| 4 METs | Climb a flight of stairs or walk up a hill? | >10 METs | Participate in strenuous sports like swimming, single tennis, football, basketball, or skiing? |

MET = metabolic equivalent.

A report of the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures. Circulation 93:1279, 1996.

Table 18-5. ESTIMATED ENERGY REQUIREMENT FOR VARIOUS ACTIVITIES*

Reilly *et al* have evaluated the predictive value of self-reported exercise tolerance for serious perioperative complications, and demonstrated that a poor exercise tolerance (could not walk 4 blocks and climb 2 flights of stairs) independently predicted a complication with an odds ratio of 1.94.⁴⁶ The likelihood of a serious adverse event was inversely related to the number of blocks that could be walked. Therefore, there is good evidence to suggest that minimal additional testing is necessary if the patient is able to relate a good exercise tolerance.

APPROACH TO THE PATIENT:FURTHER TESTING

Multiple algorithms have been proposed to determine who requires further testing. As described previously, the risk associated with the proposed surgical procedure influences the decision to perform further diagnostic testing and interventions. These Guidelines must be tempered by recent studies in which perioperative cardiac morbidity was greatly reduced by perioperative b-adrenergic blockade administration.^{47,48} With the reduction in perioperative morbidity, it has been suggested that extensive cardiovascular testing is not necessary.⁴⁹ However, until these findings can be translated into routine use with similar outcomes, further testing may be

warranted.

The algorithm to determine the need for testing proposed by the American College of Cardiology/American Heart Association Task Force is based upon the available evidence and expert opinion and integrates clinical history, surgery-specific risk, and exercise tolerance (Fig. 18-2).³¹ First, the clinician must evaluate the urgency of the surgery and the appropriateness of a formal preoperative assessment. Next, determine if the patient has undergone a previous revascularization procedure or coronary evaluation. Those patients with unstable coronary syndromes should be identified, and appropriate treatment instituted. Finally, the decision to undergo further testing depends upon the interaction of the clinical risk factors, surgery-specific risk, and functional capacity. For patients at intermediate clinical risk, both the exercise tolerance and the extent of the surgery are taken into account with regard to the need for further testing. Importantly, no preoperative cardiovascular testing should be performed if the results will not change perioperative management.

Figure 18-2. The American Heart Association/American College of Cardiology Task Force on Perioperative Evaluation of Cardiac Patients Undergoing Noncardiac Surgery has proposed an algorithm for decisions regarding the need for further evaluation. This represents one of multiple algorithms proposed in the literature. It is based upon expert opinion, and incorporates six steps. First, the clinician must evaluate the urgency of the surgery and the appropriateness of a formal preoperative assessment. Next, he or she must determine whether the patient has had a previous revascularization procedure or coronary evaluation. Those patients with unstable coronary syndromes should be identified, and appropriate treatment should be instituted. The decision to have further testing depends on the interaction of the clinical risk factors, surgery-specific risk, and functional capacity. (Adapted with permission from Eagle K, Brundage B, Chaitman B *et al*: Guidelines for perioperative cardiovascular evaluation of noncardiac surgery. A report of the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures. *Circulation* 93:1278, 1996.)

The American College of Physician Guidelines attempt to apply the evidence-based approach.⁵⁰ The initial decision point is the assessment of risk using the Detsky modification of the CRI.²¹ If patients are Class II or III, they are considered high-risk. If they are Class I, the presence of other clinical factors (according to work by Eagle *et al*³¹ or Vanzetto *et al*⁵¹) is used to further stratify risk. Those who exhibit multiple markers for cardiovascular disease according to these risk indices and who are undergoing major vascular surgery are considered appropriate for further diagnostic testing, either by dipyridamole imaging or by dobutamine stress echocardiography. The Guidelines suggest that there is insufficient evidence to recommend diagnostic testing for nonvascular surgery patients.

Pulmonary Disease

Although a great deal of attention has been focused on the cardiovascular system, perioperative pulmonary complications occur frequently and lead to significant morbidity. The presence of pulmonary disease places the patient at markedly increased risk of perioperative complications, including such problems as an intraoperative bronchospasm, the need for postoperative ventilation, and the development of atelectasis and pneumonia (Table 18-6). Several strategies have been proposed to reduce this risk and its associated perioperative morbidity (Table 18-7), but all are associated with utilization of both time and resources.

| Potential Risk Factor* | Type of Surgery | Unadjusted Relative Risk Associated with Factor |
|------------------------|-----------------------|---|
| Smoking | Coronary bypass | 3.4 |
| | Abdominal | 1.4-4.3 |
| ASA class > II | Unselected | 1.7 |
| | Thoracic or abdominal | 1.5-3.2 |
| Age > 70 yr | Unselected | 1.9-2.4 |
| | Thoracic or abdominal | 0.9-1.9 |
| Obesity | Unselected | 1.3 |
| | Thoracic or abdominal | 0.8-1.7 |
| COPD | Unselected | 2.7-3.6 |
| | Thoracic or abdominal | 4.7 |

*ASA = American Society of Anesthesiologists; COPD = chronic obstructive pulmonary disease. Adapted from Smetana GW: Preoperative pulmonary evaluation. *N Engl J Med* 340(12):942, 1999.

Table 18-6. POTENTIAL PATIENT-RELATED RISK FACTORS FOR POSTOPERATIVE PULMONARY COMPLICATIONS

| |
|---|
| Preoperative |
| Encourage cessation of cigarette smoking for at least 8 weeks |
| Treat airway obstruction in patients with chronic obstructive pulmonary disease or asthma |
| Administer antibiotics and delay surgery if respiratory infection is present |
| Begin patient education regarding lung-expansion maneuvers |
| Intraoperative |
| Limit duration of surgery to less than 3 hr |
| Use spinal or epidural anesthesia* |
| Avoid use of pneumoperitoneum |
| Use laparoscopic procedures when possible |
| Substitute less ambitious procedure for upper abdominal or thoracic surgery when possible |
| Postoperative |
| Use deep-breathing exercises or incentive spirometry |
| Use continuous positive airway pressure |
| Use epidural analgesia* |
| Use intercostal nerve blocks* |

* This strategy is recommended, although variable efficacy has been reported in the literature. Adapted from Smetana GW: Preoperative pulmonary evaluation. *N Engl J Med* 340(12):942, 1999.

Table 18-7. RISK-REDUCTION STRATEGIES

The evaluation of the patients should include a determination of the type of pulmonary disease, severity, and reversibility. A history of reactive airway disease places the patient at risk for developing bronchospasm perioperatively. In patients with asthma, it is important to determine the reversibility of symptoms, *i.e.*, if the disease is currently active or if the patient is in "optimal" medical condition. Frequently, severe asthmatics may wheeze despite intensive medical therapy. Current medications, as well as the recent use of steroids, can be used to determine the optimal preoperative medical regimen. A steroid pulse is warranted in many patients with significant asthma undergoing a major surgical procedure.

The evaluation of the patient with chronic obstructive pulmonary disease (COPD) is complex and depends upon the extent of the surgical procedure. In severe COPD, the patient develops a barrel chest, distant breath sounds, and use of accessory muscles of respiration. Determination of any symptoms of wheezing is as important as in the asthmatic. The onset or exacerbation of wheezing symptoms may indicate a new pulmonary process, such as bronchitis or pulmonary infection. Such patients will frequently benefit from delay of surgery and institution of antibiotic therapy. Symptoms of dyspnea and reduced exercise tolerance identify those at increased risk, while the absence of such symptoms with moderate exercise is rarely associated with advanced disease. Dales *et al*, using a modified pneumoconiosis research unit questionnaire concerning dyspnea, demonstrated an incidence of complications after thoracotomy that was approximately double (53%) in the group who were "unable to walk more than 100 yards on the level without a rest" or "breathless on talking, dressing, or unable to leave the house because of breathlessness" compared with those having no abnormal dyspnea.⁵² The use of further noninvasive tests prior to thoracotomy has been reviewed extensively elsewhere^{53,54} and 55 (see also Chapter

30). Although preoperative testing can identify patients at high risk for complications, implementation of perioperative interventions to reduce morbidity may be the most effective approach.⁵⁶

Patients should also be evaluated for a history of sleep apnea. Sleep apnea suggests intermittent airway obstruction, which is associated with difficulty in controlled ventilation. Additionally, these patients frequently have a difficult airway. Although central sleep apnea may not be as difficult as sleep apnea caused by airway issues, a thorough evaluation is frequently required to identify those patients in whom a fiberoptic intubation is prudent.

Smoking is an important risk factor for both cardiac and pulmonary disease. The value of smoking cessation has been reviewed.⁵⁷ Acute cessation of smoking for 24 hours does reduce the quantity of methemoglobin and can improve oxygenation. However, cessation between 24 hours and 6 weeks is associated with an increased incidence of morbidity, presumably secondary to decreased mucociliary clearance.⁵⁸ Cessation greater than 6 weeks returns oxygenation and mucociliary clearance to baseline, although not necessarily to normal.

The management of the patient with a recent cough or cold represents a difficult dilemma. The evidence regarding the increased risk of respiratory complications in such patients is controversial. One large retrospective series did not demonstrate an increased risk of complications in patients with uncomplicated upper respiratory infections, whereas several other studies did demonstrate a difference, especially if endotracheal intubation was performed.^{59,60,61,62} and 63 If the procedure is urgent or emergent, surgery should proceed. However, if surgery is elective, the risk of delay for several weeks must be balanced against proceeding with surgery at a potentially increased risk.

Endocrinopathies

There are several endocrine diseases that have implications to the anesthesiologist, many of which are covered in greater detail in [Chapter 41](#). Diabetes is an example of a disease that affects multiple organ systems. Diabetes accelerates the progression of atherosclerosis, which is frequently silent. Although the duration of diabetes affects the development of end-organ damage, the presence of autonomic dysfunction identifies the group at highest risk for silent myocardial ischemia.³⁵ Autonomic dysfunction is also associated with a greater hemodynamic lability during induction of anesthesia.⁶⁴ It is important to determine the current medication regimen and recent changes. One method of determining current control is a history of recent episodes of hypo- or hyperglycemia and the need for acute medical interventions. This information is critical in determining an appropriate glucose management plan perioperatively. Several options for appropriate management are outlined in [Table 18-8](#).

Table 18-8. PROTOCOL FOR TIGHT METABOLIC DIABETES MELLITUS CONTROL

Both thyroid and parathyroid disease have systemic manifestations that can affect the perioperative plan ([Table 18-9](#)). Although thyroid function tests are the best method of determining a euthyroid state, clinical history is frequently sufficient. Part of the preoperative evaluation should focus on identifying the presence or absence of signs and symptoms of hyperthyroidism or hypothyroidism. The presence of hypothyroidism is marked by a susceptibility to depressant drugs and the tendency to develop hypothermia, hypoventilation, hyponatremia, and hypoglycemia. In the case of hyperthyroidism, the anesthesiologist should be most concerned with the development of thyroid storm, with its manifestation of a hypermetabolic state. In addition to the systemic manifestations of the disease, a large thyroid mass may distort the airway. If the thyroid causes significant airway obstruction, the patient may have symptoms of wheezing, especially on lying flat. In such patients, a chest x-ray is indicated to evaluate for tracheal narrowing or deviation. If the symptoms are severe, a CT scan of the trachea may provide additional details of the area of narrowing and minimal diameter. Patients with hyperparathyroidism have hypercalcemia, and a preoperative serum calcium level should be obtained. Preoperative preparation of the patient with hypercalcemia includes correction of hypovolemia and dilution of the hypercalcemia.

| | Hyperthyroidism | Hypothyroidism | Hyperparathyroidism |
|------------------|--|---|--|
| General | Weight loss, heat intolerance, warm moist skin | Weight gain, cold intolerance | Weight loss, polydipsia |
| Cardiovascular | Tachycardia, atrial fibrillation, congestive heart failure | Bradycardia, congestive heart failure, arrhythmias, pericardial or pleural effusion | Hypertension, heart block |
| Neurologic | Nervousness, tremor, hyperreflexia | Slow mental function, mental retardation | Weakness, lethargy, headache, insomnia, gastric depression |
| Musculoskeletal | Muscle weakness, bone resorption | Large tongue, myxedema | Bone pain, arthritis, pathologic fractures |
| Gastrointestinal | Diarrhea | Delayed gastric emptying | Anorexia, nausea, vomiting, constipation, epigastric pain |
| Hematologic | Anemia, leukocytopenia | Impaired liver water clearance | Polyuria, hematuria |

Adapted from *Bascom M.D. Anesthesia for the patient with endocrine disease*, Part 1. *Can Res Clin Anesth* 4:61, 1987.

Table 18-9. CLINICAL MANIFESTATIONS OF THYROID AND PARATHYROID DISEASES

Mortality for surgical resection of a pheochromocytoma has decreased during the last several decades, presumably due to improved perioperative care.⁶⁵ The critical issue is to identify patients with a pheochromocytoma prior to other types of surgical procedure, since surgery in a patient with an undiagnosed pheochromocytoma can still lead to significant morbidity and mortality. The classic findings include intermittent hypertension, headache, sweating, and tachycardia. In patients with other endocrine tumors, a pheochromocytoma should be excluded as a cause of unexplained hypertension as part of a multiple endocrine neoplasia syndrome. The preoperative preparation of the patient with a pheochromocytoma is complex, and a full discussion can be found in [Chapter 41](#).

Adrenal cortical suppression can be seen perioperatively in a significant percentage of surgical patients. There are multiple etiologies including primary tumors of the adrenal cortex, tumors of the pituitary gland, and, most commonly, recent or prolonged steroid use. In patients with prolonged use of glucocorticoids, Cushing's syndrome can develop. The hallmark of this syndrome includes truncal obesity, moon facies, skin striae, easy bruisability, hypertension, and hypovolemia. Preoperative preparation includes correction of fluid and electrolyte abnormalities. In patients on long-term corticosteroids, perioperative steroid supplementation is indicated to cover the stress of anesthesia and surgery. In patients who have had a short course of steroids within the 12 months prior to surgery, the use of supplemental steroids is somewhat controversial, although most clinicians favor their use ([Table 18-10](#)).⁶⁶

| | |
|----------------------|--|
| For minor surgery | The patient should take 1.5-2 times his or her usual prednisone dosage on the evening of surgery. The following day the patient should take his or her normal prednisone dose (or postoperative equivalent if that cannot be used). The surgeon and anesthesiologist should be aware that the patient is glucocorticoid-dependent and should be prepared to administer more "rescue" if the surgery becomes prolonged or more extensive. |
| For moderate surgery | The patient should be given 2 times his or her usual glucocorticoid dosage orally (if possible) on the evening of surgery and/or 25 mg hydrocortisone or 100 mg dexamethasone 1-2 hours before the operation, then 25 mg hydrocortisone or 100 mg dexamethasone in the morning after the operation. Then the dose should be rapidly tapered over 48 hr to the usual dose of the postoperative course in uncomplicated cases. |
| For major surgery | The patient should be given 2 times his or her usual glucocorticoid dosage orally (if possible) on the evening of surgery and/or 100 mg hydrocortisone or 100 mg dexamethasone 1-2 hours before the operation, then 100 mg hydrocortisone or 100 mg dexamethasone in the morning after the operation. After the operation, 100 mg of each should be administered and then rapidly tapered (over 48-72 hr) to the patient's usual glucocorticoid dosage of the postoperative course in uncomplicated cases. |

Table 18-10. PERIOPERATIVE CORTICOSTEROID COVERAGE

Other Organ Systems

The anesthesiologist should evaluate for the presence of hepatic or renal disease. For patients with liver disease, the synthetic function may be decreased and the volume of distribution is increased. Both of these factors may influence the effects of anesthetic drugs. Most of the coagulation factors are produced in the liver, and hepatic dysfunction is associated with coagulopathies perioperatively. For patients in whom poor synthetic function is suspected, prothrombin time is the best screening test.

The presence of renal disease has important implications for both the metabolism of drugs and fluid management. As part of the preoperative evaluation, it is important to determine the type of dialysis, the last dialysis, the serum potassium, and hematocrit level. Patients with chronic renal failure, especially those on dialysis, are prone to congestive heart failure, hyperkalemia, and platelet dysfunction. After hemodialysis, patients may actually be hypovolemic, and require administration of fluid prior to induction of general anesthesia. Patients frequently exhibit chronic anemia, which is responsive to erythropoietin treatment.⁶⁷ These patients exhibit multiple mechanisms to compensate for the low hematocrit level, which allow them to tolerate a lower hematocrit perioperatively than other patients. However, these compensatory mechanisms must be balanced against the high incidence of coronary artery disease in selected renal patients.

The anesthesiologist must be concerned with the presence of infectious diseases. Part of the questioning should be directed at determining the presence of hepatitis and human immunodeficiency virus (HIV) infection. Although universal precautions should be used in all patients, knowledge of disease state should increase safety.

Multiple hematologic problems can have an impact on the anesthesiologist. Patients who demonstrate anemia (hematocrit < 10g · dl⁻¹) preoperatively should be evaluated for the cause, although anemia of chronic disease is frequently the etiology. In patients with gastrointestinal bleeds or systemic diseases such as chronic renal failure, further evaluation is unnecessary. However, a low hematocrit level may signify sickle cell disease or thalassemia. The perioperative management of hemoglobinopathies is reviewed in [Chapter 19](#).

An area of major concern and continued debate is the evaluation for coagulation disorders. A coagulation disorder can affect the anesthesiologist's decision to perform regional anesthesia and direct perioperative utilization of blood products. The patient should be questioned regarding a history of a bleeding diathesis, such as easy bruising, bloody noses, or bleeding from the gums. The use of any medications that can affect platelet function (aspirin, other NSAIDs, anticoagulants) should be determined. Platelet dysfunction is associated with bleeding of the mucocutaneous surfaces, such as petechiae, epistaxis, hematuria. The anesthesiologist should also review any in-hospital medications to determine whether low-molecular-weight heparins have been given.

Musculoskeletal disorders can present physical obstacles to the anesthesiologist, as well as having systemic manifestations. The presence of muscular disorders has been associated with an increased risk for malignant hyperthermia, and should be included in the preoperative history.⁶⁸ Osteoarthritis is common in the population, and may lead to a more difficult intubation or difficulty in positioning for regional anesthesia. Rheumatoid arthritis is less common, but may lead to greater problems perioperatively. These patients may have atlanto-occipital instability and are at risk for myocarditis, pleuritis, and restrictive lung disease. It is important in such patients to perform a thorough review of systems.

The extent of the neurologic history frequently depends upon the surgical procedure. Neurologic deficits can be divided into those primarily affecting the central versus peripheral system. A history of stroke identifies patients with increased risk of perioperative stroke. Evaluation of any residual neurologic defects as a baseline status should be performed in order to compare any changes postoperatively. In patients with a recent trauma, signs of increased intracranial pressure should be elicited. The presence of a change in mental status, lethargy, headache, or change in vision should alert the anesthesiologist to increased intracranial pressure and a risk for herniation. The *Glasgow Coma Scale* is frequently used to assess the level of consciousness ([Table 18-11](#)). Physical signs may include hypertension, bradycardia, arrhythmias, focal sensory or motor deficits, and slurred speech.

| Response | Score |
|-------------------------|-------|
| Eye Opening | |
| Spontaneous | 4 |
| To speech | 3 |
| To pain | 2 |
| Nil | 1 |
| Best Motor Response | |
| Obeys | 6 |
| Localizes | 5 |
| Withdraws (flexion) | 4 |
| Abnormal flexion | 3 |
| Extensor response | 2 |
| Nil | 1 |
| Verbal Response | |
| Oriented | 5 |
| Confused conversation | 4 |
| Inappropriate words | 3 |
| Incomprehensible sounds | 2 |
| Nil | 1 |

Table 18-11. GLASGOW COMA SCALE

PHYSICAL EXAMINATION

The physical examination can be divided into two parts: a general examination and a specific examination guided by the preoperative history. As anesthesiologists, we are acutely concerned with the airway. Evaluation of the airway involves determining the thyromental distance, the ability to flex and extend the neck, and aperture opening. Recently, the Mallampati classification has been used as a method of assessing the airway ([Table 18-12](#)).⁶⁹ The Mallampati class has met with only moderate success (low positive predictive value) in identifying patients with a difficult intubation.^{70,71} In patients who have sustained a recent trauma, assessment of the stability of the cervical spine is critical. In appropriate patients, the presence of pain on movement should be assessed. Otherwise, radiographic examination may be required.

| Class | Direct Visualization, Patient Seated | Laryngoscopic View |
|-------|--------------------------------------|-----------------------|
| I | Soft palate, fauces, uvula, pillars | Entire glottic |
| II | Soft palate, fauces, uvula | Posterior commissure |
| III | Soft palate, uvular base | Tip of epiglottis |
| IV | Hard palate only | No glottal structures |

Table 18-12. AIRWAY CLASSIFICATION SYSTEM

The cardiovascular examination includes determination of blood pressure and auscultation of the heart. Determination of blood pressure can vary between examinations and between extremities. Frank *et al* demonstrated a marked difference between left- and right-arm blood pressures in patients with vascular disease.⁷² This may have important implications in patients with altered cerebrovascular autoregulation and in determining appropriate blood pressure limits. In addition, blood pressure measurements exhibit a circadian variation in normal individuals. Many demonstrate “white coat hypertension”—that is, their blood pressure is elevated only in an examination setting.⁷³ The preoperative setting may also be a circumstance that occasions abnormally elevated measurements owing to anxiety. However, Bedford *et al* reported that the admission blood pressure was the best predictor of response to laryngoscopy.⁷⁴ Therefore, the initial blood pressure may also provide prognostic information.

The cardiac examination should include determination of the rhythm, the presence of murmurs and the presence of third or fourth heart sounds. If a murmur is present, it is important to determine its relation to the phase of the cardiac cycle and radiation pattern. Frequently, soft murmurs are more significant than loud murmurs. Since a diagnosis of aortic stenosis carries a high risk of perioperative morbidity and mortality, a systolic murmur radiating to the carotids frequently deserves further evaluation, particularly if symptoms are present (angina, congestive heart failure, syncope).¹⁵

Further examination of the cardiovascular system should be directed by the history. For example, more extensive examination of peripheral pulses for both strength and murmurs may be indicated in patients with vascular disease.

Examination of the lungs should focus on auscultation for sounds of rales suggestive of congestive heart failure and the presence of wheezing indicative of reactive airway disease. In patients who wheeze, the relationship of the wheezing to the phase of the respiratory cycle and position can help differentiate the etiology.

The neurologic examination may be cursory in healthy patients, or extensive in patients with co-existing disease. Testing of strength, reflexes, and sensation may be important in patients if the anesthetic plan or surgical procedure may result in a change in the condition. For example, the presence of a peripheral neuropathy is important information in a patient scheduled for a toe amputation since these patients frequently require minimal anesthesia if the neuropathy is severe. Similarly, patients undergoing carotid endarterectomy may have a baseline neurologic deficit, which affects the postoperative examination.

ROUTINE LABORATORY DATA (Table 18-13)

Table 18-13. RECOMMENDED LABORATORY TESTING SYSTEM UTILIZED AT THE JOHNS HOPKINS HOSPITAL

The Value of Preoperative Testing: Normal Values

In attempting to determine the optimal choice of preoperative tests, it is important to understand the interpretation of the results. Ideally, tests would either confirm or exclude the presence of a disease; however, the vast majority of tests only increase or decrease the probability of disease. In determining reference ranges for diagnostic tests, values that fall outside of the 95% confidence intervals for normal individuals are considered abnormal. Therefore, up to 5% of normal individuals can have “abnormal” test results. In order to determine its clinical relevance, a test must be interpreted within the context of the clinical situation. Performing tests in patients with no risk for having the pathophysiologic process of interest can yield a high number of false-positive results. For example, a low potassium ($3.0 \text{ mg} \cdot \text{dl}^{-1}$) in an otherwise healthy individual is most likely a normal result. Interpreting this test as abnormal, and initiating treatment, could lead to harm without any benefit.

The Value of Preoperative Testing: Bayesian Analysis

The use of noninvasive testing is another area in which the clinical situation significantly affects the interpretation. It is rare for a test result to be pathognomonic for a disease state; that is, no test is 100% sensitivity and specific. For example, exercise or pharmacologic stress testing has sensitivities ranging from 60–90% and specificities ranging from 60–80% for a significant coronary artery stenosis. In order to interpret the results of a noninvasive test, it is important to know the prevalence of disease in the population as well as the sensitivity and specificity of the test. If a test is used in a population with a very low prevalence of disease, a positive result is frequently a false positive. Similarly, a negative result in a population with a very high prevalence of disease may be a false negative. Bayes' theorem suggests a test is most useful in a population with a moderate probability of disease.⁷⁵

Risks and Costs Versus Benefits

The use of medical testing is associated with significant cost, both in real dollars and in lost opportunity and potential harm. Cardiovascular testing in vascular surgery patients alone has been estimated to cost more than \$1 billion annually.⁷⁶ Routine preoperative testing has been estimated to cost \$3 billion annually. In an era of limited resources and capitated care, resources spent on inappropriate testing may lead to a lack of resources for other areas of medical care or potentially a decrease in reimbursement of physicians. From the patient's perspective, each test is associated with time away from other areas, *i.e.*, lost opportunity. Finally, an “abnormal” test that is later determined to be a false result can lead to significant cost and real harm. For example, a positive exercise electrocardiographic stress test in a healthy 40-year-old female may lead to coronary angiography. Coronary angiography is not a benign procedure, and can lead to vascular injuries. Based upon Bayesian analysis, a positive test result in this patient is most likely a false positive, and the test was inappropriately used. Therefore, the woman and her physician would gain no additional information, thousands of dollars in medical costs would accrue, and she would sustain morbidity.

Several studies have evaluated the implications of reduced testing. Kaplan *et al* studied the preoperative laboratory screening pattern from 2000 patients undergoing elective surgery over a 4-month period.⁷⁷ Of the routinely ordered tests, 60% would not have been performed if testing had been done only for defined indications, and only 0.22% of these demonstrated abnormalities that might influence perioperative management. The authors concluded that routine testing contributed little to patient care.

Golub *et al* retrospectively reviewed the records of 325 patients who had undergone preadmission testing prior to ambulatory surgery.⁷⁸ Of these, 272 (84%) had at least one abnormal screening test result, while only 28 surgeries were delayed or canceled. The authors estimated that only three patients potentially benefited from preadmission testing, including a new diagnosis of diabetes in one and nonspecific ECG changes in two, one of which had known ischemic heart disease.

In a study published in 1991, Narr and colleagues at the Mayo Clinic demonstrated minimal benefits from routine testing and proposed that routine laboratory screening tests were not required in healthy patients.⁷⁹ In a follow-up study published in 1997, a cohort of patients who had no preoperative testing during 1994 was reviewed and found to include no deaths or major perioperative morbidity.⁸⁰ They concluded that current anesthetic and medical practices rapidly identify indications for laboratory evaluation when necessary and therefore routine testing was not indicated in this healthy cohort.

Even if testing better defines a disease state, the risks of any intervention based upon the results may outweigh the benefit. Cardiovascular testing is a classic example (Fig. 18-3). If a noninvasive test is positive, coronary angiography may be performed. A positive angiogram may then result in coronary artery bypass grafting prior to

the planned noncardiac surgery. Although cardiovascular morbidity and mortality may be reduced in patients with significant coronary artery disease who have undergone coronary revascularization, the morbidity associated with both the testing and revascularization procedure may be greater than any potential benefit. Fleisher *et al* has suggested the use of decision analysis as a method of quantifying these risks and benefits.⁴

Figure 18-3. A decision algorithm evaluating the decision between vascular surgery alone or coronary artery revascularization before vascular surgery. There are currently no randomized trials to address the optimal strategy. By outlining the multiple decision points at which a patient can sustain mortality by choosing to undergo coronary revascularization first, the optimal strategy for preoperative evaluation can be demonstrated. Specifically, variation in mortalities at each decision point can change the optimal strategy. (Reproduced with permission from Fleisher LA, Skolnick ED, Holroyd KJ, Lehmann HP: Coronary artery revascularization before abdominal aortic aneurysm surgery: A decision analytic approach. *Anesth Analg* 79:661, 1994.)

Complete Blood Count and Hemoglobin Concentration

The use of a preoperative hemoglobin has been suggested as the only test necessary in many patients prior to elective surgery; however, even this minimal standard has been questioned. Baron *et al* reviewed the records of 1863 pediatric patients scheduled for elective outpatient procedures.⁸¹ In only 1.1% of patients was the hematocrit abnormal, and in none of these patients was the procedure canceled or anesthetic plan modified. However, a baseline hematocrit is still indicated in any procedure with a risk of blood loss.

The standard regarding the lowest acceptable perioperative hematocrit and indication for a preoperative transfusion has changed during the past decade. Traditionally, the minimum hematocrit was considered to be $10 \text{ g} \cdot \text{dl}^{-1}$. However, concern over blood-borne infections has resulted in a general acceptance of lower levels. The current recommendations of the National Blood Resource Education Committee is that a hemoglobin of $7 \text{ g} \cdot \text{dl}^{-1}$ is acceptable in patients without systemic disease.⁸² In patients with systemic disease, signs of inadequate systemic oxygen delivery (tachycardia, tachypnea) are an indication for transfusion. In a retrospective study, a hematocrit of $<29\%$ postoperatively in vascular surgery patients was associated with a significantly increased incidence of myocardial ischemia and infarction.⁸³ Therefore, in patients with active coronary artery disease, a higher hematocrit may be indicated.

Electrolytes

In the past, patients routinely received a chemistry panel prior to surgery. These panels can include as few as 7 tests and may include more than 36 tests. Because of technology issues, it may be cheaper to obtain a standard battery than to determine one particular test. However, testing rarely leads to any change in perioperative management.

There are numerous guidelines regarding the need for preoperative electrolytes. The only consensus is the lack of routine testing in asymptomatic adults, although a creatinine and glucose has been recommended in older patients. In patients with systemic diseases or on medications that affect the kidneys, a BUN and creatinine are indicated.

Coagulation Studies

Coagulation disorders can have significant impact on the surgical procedure and perioperative management. However, abnormal laboratory studies in the absence of clinical abnormalities will rarely lead to perioperative problems. Patients with known inherited coagulopathies, such as hemophilia or von Willebrand's disease, require preoperative preparation of the patient. It is important to identify such disorders from prior history or bleeding problems. A prothrombin, partial thromboplastin time analysis is indicated in the presence of previous bleeding disorders such as following injuries, after tooth extraction or surgical procedures, and in patients with known or suspected liver disease, malabsorption or malnutrition, and on certain medications such as antibiotics and chemotherapeutic agents.

Bleeding time has been advocated as a means of determining the presence of a qualitative platelet defect. It can be performed in patients with low platelets ($<100,000/\text{mm}^3$), patients with medical conditions that affect platelets (e.g., uremia), or patients on anti-platelet agents. Although this information may be important from the surgeon's perspective, it rarely affects anesthetic care unless a regional technique is planned. However, several recent reviews have questioned the value of this test in clinical practice.^{84,85} The test is extremely operator-dependent, and may be invalid in inexperienced hands. It would therefore be best to determine the limits for the individual performing the test. Since this is rare in clinical practice, some authors have suggested that the test should be abandoned in favor of clinical history. In the absence of a clinical bleeding diathesis, complications are extremely rare. If such a history exists, it may be prudent to avoid regional anesthesia.

Urinary Analysis

A routine preoperative urinary analysis (UA) is rarely indicated. O'Connor and Drasner reviewed the records of 486 elective surgeries in children, of which only two demonstrated an abnormal UA result.⁸⁶ One of these results was contaminated, and the cancellation of surgery resulted in a complication (incarcerated inguinal hernia) requiring emergency surgery. The other abnormal test was a probable asymptomatic bacteriuria. The authors suggest that a routine UA adds little to the preoperative evaluation of a healthy child, and should be omitted. Lawrence *et al* determined the cost-effectiveness of preoperative urinalysis in non-prosthetic knee procedures and estimated the costs at \$1,500,000 per wound infection prevented.⁸⁷ Therefore, preoperative UA is rarely performed currently.

Pregnancy Testing

Routine pregnancy testing in women of child-bearing potential is a subject of considerable debate. The rationale is that specific agents may be avoided, or surgery may be delayed. Information regarding the last menstrual period can help define the potential, but does not eliminate the possibility. Roizen and Cohn suggest that pregnancy testing should be limited to females who believe they are pregnant or cannot tell if they are pregnant.⁸⁸ However, a number of studies have evaluated the validity of history as a means of assessing pregnancy status in adolescents with conflicting results.^{89,90} and ⁹¹ Current practice varies dramatically among centers and anesthesiologists, and may be a function of the population served with regard to the need to routinely test those women with a negative pregnancy history.⁹²

Chest Radiographs

A preoperative chest x-ray can identify abnormalities that may lead to either delay or cancellation of the planned surgical procedure or modification of perioperative care. For example, identification of pneumonia, pulmonary edema, pulmonary nodules, or a mediastinal mass could all lead to modification of care. However, routine testing in the population without risk factors can lead to more harm than benefit. Roizen has demonstrated substantial harm from additional procedures based upon shadows performed solely as a routine preoperative chest x-ray.⁸⁸

The American College of Physicians suggests that a chest x-ray is indicated in the presence of active chest disease or an intrathoracic procedure, but not solely on the basis of advanced age alone.⁹³ Other guidelines suggest that a preoperative chest x-ray is reasonable in patients over the age of 60 years. In a meta-analysis, Archer *et al* reviewed the published reports from 1966 to 1992 in the English, French, and Spanish literature.⁹⁴ Twenty-one reports were identified with sufficient data to evaluate the use of testing. On average, abnormalities were reported in 10% of routine preoperative chest x-rays, of which only 1.3% were unexpected. These findings result in modification in management in only 0.1% of patients, with unknown influence on outcome. The authors estimated that each finding that influenced management would cost \$23,000, concluding that routine chest x-rays without a clinical indication were not justified. Therefore, a preoperative chest x-ray is indicated

in patients with a history or clinical evidence of active pulmonary disease, and *may* be indicated routinely only in patients with advanced age.

Cardiovascular Tests

Electrocardiogram

The preoperative 12-lead electrocardiogram can provide important information on the status of the patient's myocardium and coronary circulation. Evidence of active ischemia can be detected and usually requires changes in at least two leads. The sensitivity of abnormalities on the 12-lead ECG as a marker for specific types of heart disease depends on the prevalence of the disease in that patient population. Abnormal Q waves in high-risk patients are highly suggestive of a past myocardial infarction. Patients with Q-wave infarctions are known to be at increased risk of a perioperative cardiac event, and have a worse long-term prognosis.

It has been estimated that approximately 30% of infarctions are silent and only detected on routine ECG, with the highest incidence in patients with diabetes or hypertension. According to the Framingham study, long-term prognosis is not altered by the lack of symptoms.³³ The absence of Q waves on the 12-lead ECG does not exclude the occurrence of a Q-wave myocardial infarction in the past. It has been shown that 5–27.1% of Q waves disappear over a 10-year period.⁹⁵ Those patients in whom the electrocardiogram reverts to normal have improved survival compared with those with persistent abnormalities, with or without Q waves. The presence of Q waves on a preoperative ECG in a high-risk patient, regardless of symptoms, should alert the anesthesiologist to the increased perioperative risk and the possibility of active ischemia in that patient.

It has not been established that the information obtained from the preoperative 12-lead electrocardiogram affects clinical care. In a retrospective study conducted in the early 1970s to determine how the preoperative ECG was used, no operations were delayed based upon preoperative ECG, even in the presence of new Q-waves.⁹⁶ Carlner *et al* found that preoperative 12-lead ST-T wave abnormalities occurred more frequently in patients who subsequently had more complicated postoperative courses.⁹⁷ Although changes on the preoperative electrocardiogram may not result in delay of surgical procedures, the increased vigilance by the anesthesiologist may influence intraoperative monitoring and treatment. However, in a retrospective review of adults undergoing ambulatory surgery, 42.7% had electrocardiographic abnormalities.⁹⁸ The preoperative electrocardiogram was not predictive of perioperative complications, which occurred in only 1.6% of the patients. The authors concluded that a preoperative electrocardiogram rarely helps perioperative management in this group. In contrast, Landesberg *et al* reported a significantly increased risk of a perioperative cardiac event in patients with left ventricular hypertrophy or ST segment changes on the preoperative ECG.⁹⁹ Current recommendations vary, but include the need for a preoperative electrocardiogram in the presence of systemic cardiovascular disease (e.g., hypertension, peripheral vascular disease), age over 40 in males and over 50 in females.

Noninvasive Cardiovascular Testing

The exercise electrocardiogram has been the traditional method of evaluating individuals for the presence of coronary artery disease. It represents the least invasive and most cost-effective method of detecting ischemia, with a reasonable sensitivity (68–81%) and specificity (66–77%) for identifying coronary artery disease.¹⁰⁰ The goal of the test is to provoke ischemia by exercise, thus causing an increase in myocardial oxygen demand relative to myocardial oxygen supply. Electrocardiographic signs of myocardial ischemia and clinical signs of left ventricular dysfunction are considered positive. A decrease in blood pressure in response to exercise has been associated with global ventricular dysfunction in humans. Syncope during the test also signifies decreased cardiac output. Either sign signifies poor dynamic function, and is much more ominous than ST segment depression alone. A positive exercise electrocardiographic stress test can alert the anesthesiologist that the patient is at risk for ischemia at a wide range of heart rates, with the greatest risk in those who develop ischemia at low workloads during the test. However, as outlined above, the ability to exercise suggests that no further testing is necessary, and therefore exercise electrocardiography is rarely indicated.

A significant number of high risk patients are either unable to exercise or have contraindications to exercise. In surgical patients, this phenomenon is most evident in those patients with claudication or an abdominal aortic aneurysm undergoing vascular surgery, both of which have a high rate of perioperative cardiac morbidity. Therefore, pharmacologic stress testing and ambulatory electrocardiography have become popular, particularly as preoperative tests in vascular surgery patients.

Pharmacologic stress for the detection of CAD can be divided into two categories: (1) those that result in coronary artery vasodilation, such as dipyridamole, and (2) those that increase myocardial oxygen demand, such as dobutamine. The coronary artery vasodilators work by producing differential flows in normal coronary arteries when compared to those with a stenosis. Several authors have shown that the presence of a redistribution defect on dipyridamole thallium imaging in patients undergoing peripheral vascular surgery is predictive of postoperative cardiac events (Fig. 18-4).^{101,102,103} and ¹⁰⁴ This work has been extended to include patients undergoing nonvascular surgery.⁴⁵ In order to increase the predictive value of the test, several strategies have been suggested. Lung uptake, left ventricular cavity dilation, and redistribution defect size have all been shown to be predictive of subsequent morbidity. Fleisher *et al* demonstrated that the delineation of “low” and “high” risk thallium scans markedly improved the tests predictive value.⁴⁵ They demonstrated that only patients with “high” risk thallium scans were at increased risk for perioperative morbidity and long-term mortality.

Figure 18-4. A dipyrindamole-thallium SPECT image demonstrating a reversible defect. The top image demonstrates defects consistent with areas of low perfusion or ischemia, which fills in on subsequent imaging (*bottom*). (See upper left portion of image.)

The ambulatory ECG (AECG or Holter) provides a means of continuously monitoring the electrocardiogram for significant ST segment changes during the preoperative period. Raby demonstrated that the presence of silent ischemia is a strong predictor of outcome, while its absence was associated with a good outcome in 99% of patients.¹⁰⁵ Other investigators have demonstrated the value of silent AECG monitoring, although the negative predictive values have not been as high as originally reported.⁴⁵ Fleisher *et al* demonstrated a similar predictive value of dipyridamole thallium imaging and AECG monitoring; however, the quantity of silent ischemia could not be used to identify those patients at greatest risk who might benefit from further testing and coronary revascularization.⁴⁵

Stress echocardiography has received attention as a preoperative test. The appearance of new or worsened regional wall motion abnormalities is considered a positive test. These represent areas at risk for myocardial ischemia. The advantage of this test is that it is a dynamic assessment of ventricular function. Dobutamine echocardiography has also been studied and found to have among the best positive and negative predictive.¹⁰⁶ Poldermans *et al* demonstrated that the group at greatest risk comprised those who demonstrated regional wall motion abnormalities at low heart rates.^{107,108}

Several groups have published meta-analyses of preoperative diagnostic tests. Mantha *et al* demonstrated good predictive values of AECG monitoring, radionuclide angiography, dipyridamole thallium imaging, and dobutamine stress echocardiography.¹⁰⁹ Shaw *et al* also demonstrated good predictive values of dipyridamole thallium imaging and dobutamine stress echocardiography.¹¹⁰ Both studies demonstrated the superior predictive value of dobutamine stress echocardiography; however, there was significant overlap of the confidence intervals with other tests. However, the most important determinant with respect to the choice of preoperative testing is the expertise at the local institution. The decision to perform further invasive testing and management should be based on the principles outlined above, *i.e.*, the ability of the intervention to affect both short- and long-term health.

Assessment of Ventricular and Valvular Function

There are multiple methods to assess ejection fraction and valvular function. The least invasive method is echocardiography. Echocardiography can be used to assess static function or can be combined with exercise or pharmacologic stress to assess dynamic function. It is also very effective in evaluating valvular function and

diagnosing valve area. Radionuclide angiography has also been used as a both a static and dynamic measure of ejection fraction.

A preoperative resting echocardiography can determine the presence of ventricular dysfunction, regional wall motion abnormalities, ventricular wall thickness, and valvular function. Pulse wave Doppler can be used to obtain the velocity time integral. Ejection fraction can then be calculated by determining the cross-sectional area of the ventricle. Several investigators have examined the predictive value of ejection fraction using either echocardiographic or radionuclide measurements. Kazmers and colleagues found that a poor ejection fraction (<35%) was the best predictor of perioperative outcome after vascular surgery.¹¹¹ In contrast, Franco and colleagues found no difference in perioperative morbidity based upon ejection fraction.¹¹² Similarly, McEnroe and colleagues were unable to demonstrate a difference.¹⁷ Importantly, Halm *et al* demonstrated that the ejection fraction did not add additional prognostic information over standard clinical history.¹¹³

Echocardiography can provide important information regarding valvular function. This information may have important implications for both cardiac and noncardiac surgery, and is discussed more fully later in the book. In particular, aortic stenosis has been associated with a worse prognosis in noncardiac surgical procedures, and knowledge of valve lesions can modify management chances and treatment of hemodynamic dysfunction.¹⁵

Coronary Angiography

Coronary angiography represents the gold standard for defining coronary anatomy. Information regarding ventricular and valvular function can also be assessed. Finally, hemodynamic indices can be determined. For example, ventricular pressure and gradients across valves can be calculated.

In patients undergoing coronary artery bypass grafting, the information is routinely available. As described above, certain lesions, *i.e.*, left main disease, may be associated with greater perioperative risk. Certain disease types may also increase risk. Diffuse atherosclerosis in small vessels, as seen in diabetics, may lead to incomplete revascularization, and a risk for developing post-bypass ischemia.

In patients undergoing noncardiac surgery, the decision to perform coronary angiography may be the result of a positive preoperative test or may be the first test in a patient with a very high probability of significant disease. The test is then used by the cardiologist to determine whether coronary artery revascularization is an option.

Unlike the exercise or pharmacologic stress tests described above, coronary angiography provides the clinician with anatomic, not functional, information. Although a critical stenosis delineates an area at risk for developing myocardial ischemia, the functional response to that ischemia cannot be determined by angiography alone. Although coronary artery disease is undoubtedly the substrate for a perioperative MI, the critical stenosis may not be the underlying pathophysiology. In the ambulatory population, many infarctions are the result of acute thrombosis of a noncritical stenosis. Therefore, the value of routine angiography prior to noncardiac surgery depends on the ability to correct the lesions that cause morbidity.

Pulmonary Function Tests

Pulmonary function tests can be generally divided into two categories, spirometry and an arterial blood gas. Spirometry can provide information on forced vital capacity (FVC), forced expiratory volume in 1 sec (FEV₁), ratio of FEV₁/FVC, and average forced expiratory flow from 25 to 75%. Although each of these measures has a sound physiologic basis, their practical assessment can vary greatly among healthy persons. Objective measures defining high risk for pulmonary resection have been proposed.⁵⁹ For nonpulmonary surgery, they rarely provide additional information beyond that obtained from history. The one possible indication is the use of pulmonary function testing with bronchodilator therapy to assess responsiveness in a patient who is wheezing.

With the advent of the pulse oximeter, the use of preoperative arterial blood gas sampling has become less important. It may still be indicated, since determining the baseline CO₂ is useful in managing postoperative ventilation settings and resting hypercapnia is associated with increased perioperative risk. However, the physical act of obtaining an arterial blood gas can lead to hyperventilation and change the PaCO₂. One method of assessing the probability of CO₂ retention is evaluation of the serum bicarbonate. A normal serum bicarbonate will virtually exclude the diagnosis of CO₂ retention. If the serum bicarbonate is elevated, then an arterial blood gas either preoperatively or immediately prior to induction may be indicated.

Another indication for an arterial blood gas has been determination of oxygen concentration. With the advent and availability of pulse oximetry in the preoperative screening clinic, this is rarely an indication.

SUMMARY

The preoperative evaluation of the surgical patient continues to be an important component of the anesthesiologist's role. A thorough history and physical examination can be used to identify those medical conditions that might affect perioperative management and direct further laboratory testing. In the current era of capitated care and the desire to reduce inappropriate utilization of medical technology, the anesthesiologist can have a significant impact on health resource utilization by performing appropriate laboratory tests. By combining data from the history, physical examination, exercise tolerance, and the stress of the surgical procedure, inappropriate testing can be reduced; but more importantly, appropriate screening tests will be performed.

Knowledge of the pathophysiologic characteristics of coexisting diseases and an understanding of the implications of concomitant drug therapy are essential for the optimal management of anesthesia for an individual patient. In many instances, the nature of the coexisting disease has more impact on the management of anesthesia than does the actual surgical procedure. A variety of rare disorders may influence the selection and conduct of anesthesia (Table 19-1). Economic constraints have increased the likelihood that patients with these diseases will present for outpatient surgery with little time for complete preoperative evaluation. Recent advances in molecular genetics and cellular biology have clarified the understanding of the pathophysiology of many uncommon diseases. Consequently, anesthesiologists must periodically update their diagnostic skills and clinical knowledge to recognize when additional evaluation or treatment may be required.

MUSCULOSKELETAL DISEASES

Muscular Dystrophy

Research in the past ten years has dramatically increased the understanding of the defects in the cellular architecture of muscle in patients with muscular dystrophy. The key discovery was that patients with Duchenne's muscular dystrophy lack the muscle protein dystrophin, an important component of the cytoskeleton of muscle cells.¹ Since the discovery of dystrophin, a number of other proteins have been identified that also contribute to the stability of muscle cell membranes. These proteins include merosin, dystroglycans, sarcoglycans, utrophin, syntrophin, and dystrobrevin.^{2,3} It is now known that dystrophin and the dystrophin-associated proteins form a complex structural network extending from the extracellular matrix to the submembrane complex that maintains the integrity of the muscle cell membrane (Fig. 19-1). The absence or deficiency of one of these proteins will result in a weakened muscle membrane that is susceptible to damage (Table 19-2).

Table 19-2. TYPES OF MUSCULAR DYSTROPHY

The muscular dystrophies are characterized by a progressive but variable rate of loss of skeletal muscle function. Although many of the initial signs and symptoms of muscular dystrophy are a result of skeletal muscle dysfunction, many studies have demonstrated that cardiac and smooth muscle are also affected. Consequently, the evaluation of cardiac function is important in patients with muscular dystrophy. In some types of muscular dystrophy, cardiac muscle dysfunction may be more significant than skeletal muscle dysfunction.

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy, the most severe of the muscular dystrophies, is produced by a genetic abnormality resulting in a lack of production of dystrophin. Duchenne's dystrophy is characterized by painless degeneration and atrophy of skeletal muscle. This disorder is a sex-linked recessive trait that is clinically evident in boys. Progressive skeletal muscle weakness produces symptoms between the ages of 2 and 5 years. Progressive limitation of movement usually confines the patient to a wheelchair by 12 years of age. Axial skeletal muscle imbalance produces kyphoscoliosis, which often requires operative instrumentation for stabilization. Death occurs when patients are between 15 and 25 years old and is usually secondary to congestive heart failure or pneumonia. Serum creatine kinase levels reflect the progression of the disease. Early in the patient's life, the creatine kinase level is elevated. Later, as significant amounts of skeletal muscle have degenerated, the creatine kinase level decreases.

It is very evident that smooth muscle and cardiac muscle are also affected in patients with muscular dystrophy. Smooth muscle involvement results in intestinal tract hypomotility, delayed gastric emptying, and acute gastroparesis.^{4,5} Most patients with Duchenne's muscular dystrophy have evidence of myocardial degeneration. The degeneration of myocardial tissue is reflected in the progressive loss of R-wave amplitude in the lateral precordial electrocardiogram (ECG) leads with aging.^{6,7} Progressive loss of myocardial tissue can result in reduced myocardial contractility, dilated cardiomyopathy, ventricular dysrhythmias, mitral regurgitation (papillary muscle dysfunction), and right ventricular outflow obstruction.^{8,9}

Degeneration of respiratory muscles can be measured by pulmonary function testing, which reveals a restrictive disease pattern. Diminished muscle strength produces an ineffective cough, resulting in retention of pulmonary secretions, pneumonia, and death.

Although the genetic defect for Duchenne's muscular dystrophy is known, successful genetic therapy remains elusive. Other therapeutic modalities include myoblast transplantation and administration of muscle protein precursors. Most therapy is directed at prevention of musculoskeletal deformities. Treatment of selected patients with ACE inhibitors and/or b-adrenergic blockers may retard the development of congestive heart failure.⁹

Becker's Muscular Dystrophy

Becker's muscular dystrophy is similar to Duchenne's muscular dystrophy, but the onset is later in life and slower in progression. Patients afflicted with Becker's muscular dystrophy often remain ambulatory until 60 years of age. Patients with Becker's muscular dystrophy have abnormal dystrophin or reduced levels of normal dystrophin, which explains the milder clinical course when compared to Duchenne's muscular dystrophy. Recent research has established that cardiac abnormalities such as cardiomyopathy and ventricular dysrhythmias are common in patients with Becker's muscular dystrophy.^{10,11} and ¹²

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy is an X-linked recessive disease that is characterized by contractures of the elbows, ankles, and spine as well as humeropectoral weakness. The skeletal muscle manifestations are usually mild, whereas cardiac conduction defects can be fatal.^{13,14} Emery-Dreifuss muscular dystrophy is caused by a deficiency of emerin, a protein found in the nucleus of skeletal muscle cells and near the intercalated disks of cardiac muscle.¹⁵ This distribution of emerin may explain why cardiac muscle is more severely affected than skeletal muscle.

Limb Girdle Muscular Dystrophy

Patients with limb girdle dystrophy exhibit weakness of the muscles of the shoulder and pelvic girdles. Although most cases of limb girdle dystrophy are inherited as an autosomal recessive trait, some forms are inherited as autosomal dominant traits. Limb girdle dystrophy is caused by an abnormality in the sarcoglycan proteins.¹⁶ Cardiac abnormalities such as dilated cardiomyopathy and atrioventricular conduction disturbances have been reported in patients with limb girdle muscular dystrophy.^{17,18}

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy is inherited as an autosomal dominant trait. Patients with this abnormality have diverse clinical manifestations. In addition to weakness of the facial, scapulohumeral, anterior tibial, and pelvic girdle muscles, retinal vascular disease, deafness, and neurologic abnormalities have also been described.¹³ Of patients with facioscapulohumeral muscular dystrophy, 5% have cardiac conduction defects and cardiac dysrhythmias.¹⁹

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy typically presents in late adulthood. The primary clinical manifestations are ptosis and dysphagia. Weakness of the muscles of the head, neck, and arms may also develop. Although dysphagia has been attributed to weakness of pharyngeal skeletal muscle, esophageal smooth muscle dysfunction occurs in most patients.²⁰

Congenital Muscular Dystrophy

Congenital muscular dystrophy is characterized by early onset (*in utero* or infancy), muscle weakness, and mental retardation. These types of muscular dystrophy are caused by genetic defects that affect production of muscle proteins of the surface of the sarcolemma. Included in this group of muscular dystrophy are merosin-deficient muscular dystrophy, Fukuyama muscular dystrophy, Walker-Warburg syndrome, Ullrich's disease, and muscle-eye-brain (MEB) disease.²¹

Management of Anesthesia

Most of the significant complications from anesthesia in patients with muscular dystrophy are secondary to the effects of anesthetic drugs on myocardial and skeletal muscle. Myocardial dysfunction makes these patients more sensitive to the myocardial depressant effects of potent inhaled anesthetics. There are numerous reports of cardiac arrest having occurred during induction of anesthesia.²² These arrests are associated with rhabdomyolysis and hyperkalemia and have occurred with volatile anesthetics alone or in combination with succinylcholine. In view of the weakened muscle structure of patients with muscular dystrophy, succinylcholine may produce muscle membrane damage and release of intracellular contents. Consequently, succinylcholine is best avoided in patients with muscular dystrophy. The effect of volatile anesthetics on abnormal skeletal muscle is not known. However, it could be speculated that volatile anesthetics, by releasing calcium from the sarcoplasmic reticulum, could produce muscle membrane damage and rhabdomyolysis. Sevoflurane is a less potent stimulus for release of calcium from the sarcoplasmic reticulum

and may be the preferred volatile agent for patients with Duchenne's muscular dystrophy.²³ Some patients with muscular dystrophy may be susceptible to malignant hyperthermia, but this is unpredictable.^{24,25 and 26}

Nondepolarizing muscle relaxants can be used, although patients with Duchenne's muscular dystrophy may require a longer recovery time.²⁷ The response to mivacurium, however, is normal.²⁸ The response of patients with other forms of muscular dystrophy is variable.²⁹ Consequently, close monitoring of neuromuscular function is indicated. Degeneration of gastrointestinal smooth muscle with hypomotility of the intestinal tract and delayed gastric emptying in conjunction with impaired swallowing mechanisms may increase the risk of perioperative aspiration of gastric contents.

After surgery, the patient with Duchenne's muscular dystrophy must be closely monitored for evidence of pulmonary dysfunction and retention of pulmonary secretions. Vigorous respiratory therapy and ventilatory support may be required.

The Myotonias

The myotonias comprise a group of diseases having very different genetic and molecular origins but exhibiting a common clinical feature. Myotonia, the delayed relaxation of skeletal muscle after voluntary contraction, is the basic clinical feature of these diseases.³⁰ Typically, a myotonic contracture is not relieved by regional anesthesia, nondepolarizing muscle relaxants, or deep anesthesia. Relaxation may be induced by infiltration of the muscle with local anesthetic.

Recent advances in molecular biology and genetics have clarified much of the confusion about the myotonic disorders. Myotonic diseases are caused by genetic abnormalities that produce defects in sodium or chloride channels or proteins which alter ion channel function in muscle cells (Table 19-3).³¹ Since myotonia is caused by abnormal ion channel activity, administration of drugs that depress sodium influx into the cell and delay return of membrane excitability, such as quinine, tocainide, or mexilitene, may relax myotonic contracture.³² Examples of myotonic disorders are myotonic dystrophy, hyperkalemic periodic paralysis, paramyotonia congenita, congenital myotonia, and proximal myotonic myopathy.

Table 19-3. CLASSIFICATION OF MYOTONIC DYSTROPHY

Myotonic Dystrophy (Steinert's Disease)

Myotonic dystrophy is the most common form of the myotonias. Myotonic dystrophy is an autosomally dominant inherited disorder (incidence 1 in 8000) with symptoms occurring during the second and third decades of life. In addition to myotonia, other clinical features associated with myotonic dystrophy include muscle degeneration, cataracts, premature balding, diabetes mellitus, thyroid dysfunction, adrenal insufficiency, gonadal atrophy, and cardiac conduction abnormalities. Myotonic dystrophy is the result of an enlarged trinucleotide repeat of cytosine, thymine, and guanine (CTG) on chromosome 19. This defect produces a decrease in protein kinase which results in degeneration of the sarcoplasmic reticulum.³³

Cardiac abnormalities have been well described in patients with myotonic dystrophy. Although myocardial contractile tissue degenerates and may reduce ventricular function, as evidenced by left ventricular diastolic dysfunction, cardiac failure is rare.³⁴ Prominent cardiac features of myotonic dystrophy include conduction delays (atrioventricular block), atrial flutter and fibrillation, and ventricular dysrhythmias.^{35,36} First-degree atrioventricular block may actually precede the onset of clinical symptoms of myotonic dystrophy. Sudden death may be a result of the abrupt onset of third-degree atrioventricular block. Although mitral valve prolapse occurs in 20% of patients with myotonic dystrophy, the prolapse is secondary to geometric changes of the heart caused by thoracic deformation. Systemic complications from mitral valve prolapse usually do not occur in patients with myotonic dystrophy.³⁷

Pulmonary function studies demonstrate restrictive lung disease, mild arterial hypoxemia, and diminished ventilatory responses to hypoxia and hypercapnia.³⁸ Brain stem respiratory control mechanisms may also be defective.³⁹ Weakness of respiratory muscles diminishes the effectiveness of cough and may lead to pneumonia. Myotonia of respiratory muscles can produce intense dyspnea, requiring therapy with procainamide.⁴⁰ Alteration of smooth muscle function produces gastric atony and intestinal hypomotility. Pharyngeal muscle weakness in conjunction with delayed gastric emptying increases the risk for aspiration of gastric contents.⁴¹

Pregnancy often produces an exacerbation of myotonic dystrophy. It has been suggested that increased progesterone levels of pregnancy contribute to increased symptoms. Congestive heart failure is also more likely to occur during pregnancy.⁴² Cesarean section must often be performed because of uterine smooth muscle dysfunction.⁴³

Therapy for patients with myotonic dystrophy has been mostly palliative and includes respiratory muscle training and the administration of androgenic steroids.^{44,45} Patients with cardiac dysrhythmias may require pacemaker implantation, cardioversion, or catheter ablation of ventricular reentry pathways. Embryo preimplantation diagnosis of myotonic dystrophy may also be effective in reducing the number of infants born with myotonic dystrophy.⁴⁶

Other Myotonias

Congenital myotonic dystrophy is an early-onset form of myotonic dystrophy. Some patients have very mild symptoms such as a swallowing dysfunction as a result of the inability to relax the oropharyngeal muscles. This condition often improves with age and does not affect a patient's life expectancy. Some infants, however, have an early-onset form characterized by hypotonia, respiratory distress, and aspiration pneumonia. Mechanical ventilation is often required and mortality during infancy is high.⁴⁷

Paramyotonia is the rarest of the myotonic diseases. Myotonic contracture develops when the patient is exposed to cold, and warming relaxes the contracted muscle. Hypokalemia has also been reported to produce skeletal muscle weakness in patients with paramyotonia.⁴⁸

Proximal myotonic myopathy was described in 1994. Patients with proximal myotonic myopathy have many of the clinical features that patients with myotonic dystrophy have. Patients with proximal myotonic myopathy, however, do not have the same chromosomal abnormalities as patients with myotonic dystrophy. Muscle pain is a prominent feature of proximal myotonic dystrophy.⁴⁹

Management of Anesthesia

Considerations for anesthesia in patients with myotonic dystrophy include the presence of cardiac and respiratory muscle disease and the abnormal responses to drugs used during anesthesia.⁵⁰ Succinylcholine produces an exaggerated contracture and its use should be avoided (Fig. 19-2). Succinylcholine-induced myotonia can make ventilation of the lungs and tracheal intubation difficult or impossible.⁵¹ Most patients with myotonic dystrophy develop a chronic myopathy. Consequently, the response to nondepolarizing muscle relaxants may be unpredictable. It would be prudent to use shorter-acting muscle relaxants such as mivacurium or atracurium and monitor the response to the muscle relaxant.^{52,53}

Figure 19-2. Administration of low doses of succinylcholine to a patient with myotonic dystrophy produces an exaggerated contraction of skeletal muscle. (Reprinted with permission from Mitchell MM, Ali HH, Savarese JJ: Myotonia and neuromuscular blocking drugs. *Anesthesiology* 49:44, 1978.)

Mivacurium is an especially attractive choice, as reversal of neuromuscular blockade is usually not necessary. Neostigmine has been reported to induce myotonia.⁵⁴ The response to a peripheral nerve stimulator must be carefully interpreted because muscle stimulation may produce myotonia, which can be misinterpreted as sustained tetanus when significant neuromuscular blockade still exists (personal observation). Patients with myotonic dystrophy are quite sensitive to the respiratory depressant effects of opioids, barbiturates, benzodiazepines, and inhaled anesthetics. Severe respiratory depression has also been reported after the administration of epidural morphine for postoperative analgesia.⁵⁵ Increasing respiratory depression parallels the progression of the disease and may develop as a result of depression of central respiratory centers as well as a peripheral muscle effect.⁵⁶ In a study of more than 200 patients with myotonic dystrophy undergoing surgery, respiratory complications were more likely to occur in the early postoperative period after upper abdominal surgery or in those patients in whom preoperative upper extremity weakness was clinically evident.⁵⁷ Although no specific anesthetic technique has been shown to be preferable, reported responses to propofol have been varied. One report described an uneventful intraoperative course and rapid emergence, while other reports described exaggerated respiratory depression, hypotension, and generalized myotonia.^{58,59} and ⁶⁰ Since smooth muscle function is affected by myotonia, gastrointestinal motility is decreased and gastric emptying is delayed. Consequently, precautions should be used to prevent pulmonary aspiration.⁶¹

Because patients with myotonic dystrophy have cardiac conduction abnormalities and mitral valve prolapse, cardiac dysrhythmias may occur. The preoperative ECG should be carefully examined for signs of atrioventricular conduction delay. Use of anesthetics known to delay conduction in the His-Purkinje system, specifically halothane, should be avoided.

Skeletal muscle weakness and myotonia are exacerbated during pregnancy. Labor is typically prolonged, and there is an increased incidence of postpartum hemorrhage from placenta accreta.⁶² Although regional anesthesia may not prevent myotonia, spinal and epidural anesthesia have been successfully used for both pregnant and nonpregnant patients with myotonic dystrophy.^{63,64} If general anesthesia is administered, it should be anticipated that these patients will be sensitive to respiratory depressant drugs and will have a decreased ability to clear pulmonary secretions.⁶⁵

Familial Periodic Paralysis

Traditionally, there were three recognized forms of familial periodic paralysis: hyperkalemic, normokalemic, and hypokalemic. In recent years, however, the normokalemic form was found to be a variant of the hyperkalemic type and is no longer recognized as a separate disease. Although the hyperkalemic and hypokalemic forms of familial periodic paralysis are both autosomally dominant inherited diseases that share the common clinical feature of intermittent, acute episodes of skeletal muscle weakness, these disorders have very different cellular mechanisms (Table 19-4).

| HYPOKALEMIC |
|--|
| Calcium channel defect |
| Potassium level <3 mEq·L ⁻¹ during symptoms |
| Precipitating factors |
| High-glucose meals |
| Strenuous exercise |
| Glucose-insulin infusions |
| Stress |
| Hypothermia |
| Other Features |
| Cardiac dysrhythmias |
| Signs of hypokalemia on ECG |
| HYPERKALEMIC |
| Sodium channel defect |
| Potassium level normal or >5.5 mEq·L ⁻¹ during symptoms |
| Precipitating factors |
| Rest after exercise |
| Potassium infusions |
| Metabolic acidosis |
| Hypothermia |
| Other Features |
| Skeletal muscle weakness may be localized to tongue and eyelids |

Table 19-4. CLINICAL FEATURES OF FAMILIAL PERIODIC PARALYSIS

Hyperkalemic Periodic Paralysis. Patients with hyperkalemic periodic paralysis have evidence of myotonia as well as episodes of muscle weakness. Hyperkalemic periodic paralysis is caused by a sodium channel mutation.⁶⁶ Episodes of weakness lasting several hours can occur during rest after exercise, infusions of potassium, metabolic acidosis, or hypothermia. The weakness may be so severe as to produce respiratory distress. The hyperkalemia is often transient, occurring only at the onset of weakness. Consequently, potassium levels measured during the episode of weakness may be normal or even decreased. Treatment consists of a low-potassium diet and the administration of thiazide diuretics.

Hypokalemic Periodic Paralysis. Hypokalemic periodic paralysis is caused by a calcium channel mutation.⁶⁷ Paralysis may be produced by ingestion of carbohydrate loads, strenuous exercise, and infusion of glucose and insulin. Paralysis is usually incomplete, affecting the limbs and trunk, but sparing the diaphragm. Respiratory distress may, however, be caused by vocal cord paralysis.⁶⁸ The low potassium levels present during acute episodes often produce cardiac dysrhythmias and may require treatment with calcium channel blockers.⁶⁹ Treatment consists of potassium infusion and the administration of acetazolamide, a carbonic anhydrase inhibitor.⁷⁰ Permanent skeletal muscle weakness occurs in most patients with hypokalemic periodic paralysis as they age.⁷¹

Management of Anesthesia

The primary goal of perioperative management of patients with both forms of periodic paralysis is maintenance of normal potassium levels and avoidance of events that may precipitate weakness.^{72,73} If possible, any electrolyte abnormality should be corrected before surgery. During periods of weakness these patients may be sensitive to nondepolarizing muscle relaxants. Doses of these drugs should be reduced and the response monitored with a peripheral nerve stimulator.⁷⁴ Short-acting muscle relaxants are preferred to longer-acting neuromuscular blockers. Succinylcholine is best avoided as its administration may alter serum potassium levels. Metabolic changes (acidosis or alkalosis) or medications (glucose and insulin, diuretics, β -adrenergic agonists) that reduce potassium levels may initiate an episode of paralysis. Since changes in potassium levels may actually precede the onset of clinical muscle weakness, serial measurement of potassium levels during prolonged surgical procedures and in the early postoperative period should be considered.^{75,76} The ECG should be continuously monitored for evidence of potassium-related dysrhythmias. Other recommendations include the avoidance of large carbohydrate loads and hypothermia. It should be remembered that any cause of severe potassium depletion, such as renal tubular acidosis or chronic diarrhea, can produce muscle weakness in patients with the hypokalemic form of periodic paralysis.^{77,78}

After surgery, adequate skeletal muscle strength must be ascertained before mechanical ventilation of the lungs is discontinued. Regional anesthesia may also be considered.^{79,80} Malignant hyperthermia has been associated with both forms of familial periodic paralysis.^{81,82}

Myasthenia Gravis

Myasthenia gravis is a disease of the neuromuscular junction caused by a decrease in the population of acetylcholine receptors. The incidence is 1 in 20,000, and women are affected twice as frequently as men. Myasthenia gravis is an autoimmune disease because 70–90% of myasthenic patients have circulating

anti-acetylcholine receptor antibodies.⁸³ Anti-acetylcholine receptor antibodies damage the postsynaptic membrane via a complement-mediated reaction. This results in increased degradation and decreased formation of acetylcholine receptors.⁸⁴ There is an apparent breakdown in tolerance of T and B cells to the acetylcholine receptor. This lack of tolerance activates T-helper cells, which produce antibodies specific for acetylcholine receptors. This process most likely originates in the thymus, as 90% of patients have histologic abnormalities of the thymus gland, including thymoma, hyperplasia, or atrophy.⁸⁵ Thymomas are more likely to occur in patients older than 30 years, whereas thymic hyperplasia occurs in younger patients. Although the evidence implicating anti-acetylcholine receptor antibodies is compelling, there is a poor correlation between levels of circulating antibodies and the clinical severity of the disease. Many myasthenic patients also have detectable anti-nuclear, anti-thyroid, and anti-muscle antibodies. Consequently, other autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, pernicious anemia, and thyroiditis are associated with myasthenia gravis.

The clinical hallmark of myasthenia gravis is skeletal muscle weakness. Typically, the weakness is exacerbated by repetitive muscle use and there are periods of exacerbation alternating with remission. Any skeletal muscle may be affected, although there is a predilection for muscles innervated by cranial nerves, which leads to dysphagia, dysarthria, and pulmonary aspiration. Initial symptoms include diplopia, difficulty speaking and swallowing, or limb muscle weakness.⁸⁶ Although respiratory insufficiency is not a common presenting symptom, its presentation can be quite dramatic.⁸⁷ Consequently, undiagnosed myasthenia gravis should be included in the differential diagnosis of respiratory failure.

There are several types of myasthenia gravis. The classification is based on skeletal muscle groups affected as well as the age of onset (Table 19-5). Types of myasthenia include generalized, ocular, bulbar, and shoulder-girdle. A staging system (Osseman) based on the severity of the disease is commonly used.⁸⁸ Type I presents with ocular signs and symptoms only; Type IIA comprises generalized mild muscle weakness; Type IIB is characterized by generalized moderate weakness or bulbar dysfunction or both; Type III includes acute fulminant presentation or respiratory dysfunction or both; and Type IV is late, severe generalized myasthenia.

| Subtype | Onset | Sex | Thymus | Course |
|-----------------------|-----------|---------------------|----------------------------------|---|
| Neonatal myasthenia | Transient | Both sexes | Normal | Transient |
| Congenital myasthenia | <2 yr | Male > female | Normal | Nonfluctuating, compatible with long-term survival |
| Jerinski myasthenia | 1-2 yr | Female > male (3:1) | Hypoplasia | Steady progressive, tendency to relapse and remission |
| Mild myasthenia | 20-40 yr | Female > male | Hypoplasia > hyperplasia | Remission usually within 1-5 yr |
| Severe myasthenia | >40 yr | Male > female | Thymoma (large or badly treated) | Rapid progress, higher mortality |

Reprinted with permission from Basila A. Aronson and myasthenia gravis. *Curr Opin Neurol*, 1992.

Table 19-5. DIFFERENT PRESENTATIONS OF MYASTHENIA GRAVIS

Many conditions such as viral infections, pregnancy, extreme heat, stress, and surgery may initiate or exacerbate the symptoms of myasthenia gravis, but the responses are very unpredictable. Although some pregnant myasthenics undergo a remission of symptoms during pregnancy, 20–40% report an increased severity of symptoms during gestation.⁸⁹ Postpartum respiratory failure and death can occur. Of neonates born to myasthenic women, 15–20% have transient myasthenia resulting from the passive placental transfer of anti-acetylcholine receptor antibodies. Neonatal myasthenia begins 12–48 hours after birth and may persist for several weeks. Neonatal skeletal muscle strength must be carefully monitored during the early neonatal period.⁹⁰

Patients with a thymoma and myasthenia gravis frequently have related heart disease that manifests as focal myocarditis and atrial fibrillation or atrioventricular block.⁹¹ Although left ventricular systolic function is usually normal, left ventricular diastolic filling may be impaired, heralding the early stages of a decrease in cardiac performance.⁹²

A myasthenic crisis will occur in 15–20% of patients during the course of their disease. Myasthenic crises are often precipitated by pneumonia or upper respiratory infections and result in respiratory failure requiring mechanical ventilation.⁹³

The diagnosis of myasthenia gravis is based on the clinical history, the edrophonium test, electromyography, and the detection of circulating anti-acetylcholine receptor antibodies.⁹⁴ No single test is, however, definitive. For example, the administration of edrophonium can improve strength both in myasthenics and in patients with other neuromuscular disorders.

Treatment modalities for myasthenia gravis include cholinesterase inhibitors, thymectomy, corticosteroids, plasmapheresis, and immunosuppressants. The primary treatment for myasthenia gravis since the 1940s has been the administration of cholinesterase inhibitors such as physostigmine and neostigmine.⁸⁶ These drugs function by effectively increasing the concentration of acetylcholine at the nicotinic postsynaptic membrane. Consistent control of myasthenia with cholinesterase inhibitors can be quite challenging. For example, underdosage will result in increased skeletal muscle weakness, whereas overdosage will produce a “cholinergic crisis.” Excessive doses of cholinesterase inhibitors produce abdominal cramping, vomiting, diarrhea, salivation, bradycardia, and skeletal muscle weakness that mimics the weakness of myasthenia. Corticosteroids produce remission in 80% of patients with myasthenia but also produce significant drug side effects during long-term therapy. Immunosuppressive therapy with azathioprine, cyclophosphamide, or cyclosporine has been shown to reduce anti-acetylcholine receptor antibody levels and produce clinical improvement. Hazards of immunosuppressive therapy include infection and malignancy. Plasmapheresis, by reducing anti-acetylcholine receptor antibody levels, produces improved muscle strength and is a very effective treatment for patients in myasthenic crisis.⁹⁵ The effects of plasmapheresis are short-lived, and long-term therapy with plasmapheresis is impractical. The administration of intravenous immunoglobulin may also improve strength in some patients with myasthenia.⁹⁶

Thymectomy is highly effective for the treatment of myasthenia gravis and is usually recommended for adults with myasthenia. There is, however, considerable controversy among surgeons with regard to the timing of thymectomy and the surgical approach (transsternal versus transcervical).^{97,98} There is no universally reliable single therapy for myasthenia gravis. Successful management depends on an experienced neurologist or internist who can orchestrate the different therapeutic modalities at the proper time.⁹⁹

Management of Anesthesia

The primary concern in anesthesia for the patient with myasthenia gravis is the potential interaction between the disease, treatment of the disease, and neuromuscular blocking drugs. The uncontrolled or poorly controlled myasthenic patient is exquisitely sensitive to nondepolarizing muscle relaxants. Even small, defasciculating doses of nondepolarizers can produce significant respiratory muscle paralysis and respiratory distress.¹⁰⁰ It should be anticipated that any patient with myasthenia, no matter how localized, will have increased sensitivity to nondepolarizing muscle relaxants (Fig. 19-3). Numerous studies have demonstrated this increased sensitivity.^{101,102} Because of rapid elimination, however, mivacurium, atracurium, rocuronium, and rapacurium can be effectively titrated to produce satisfactory muscle relaxation with minimal risk of prolonged postoperative paralysis.^{103,104,105,106} and ¹⁰⁷ Treatment of myasthenia with cholinesterase inhibitors can influence the response to both depolarizing and nondepolarizing neuromuscular blocking drugs.¹⁰⁸ The response to succinylcholine is unpredictable. The untreated myasthenic is usually resistant to the effects of succinylcholine; however, the myasthenic patient treated with cholinesterase inhibitors may exhibit resistant, prolonged, or normal responses to succinylcholine.^{109,110} As would be anticipated, the duration of neuromuscular blockade produced by succinylcholine is inversely related to the plasma cholinesterase level.¹¹¹ Successive doses of succinylcholine can produce a progressive prolongation of neuromuscular blockade in patients with myasthenia.¹¹² Because of the myasthenic patient’s unpredictable response to succinylcholine, a short-acting nondepolarizing muscle relaxant is preferred.

Figure 19-3. Dose–response for vecuronium in normal patients and patients with myasthenia gravis. (Reprinted with permission from Eisenkraft JB, Book WJ, Papatestas AE: Sensitivity to vecuronium in myasthenia gravis: A dose–response study. *Can J Anaesth* 37:301, 1990.)

The tremendous variability in the response of myasthenic patients to the different types of neuromuscular blocking drugs warrants careful monitoring with a peripheral nerve stimulator and correlation with clinical signs of recovery from neuromuscular blockade. Since halogenated inhaled anesthetics depress neuromuscular transmission in myasthenic patients, neuromuscular blocking drugs may not be required.^{113,114} There is no specific anesthetic technique that is superior to others for patients with myasthenia. Inhaled and intravenous anesthetics have been successfully employed.¹¹⁵ Analgesic techniques such as regional anesthesia and/or neuraxial narcotic administration may decrease the likelihood of postoperative respiratory depression from the systemic administration of opioids.^{116,117} At the conclusion of surgery, complete recovery from neuromuscular blockade must be established before tracheal extubation and withdrawal of ventilatory support. Risk factors that increase the likelihood of postoperative ventilatory insufficiency include: (1) duration of myasthenia of > 6 years; (2) history of chronic respiratory disease; (3) treatment doses of pyridostigmine > 750 mg · day⁻¹; and (4) preoperative vital capacity < 2.9 l.¹¹⁸ The need for postoperative ventilatory support after thymectomy is substantially greater when a transsternal surgical approach is used instead of a transcervical approach.^{119,120} The patient with myasthenia gravis requiring mechanical ventilation can be one of the most challenging to wean from ventilatory support. Skeletal muscle strength can vary greatly during a short period of time. It is imperative that sustained respiratory muscle strength be confirmed before tracheal extubation and resumption of independent, spontaneous ventilation.

Exacerbation of myasthenia gravis may occur in late pregnancy and the early postpartum period. Consequently, skeletal muscle relaxation produced by regional anesthesia in conjunction with inherent muscle weakness may lead to hypoventilation. Because 15–20% of infants born to myasthenic mothers may exhibit transient neonatal myasthenia within 1–21 days after birth, anticholinesterase therapy and mechanical ventilation may be necessary.

Myasthenic Syndrome (Lambert-Eaton Syndrome)

The myasthenic syndrome is a disorder of neuromuscular transmission associated with carcinomas, particularly small cell carcinoma of the lung (Table 19-6).¹²¹ The onset of the myasthenic syndrome may actually precede discovery of the malignancy by as much as five years. Myasthenic syndrome is an autoimmune disease in which immunoglobulin G (IgG) antibodies against voltage-gated calcium channels (presynaptic) are produced.¹²² In those cases associated with carcinoma, the autoantibodies are directed at calcium channels in the tumor; these autoantibodies, however, cross-react with calcium channels at the neuromuscular junction.¹²³ The result is a decreased release of acetylcholine in response to nerve stimulation. Typically, the patient is a man, 50–70 years old, complaining of proximal extremity weakness that markedly affects gait and the ability to stand and climb stairs. Rarely, the clinical presentation may be respiratory failure.^{124,125} Autonomic dysfunction, such as xerostomia, impotence, orthostatic hypotension, constipation, and altered sweating responses, has also been reported.¹²⁶

| | Myasthenic Syndrome | Myasthenia Gravis |
|------------------------------|---|---|
| Manifestations | Proximal limb weakness (arms > legs) Exercise improves with strength Muscle pain common Reflexes absent or decreased | Extracocular, bulbar, and facial muscle weakness Fatigue with exercise Muscle pain uncommon Reflexes normal |
| Gender | Male > female | Female > male |
| Coexisting pathology | Small cell carcinoma of the lung | Thymoma |
| Response to muscle relaxants | Sensitive to succinylcholine and non-depolarizing muscle relaxants Poor response to anticholinesterases | Resistant to succinylcholine Sensitive to nondepolarizing muscle relaxants Poor response to anticholinesterases |

Table 19-6. COMPARISON OF MYASTHENIC SYNDROME AND MYASTHENIA GRAVIS

Treatment of myasthenic syndrome is initially directed at treatment of the underlying neoplasm. The most effective drug for treatment of the myasthenic syndrome is 3,4-diaminopyridine. 3,4-Diaminopyridine improves synaptic transmission by opening voltage-gated potassium channels, which increases transmitter release at the synapse.¹²⁷ Side effects of 3,4-diaminopyridine include perioral and digital paresthesias and seizures. Guanidine also enhances acetylcholine release and may be effective for the treatment of myasthenic syndrome.¹²⁸ Although the administration of pyridostigmine rarely produces a significant increase in muscle strength, pyridostigmine in combination with guanidine or 3,4-diaminopyridine may be effective. Other therapeutic modalities for myasthenic syndrome include intravenous immunoglobulin and plasmapheresis.^{129,130} Like the treatment of myasthenia gravis, effective long-term treatment of the myasthenic syndrome requires an experienced neurologist and an individualized therapeutic regimen.¹³¹

Management of Anesthesia

Patients with myasthenic syndrome are sensitive to the effects of both depolarizing and nondepolarizing muscle relaxants. Consequently, the doses of these drugs should be reduced, and neuromuscular function should be monitored carefully. Reported experience with anesthesia in patients receiving aminopyridines is limited, but it is recommended that their administration be continued up to the time of surgery.¹³² The preanesthetic administration of immunoglobulin may improve muscle strength in the perioperative period.¹³³

Because the myasthenic syndrome is difficult to diagnose, a high index of suspicion for this disorder should be maintained if unexpected muscle weakness occurs in patients with malignant tumors. Although myasthenic syndrome is most frequently associated with small cell carcinoma of the lung, muscle weakness can occur with other malignancies as well.

Guillain-Barré Syndrome (Polyradiculoneuritis)

Guillain-Barré syndrome is currently the most common cause of acute, flaccid paralysis. Guillain-Barré syndrome is an autoimmune disease triggered by a bacterial or viral infection. The list of infectious triggers is long and includes campylobacter, mycoplasma, cytomegalovirus, Epstein-Barr virus, hemophilus, parainfluenza, influenza, adenovirus, herpes simplex, and varicella.^{134,135} It is likely that the infection triggers an immune response that targets the Schwann cell membrane or myelin, resulting in demyelination and axonal degeneration.^{134,135} and ¹³⁶ Most patients have a history of a respiratory tract or gastrointestinal tract infection within 4 weeks of the onset of neurologic symptoms. Guillain-Barré syndrome is characterized by the acute or subacute onset of skeletal muscle weakness or paralysis of the legs. Sensory disturbances such as paresthesias often precede the paralysis. Typically, the paralysis progresses cephalad to include the muscles of the trunk and arms. Difficulty in swallowing and impaired ventilation resulting from intercostal muscle paralysis can occur. Progression usually occurs over 10–12 days, followed by gradual recovery. The most serious immediate problem is ventilatory insufficiency. The vital capacity should be measured frequently. If the vital capacity decreases to less than 15–20 ml · kg⁻¹, mechanical ventilation of the lungs is indicated.¹³⁷ The more rapid the onset of quadriplegia, the more likely the need for prolonged ventilatory support. Although 85% of patients with this syndrome achieve a good or full recovery, chronic or recurrent neuropathy develops in 3–5% of patients.¹³⁸ Mortality from Guillain-Barré syndrome is between 2 and 12% and occurs primarily in elderly patients with coexisting pulmonary disease.¹³⁹

Autonomic nervous system dysfunction occurs in many patients with Guillain-Barré syndrome. This dysfunction can produce wide fluctuations in blood pressure, tachycardia, cardiac dysrhythmias, and cardiac arrest.¹⁴⁰ In a manner similar to autonomic hyperreflexia, physical stimulation can precipitate hypertension, tachycardia, and cardiac dysrhythmias. Appropriate a- and b-adrenergic blockade may be required for those patients. Evidence of mild hepatic dysfunction has also been reported in patients with Guillain-Barré syndrome.¹⁴¹

In addition to ventilatory support and meticulous general medical care, the most effective treatments are plasmapheresis and high-dose intravenous immunoglobulin.^{142,143} Corticosteroids are not beneficial.

Subtypes of Guillain-Barré include acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor-sensory axonal neuropathy (AMSAN), and Fisher syndrome. Electrophysiologic studies may be helpful in differentiating among these disorders.¹⁴⁴

Management of Anesthesia

Autonomic nervous system dysfunction indicates that compensatory cardiovascular responses may be absent, resulting in significant hypotension secondary to postural changes, blood loss, or positive airway pressure. On the other hand, noxious stimuli such as laryngoscopy and tracheal intubation may produce exaggerated increases in heart rate and blood pressure. Direct-acting vasopressors may be required to control blood pressure. Cardiovascular function should be carefully monitored in the perioperative period.

The administration of succinylcholine should be avoided because of the danger of drug-induced potassium release and hyperkalemia. This risk may actually persist after clinical recovery from the disorder.¹⁴⁵ A nondepolarizing muscle relaxant with minimal cardiovascular effects, such as vecuronium, rocuronium, and rapacuronium, would be a useful choice. However, the sensitivity of patients with Guillain-Barré syndrome to nondepolarizing muscle relaxants may vary from extreme sensitivity to resistance, depending on the phase of the disease.¹⁴⁶ It is likely that mechanical ventilation will be required during the immediate postoperative period. Some patients with Guillain-Barré syndrome have pronounced sensory disturbances and may benefit from the use of epidural opioids.^{147,148}

It should be remembered that it can be very difficult to differentiate Guillain-Barré syndrome from other neurologic disorders such as anterior spinal artery syndrome or chronic inflammatory demyelinating polyneuropathy. Guillain-Barré syndrome has been reported to occur after surgery.^{149,150}

CENTRAL NERVOUS SYSTEM DISEASES

Multiple Sclerosis

Multiple sclerosis is an acquired disease of the central nervous system characterized by central nervous system inflammation and multiple sites of demyelination in the brain and spinal cord. The cause of multiple sclerosis is multifactorial and involves a complex series of immunologic events occurring in genetically susceptible individuals. Viruses have long been implicated as the cause of multiple sclerosis; however, proof of this relationship has been difficult to establish. It is speculated that molecular mimicry of viruses to myelin may serve as the immunologic trigger that causes demyelination. The similarity of the virus to myelin produces immunologic cross-reactivity which sets into motion the immunologic and inflammatory responses in the central nervous system characteristic of multiple sclerosis.¹⁵¹ Initially myelin is damaged but can be replaced by the oligodendrocytes that synthesize myelin. Ultimately, the oligodendrocytes are destroyed and myelin can no longer be replaced. Demyelination exposes the axon to harmful factors and interferes with neural transmission.¹⁵² The complex interaction between the immune and inflammatory responses with the inherent reparative processes of the body explains the relapsing nature of multiple sclerosis.¹⁵³

The symptoms of multiple sclerosis depend on the sites of demyelination in the brain and spinal cord. Demyelination of the optic tracts produces visual disturbances, whereas demyelination of the oculomotor pathways results in nystagmus. Lesions of the spinal cord cause limb weakness and paresthesias. The legs are affected more than the arms. Bowel retention and urinary incontinence are frequent complaints. Involvement of the brain stem can produce diplopia, trigeminal neuralgia, cardiac dysrhythmias, and autonomic dysfunction, while alterations in ventilation can lead to hypoxemia, apnea, and respiratory failure.^{154,155,156,157} and ¹⁵⁸ The course of multiple sclerosis is characterized by an exacerbation of symptoms at unpredictable intervals over a period of years. Residual symptoms eventually persist during remission and may lead to severe disability. In some patients the course is relatively benign, with frequent periods of demyelination followed by prolonged remission. As is typical in many immune disorders, pregnancy is associated with an improvement in symptoms, but relapse frequently occurs in the first three postpartum months.¹⁵⁹

The diagnosis of multiple sclerosis is based primarily on clinical determinations. Clinical criteria include age of onset between 10 and 50 years, neurologic signs and symptoms indicative of CNS white matter disease, two or more attacks separated by a month or more, and involvement of two or more noncontiguous anatomic areas.¹⁶⁰ Laboratory confirmation of the diagnosis can be obtained by chemical analysis of the cerebrospinal fluid and cranial magnetic resonance imaging (MRI). An estimated 70% of patients with multiple sclerosis have elevated levels of IgG in the cerebrospinal fluid, and elevated levels of albumin in the CSF are usually indicative of blood-brain barrier dysfunction.¹⁶¹ MRI has been established as a sensitive diagnostic tool for multiple sclerosis and provides direct evidence of the location of demyelinated plaques in the central nervous system. MRI is also used as a measure of the effectiveness of treatment modalities for multiple sclerosis.¹⁶²

There have been significant advances in recent years in the treatment of multiple sclerosis. Current treatment is directed at modulating the immunologic and inflammatory responses that damage myelin. Corticosteroids (methylprednisolone) are the primary agents for treatment of an acute exacerbation of multiple sclerosis. Corticosteroids have diverse effects that act to suppress cellular immune responses.¹⁶³ Corticosteroids may not, however, influence the long term course of the disease. Interferon (B-1a, B-1b) alters the inflammatory response and may augment natural disease suppression mechanisms.¹⁶⁴ Glatiramer (copolymer-1) is a mixture of polypeptides that mimics the structure of myelin and may serve as a decoy for autoantibodies. Nonspecific immunosuppressants such as azathioprine, methotrexate, cyclophosphamide, and cyclosporine have also been used, but with variable success.¹⁶⁵ Although the treatment of multiple sclerosis with intravenous immunoglobulin has been done for many years, this therapy is still experimental.¹⁶⁵ Strategies currently under research are directed at producing remyelination. Symptomatic therapy for some of the complications of multiple sclerosis include diazepam, dantrolene, and baclofen for skeletal muscle spasticity. Painful dysesthesias, tonic seizures, dysarthria, and ataxia may be treated with carbamazepine. Nonspecific therapeutic measures include the avoidance of excessive fatigue, emotional stress, and hyperthermia. Demyelinated nerve fibers are extremely sensitive to increases in temperature. A temperature increase of as little as 0.5°C may block impulse conduction in demyelinated fibers.¹⁶⁶

Management of Anesthesia

The effect of surgery and anesthesia on the course of multiple sclerosis is controversial. Some reports indicate that symptoms of multiple sclerosis are exacerbated by anesthesia, particularly regional anesthesia.^{167,168} Other studies, however, report that anesthesia does not affect the course of the disease.¹⁶⁹ A relatively high proportion of patients with multiple sclerosis who receive spinal anesthesia do have an exacerbation of symptoms after surgery.¹⁷⁰ It could be speculated that demyelinated areas of the spinal cord might be more sensitive to the effects of local anesthetics. This increased sensitivity could explain the exacerbation after spinal anesthesia. Intrathecal morphine in conjunction with spinal and general anesthesia has been used successfully in patients with multiple sclerosis.^{171,172} Epidural anesthesia has been used for labor and delivery in women with multiple sclerosis. The neurologic relapse rate, however, was greater if bupivacaine in concentrations higher than 0.25% was used.¹⁷³ It is likely that well managed epidural analgesia is associated with minimal risk of a postpartum exacerbation.¹⁷⁴ Certainly, pyrexia and, most likely, metabolic and hormonal changes induced by surgery and anesthesia could produce a neurologic exacerbation independent of the type of anesthesia. Despite the confusion in the medical literature, certain recommendations seem warranted. Before surgery, the patient should be advised that surgery and anesthesia could produce a relapse despite a well managed anesthetic. Ideally, the patient should have a thorough neurologic examination before the operation to document coexisting neurologic deficits. After surgery, the neurologic examination can be repeated so that pre- and postoperative findings can be compared. In view of the fact that spinal anesthesia can cause an unpredictable exacerbation, use of this type of anesthesia should be reserved for special situations. The patient's temperature should be monitored closely during anesthesia and measures employed to reduce alterations in body temperature.

Selection of agents for general anesthesia should take into consideration potential interactions with medications the patient is receiving. For example, patients receiving corticosteroids may need corticosteroid supplementation during the perioperative period. There are no reported adverse interactions between interferon and glatiramer. In theory, succinylcholine could produce an exaggerated release of potassium, although this has not been reported in patients with multiple sclerosis. Anticonvulsants such as carbamazepine and phenytoin can produce resistance to nondepolarizing muscle relaxants.¹⁷⁵ Autonomic dysfunction caused by multiple sclerosis may exaggerate the hypotensive effects of volatile anesthetics. Consequently, careful monitoring of cardiovascular function is indicated. Respiratory muscle weakness and respiratory control dysfunction increase the likelihood of the need for supplemental oxygen and/or mechanical ventilation during the immediate postoperative period.^{176,177}

Epilepsy

A seizure disorder is a common manifestation of many types of central nervous system diseases. A seizure results from the excessive discharge of large numbers of neurons that become depolarized in a synchronous fashion. Idiopathic seizures usually begin during childhood. The sudden onset of seizures in a young or middle-aged adult should arouse suspicion of focal brain disease, particularly a tumor. The onset of seizures after 60 years of age is usually secondary to cerebrovascular disease, but can be a result of head injury, brain tumor, or metabolic disturbances.¹⁷⁸ The onset of seizures requires a thorough neurologic evaluation to determine the etiology. Advanced neuro imaging techniques have provided powerful diagnostic tools for the determination of structural causes of epilepsy. Research in molecular biology and genetics has revealed that some forms of epilepsy are caused by mutations in ion channels. Although the current number of epileptic syndromes caused by mutations is small, there is little doubt that more will be identified.¹⁷⁹ The availability of several new antiseizure drugs has increased the therapeutic options for the treatment of epilepsy.¹⁸⁰ Selecting the right drug or drugs for the treatment of epilepsy may require trial and error to balance efficacy with side effects.¹⁸¹

There are more than 40 types of epilepsy based on several clinical features. The most common classification system is the International Classification of Epileptic Seizures (Table 19-7). A description of the most frequently encountered types of seizures follows.

| CLASSIFICATION-RELATED EPILEPSIES AND SEIZURES | |
|--|--|
| Idiopathic | |
| Benign childhood epilepsy | |
| Childhood epilepsy with occipital paroxysms | |
| GENERALIZED EPILEPSIES | |
| Idiopathic | |
| Absence epilepsy | |
| Childhood | |
| Juvenile | |
| Benign rolandic convulsions | |
| Juvenile epilepsy | |
| Juvenile | |
| Craniocervical maturation on awakening | |
| Idiopathic and/or symptomatic | |
| Lennox-Gastaut syndrome | |
| Adrenoleukodystrophic seizures | |
| Adrenomyeloneuropathy | |
| Symptomatic | |
| Symptomatic etiology | |
| UNDETERMINED EPILEPSIES AND SYNDROMES | |
| With both generalized and focal seizures | |
| Idiopathic | |
| Symptomatic etiology of infancy | |
| Acquired epileptic aphasia | |
| SPECIAL SYNDROMES | |
| Focal seizures | |
| Alcohol-related seizures | |

Table 19-7. CLASSIFICATION OF SEIZURES

Grand Mal Seizure. A grand mal seizure is characterized by generalized tonic–clonic activity. All respiratory activity is arrested and a period of arterial hypoxemia ensues. The tonic phase lasts for 20–40 seconds and is followed by the clonic phase. In the postictal phase, the patient is lethargic and confused. Initial treatment is directed toward maintaining arterial oxygenation and stopping the seizure activity. Diazepam and thiopental are effective drugs for the treatment of acute, generalized seizures. Antiseizure drugs effective for seizure control and prevention are phenytoin, valproate, felbamate, carbamazepine, and lamotrigine (Table 19-8).

| Drug | Seizure Type | Therapeutic Blood Level (mg mL ⁻¹) | Side Effects |
|---------------|--------------|--|---|
| Phenobarbital | Generalized | 15–30 | Sedation, increased drug metabolism |
| Valproate | Generalized | 50–100 | Fatigue |
| Ethosuximide | Absence | | Hepatic dysfunction |
| Ribavirin | Generalized | | Insomnia, ataxia, nausea |
| Phenytoin | Partial | 10–20 | Gingival hyperplasia |
| | Generalized | | Diplopia |
| | Partial | | Resistance to NM blockers (succinylcholine) |
| Propofol | Generalized | | Paresis |
| | Partial | | Hypotension |
| Carbamazepine | Generalized | 6–12 | Cardiotoxic, hepatic |
| | Partial | | Resistance to NM blockers |
| Lamotrigine | Generalized | | Rash |
| | Partial | | Stevens-Johnson syndrome |
| Topiramate | Generalized | | |
| | Partial | | |
| Clonazepam | Generalized | | Fatigue, somnolence |
| | Partial | | |
| Primidone | Generalized | 6–12 | Nausea, ataxia |
| | Partial | | |
| Chlorazepate | Generalized | 0.5–4.0 | Ataxia |
| Ethosuximide | Absence | 40–100 | Leukopenia |
| | | | Erythema multiforme |

Table 19-8. ANTICONVULSANT DRUGS

Focal Cortical Seizure. Focal cortical seizures, also known as Jacksonian epilepsy, may be sensory or motor, depending on the site of neuronal discharge. There is usually no loss of consciousness, although the seizure activity may spread to produce a grand mal seizure.

Absence Seizure (Petit Mal). Absence seizures, previously called petit mal seizures, are characterized by a brief loss of awareness lasting about 30 seconds. Additional manifestations include staring, blinking, and rolling the eyes. There is an immediate resumption of consciousness. Absence seizures typically occur in children and young adults. Absence seizures without other seizure activity are best treated with ethosuximide. Valproate is the drug of choice for absence seizures associated with other seizure activity.

Akinetic Seizure. Akinetic seizures are characterized by a sudden, brief loss of consciousness and loss of postural tone. These types of seizures usually occur in children and can produce severe head injury from a fall.

Myoclonic Seizure. Myoclonic seizures occur as isolated clonic jerks in response to a sensory stimulus. In most cases a single group of muscles is involved. Myoclonic seizures are often associated with degenerative and metabolic brain diseases.

Psychomotor Seizure. Psychomotor seizures are seen as an impairment of consciousness, inappropriate motor acts, hallucinations, amnesia, and unusual visceral symptoms. This type of seizure is preceded by an aura.

Status Epilepticus. Status epilepticus is defined as two consecutive tonic–clonic seizures without regaining consciousness, or seizure activity that is unabated for 30 minutes or longer.¹⁸² Status epilepticus can include all types of seizure activity. Grand mal status epilepticus is of the greatest concern because mortality can be as high as 20%. Typically, grand mal status epilepticus lasts for 48 hours with a seizure frequency of four to five per hour. As the seizure progresses, skeletal muscle activity diminishes and seizure activity may be evident only on the electroencephalogram (EEG). Respiratory effects of status epilepticus include inhibition of the respiratory centers, uncoordinated skeletal muscle activity that impairs ventilation, and abnormal autonomic activity that produces bronchoconstriction. In addition to the danger of arterial hypoxemia from inadequate airway control, there is a high likelihood of permanent neuronal damage from continued seizures.¹⁸³ Diazepam or lorazepam are considered the drugs of choice for the treatment of status epilepticus. Because the effects of the benzodiazepines are transient, a longer-acting anticonvulsant (e.g., phenytoin, phenobarbital) must also be administered. Thiopental is quite effective for the initial treatment of status epilepticus, but the effect is transient. Muscle relaxants may be required to facilitate tracheal intubation if a secured airway is necessary. Although muscle relaxants will terminate the skeletal muscle manifestations of a seizure, there is no effect on seizure activity in the brain. On rare occasions general anesthesia with isoflurane or barbiturates may be required for the treatment of status epilepticus.^{184,185}

Management of Anesthesia

Patients receiving antiseizure medications should be maintained on their normal medication regimen until the time of surgery. After the operation, medications should be given parenterally until oral intake can be resumed. In management of anesthesia for the patient with a seizure disorder, the potential influence of anticonvulsants on the response to anesthesia must be considered. Conversely, an anesthesia technique must be used that will not increase the likelihood of seizure activity. Because anticonvulsant drugs affect the liver and neuromuscular systems, the potential for significant drug interaction certainly exists. Stimulation of the hepatic microsomal enzymes by phenobarbital may accelerate and increase the magnitude of biotransformation of anesthetic drugs. Increased biotransformation of volatile halogenated anesthetics may increase the risk of organ toxicity. Other known side effects of anticonvulsants include leukopenia, anemia, and hepatitis from phenytoin; pancreatitis, hepatic failure, and coagulopathy from valproate; aplastic anemia, cardiotoxicity, and hypothyroidism from carbamazepine; leukopenia from felbamate; and rash and

hypersensitivity from lamotrigine.¹⁸⁶

Although most inhaled anesthetics, including nitrous oxide, have been reported to produce seizure activity, such activity during the administration of halothane, isoflurane, desflurane, or sevoflurane is extremely rare. Desflurane produces a dose-dependent depression of EEG activity similar to that of isoflurane.¹⁸⁷ Enflurane predictably produces spike and wave activity on the EEG, particularly when hypocarbia exists. Children seem to be especially susceptible to enflurane-induced seizure activity.¹⁸⁸ It would appear that halothane, isoflurane, sevoflurane, or desflurane are preferable to enflurane for patients with seizure disorders.

The use of ketamine is controversial. Ketamine has been shown to produce seizure activity in patients with known seizure disorders. There are, however, data indicating that ketamine is safe to use in patients with seizure disorders. It would seem reasonable to avoid the use of ketamine for patients with seizure disorders because alternative drugs such as barbiturates, benzodiazepines, and propofol are available.

There is some evidence that propofol may activate the cerebral cortex.¹⁸⁹ Most studies, however, indicate that propofol has a more depressant effect on the EEG than does thiopental, and has been noted to increase the seizure threshold in patients receiving electroconvulsive therapy.¹⁹⁰ Propofol has also been shown to terminate local anesthetic-induced seizures.¹⁹¹

Methohexital may produce seizure activity in children.¹⁹² Certainly, methohexital has been used for many patients with seizure disorders without adverse effects. Although methohexital may not be contraindicated in patients with seizures, thiopental or propofol would be useful alternatives.

Seizure activity has also been reported to occur after the administration of fentanyl, sufentanil, and alfentanil; however, other studies have found no seizure activity after the use of these opioids.^{193,194,195} and ¹⁹⁶ The reported seizure activity may represent myoclonic activity or some form of opioid-induced skeletal muscle rigidity. With the usual clinical doses, seizure activity after fentanyl and sufentanil is not likely.¹⁹⁷ Clinical doses of alfentanil have been reported to produce seizure activity.¹⁹⁸ Prolonged administration of large doses of fentanyl (200–400 $\mu\text{g} \cdot \text{kg}^{-1}$) or sufentanil (40–160 $\mu\text{g} \cdot \text{kg}^{-1}$) may produce seizures and should be used with caution in patients with seizure disorders.^{199,200} Patients being chronically treated with anticonvulsants do have an increased fentanyl requirement during surgery, which most likely reflects enhanced metabolism by hepatic enzyme induction. Another potential drug interaction in patients receiving phenytoin and carbamazepine is resistance to nondepolarizing muscle relaxants.²⁰¹

The patient with a seizure disorder should receive his or her normal therapeutic drug regimen up to and including the morning of surgery. After surgery, this regimen should be resumed as quickly as possible. A decline in blood levels of anticonvulsant drugs will increase the likelihood of postoperative seizures.

Parkinson's Disease

Parkinson's disease, one of the more common disabling neurologic diseases, affects 3% of the population older than 65 years. Parkinson's disease is a degenerative disease of the central nervous system caused by loss of dopaminergic fibers in the basal ganglia of the brain. The characteristic pathologic feature is destruction of dopamine-containing nerve cells in the substantia nigra of the basal ganglia. The cause or causes of this selective destruction are not known. Current theories of the etiology include mitochondrial dysfunction with disordered oxidative metabolism, excitotoxicity (persistent activation of glutamatergic receptors), inadequate neurotrophic support, exposure to toxins (herbicides), or viral infection.²⁰² Other than the well known postencephalitis Parkinson's disease, however, there is little evidence that Parkinson's disease is caused by a virus. It has been conclusively demonstrated that the clinical effects of Parkinson's disease are caused by dopamine deficiency. Dopamine deficiency increases activity of γ -aminobutyric acid (GABA). GABA inhibits thalamic and brainstem nuclei, which suppresses cortical motor function and thereby causes tremor, akinesia, and gait and posture abnormalities.²⁰³

The most characteristic clinical features of Parkinson's disease are resting tremor, cogwheel rigidity of the extremities, bradykinesia, shuffling gait, stooped posture, and facial immobility. These features are all secondary to diminished inhibition of the extrapyramidal motor system as a result of depletion of dopamine from the basal ganglia. Other features that occur in patients with Parkinson's disease are seborrhea, sialorrhea, orthostatic hypotension, bladder dysfunction, pupillary abnormalities, diaphragmatic spasm, oculogyric crises, and dementia. Mental depression can be severe enough to necessitate the use of antidepressant medications.

The treatment of Parkinson's disease is directed toward increasing dopamine levels in the brain but preventing adverse peripheral effects of dopamine. Levodopa is the single most effective therapy for patients with Parkinson's disease. When administered orally, however, levodopa is converted to dopamine and causes side effects such as nausea, vomiting, and hypotension. Levodopa is administered in combination with a peripheral dopamine decarboxylase inhibitor carbidopa (Sinemet; Merck, Sharp & Dohme, West Point, PA). Side effects of levodopa administration include depletion of myocardial norepinephrine stores, peripheral vasoconstriction, hypovolemia, and orthostatic hypotension. Although levodopa has significantly reduced morbidity and mortality from Parkinson's disease, there is some evidence to suggest that the administration of levodopa may accelerate the pathologic process causing Parkinson's disease. This hypothesis is highly controversial and not universally accepted, but has influenced the early treatment of Parkinson's to include other types of drugs: anticholinergics, amantadine, dopamine receptor agonists, selegiline (MAO-B inhibitor), and COMT inhibitors. The anticholinergics (trihexyphenidyl, benztropine) are effective because they counteract loss of inhibition of cholinergic neurons. Anticholinergics can worsen dementia and are reserved for younger patients in the early phases of Parkinson's disease. Amantadine is a glutamate receptor antagonist and may exert a neuroprotective effect on neurons in the basal ganglia. The dopamine receptor agonists (bromocriptine, pergolide, pramipexole, ropinorole) exert their effect directly on dopamine receptors in the brain. Side effects of the dopamine receptor agonists include pulmonary and retroperitoneal fibrosis, erythromelalgia, and Raynaud's phenomenon. Selegiline is a selective MAO-B inhibitor which decreases the metabolism of dopamine. COMT inhibitors (entacapone, tolcapone) prevent the degradation of levodopa. Many of the aforementioned types of drugs, although not entirely successful as sole agents for the treatment of Parkinson's, are quite effective in combination with levodopa.²⁰⁴ A variety of surgical techniques for the palliation of Parkinson's have been recommended. Stereotactic pallidotomy and transplantation of neural tissue have demonstrated some efficacy.²⁰⁵

Management of Anesthesia

Management of anesthesia is usually determined by potential interaction between anesthesia drugs and anti-Parkinson medications and the severity of neurologic impairment. The patient's therapeutic regimen should be administered on the morning of surgery. The half-life of levodopa is short, and interruption of therapy for more than 6–12 hours can result in severe skeletal muscle rigidity that interferes with ventilation. Phenothiazines and butyrophenones (droperidol) should be avoided because these drugs antagonize the effects of dopamine in the basal ganglia. Alfentanil has been reported to produce acute dystonic reactions in patients with untreated Parkinson's disease.²⁰⁶ Although ketamine could produce an exaggerated sympathetic nervous system response, with resultant tachycardia and hypertension, it has been used without difficulty in patients with Parkinson's disease. However, the likelihood of coexisting ischemic heart disease in the elderly patient with Parkinson's disease may make the use of ketamine less attractive. In theory, halothane could produce cardiac dysrhythmias in patients receiving levodopa, but this has not been documented. There are no reports of adverse responses to isoflurane, sevoflurane, or desflurane in patients with Parkinson's disease. The choice of muscle relaxants does not seem to be directly influenced by the presence of Parkinson's disease. Although there is one case report of hyperkalemia after the administration of succinylcholine, further investigation has demonstrated that this was an isolated occurrence.²⁰⁷

The potential hazards of drug interactions in patients taking MAO inhibitors have been well documented in the medical literature. The interaction between MAO inhibitors and meperidine appears to be the most significant. The use of selegiline for the treatment of the early phases of Parkinson's disease increases the likelihood of having to anesthetize a patient who is receiving MAO-B inhibitors. Although definitive studies of anesthesia for patients receiving selegiline have not been performed, anecdotal reports have indicated that anesthesia is usually uneventful. However, there have been reports of agitation, muscle rigidity, and hyperthermia in patients receiving meperidine and selegiline.²⁰⁸ The MAO-B enzyme acts on phenylethylamine, benzylamine, tyramine, and dopamine with little effect on epinephrine and norepinephrine.²⁰⁹ This could explain why there is less risk of massive sympathetic discharge in patients receiving selective MAO-B inhibitors. Patients with Parkinson's disease who are being treated with dopamine agonists may be at increased risk for neuroleptic malignant syndrome.²¹⁰

Autonomic dysfunction is common in Parkinson's disease. Gastrointestinal dysfunction is very common and is manifested by excessive salivation, dysphagia, and esophageal dysfunction. Consequently, the patient with Parkinson's disease should be considered at risk for aspiration pneumonitis. The most consistent cardiovascular abnormality is orthostatic hypotension. The disease process undoubtedly contributes to hypotension, which is further compounded by the tendency of anti-Parkinson drugs to produce peripheral vasodilation.²¹¹ Patients with Parkinson's disease would be more likely to manifest exaggerated decreases in blood pressure in response to inhaled halogenated anesthetics.

Respiratory complications are common in patients with Parkinson's disease. Upper airway obstruction may occur as a result of poor coordination of upper airway muscles secondary to neurotransmitter imbalance caused by the disease process or induced by the administration of antidopaminergic drugs. Some Parkinson's patients with upper airway obstruction may respond to the administration of anti-Parkinson drugs.²¹²

In the postoperative period, patients with Parkinson's disease are more susceptible to the development of mental confusion and even hallucinations. These alterations in mental function may not appear until the day after surgery.²¹³ The precise mechanism of this confusion is not known, but could have significant impact on outpatient

surgery in patients with Parkinson's disease.

Huntington's Disease (Huntington's Chorea)

Huntington's disease is a neurodegenerative disease caused by severe neuronal loss in the corpus striatum and later the cortex. Huntington's disease is one of the trinucleotide repeat disorders. The unstable trinucleotide repeat encodes the huntingtin protein. Although the function of the huntingtin protein is not known, intranuclear inclusions of huntingtin and ubiquitin are found in neuronal cells that eventually die.^{214,215} Huntington's disease is a heritable disorder that is transmitted as an autosomal dominant trait. The Huntington's gene has been identified and is expressed when the patient is 35–40 years of age. Identification of the Huntington's disease gene has provided a technique for predictive testing; however, the delayed nature of the clinical manifestations of the disease has presented legal and ethical concerns about early predictive testing.²¹⁶

Disordered movement and dementia are the clinical hallmarks of Huntington's disease. Although the chorea is the most common movement disorder, athetosis and dystonia also occur. Movement abnormalities can involve the extremities, trunk, face, eyes, oropharynx, and respiratory muscles.²¹⁷ The disease progresses for several years, and accompanying mental depression makes suicide a frequent occurrence. Death usually results from malnutrition and aspiration pneumonitis. The duration of Huntington's disease averages 17 years from the time of diagnosis to death.

There is no specific therapy for Huntington's disease. Pharmacotherapy is directed at relief of mental depression and control of movement disorders. A number of drugs that affect central nervous system neurotransmitter function have been evaluated, but show little promise. Movement disorders such as chorea do not specifically require therapy unless function is significantly diminished. Drugs that reduce dopaminergic transmission, such as phenothiazines, butyrophenones, and thioxanthines, or drugs that deplete dopamine such as tetrabenzamine and reserpine, reduce the severity of chorea.²¹⁸ Antidepressants such as the tricyclic antidepressants or serotonergic antidepressants (fluoxetine) may be effective for improving the patient's mental status.

Management of Anesthesia

Many of the manifestations of Huntington's disease are typical of patients with neurodegenerative disorders. With progression of the disease, the pharyngeal muscles become more dysfunctional and the risk of aspiration pneumonitis increases. Consequently, appropriate anti-aspiration maneuvers must be used. If preoperative and postoperative sedation are necessary, the butyrophenones or phenothiazines are logical choices. There are reported cases of neuroleptic malignant syndrome in patients with Huntington's disease, which is most likely secondary to the administration of neuroleptic drugs rather than intrinsic effects of Huntington's disease.²¹⁹ Reported anesthesia experience with patients with Huntington's disease is largely anecdotal. Although there are no specific contraindications to the use of inhaled or intravenous anesthetics, delayed awakening and generalized tonic spasms have been reported after the administration of thiopental.²²⁰ In contrast, a rapid recovery after the administration of propofol has been reported.^{221,222} Decreased plasma cholinesterase activity with a prolonged response to succinylcholine has been reported.²²³ It has been suggested that patients with Huntington's disease may be sensitive to the effects of nondepolarizing muscle relaxants, although the reported response to atracurium has been normal.^{222,224} Spinal anesthesia has been successfully administered to patients with Huntington's disease.²²⁵

Alzheimer's Disease

Alzheimer's disease is the major cause of dementia in the United States. More than four million people in the United States are afflicted with Alzheimer's disease. The disease affects a large proportion of the population older than 70 years, and is the major reason that patients are admitted to nursing homes. As life expectancy for men and women increases, a larger part of the population will be susceptible to this disease. Although dementia is caused by more than 60 disorders, Alzheimer's disease is responsible for 50–60% of the cases. Dementia is characterized by intellectual and cognitive deterioration that impairs social function. The clinical diagnosis can be made if a patient exhibits loss of memory and deficits in two or more areas of cognition. The mental status examination is central to the diagnosis of Alzheimer's disease. Any systemic cause of dementia, such as cerebral vascular disease, must be eliminated before the diagnosis of Alzheimer's disease is made. Although neuroimaging changes (CT, MRI) and alterations in the EEG are not diagnostic for Alzheimer's disease, these diagnostic techniques are useful for eliminating other causes of dementia. Pathologic changes in the brain include a characteristic cortical atrophy and the presence of neurofibrillary tangles and neuritic plaques in the presence of massive neuronal degeneration. Deposition of b-amyloid appears to be central to the process of degeneration. There is strong evidence that there are four different genetic loci that may predispose to the development of Alzheimer's. These different loci may explain the differences in clinical presentation and age of onset.²¹⁴

Because the precise pathophysiologic mechanism for Alzheimer's is unknown, there is no specific therapy. Most therapy has been directed at increasing neurotransmitter levels, especially acetylcholine. As neuronal systems degenerate, neurotransmitter systems deteriorate. Consequently, therapy has been directed at increasing acetylcholine levels by acetylcholine precursor loading, cholinesterase inhibition, direct cholinergic receptor stimulation, and indirect cholinergic stimulation.²²⁶ Although these therapies have produced clinical improvement in some patients with Alzheimer's disease, the results have not been dramatic. Currently used cholinesterase inhibitors include donepezil, tacrine, velnacrine, and a sustained-release preparation of physostigmine. Tacrine and velnacrine can produce direct hepatotoxicity.²²⁷ Therapy has also been directed at increasing neurotransmitter levels in the noradrenergic and serotonergic systems as well. Many other drugs, including cerebrovascular vasodilators, vitamins, and antidepressants, are used as adjunctive therapy for Alzheimer's disease.

Management of Anesthesia

Selection of anesthetic drugs and techniques for patients with Alzheimer's disease is guided by the patient's general physiologic condition, the degree of neurologic deterioration, and the potential for interaction between anesthetics and medications that the patient is receiving. Because of dementia, these patients are likely to be disoriented and uncooperative preoperatively. Sedative drugs, such as those used for preoperative medication, should be administered rarely because further mental confusion could result. Anesthetics known to result in rapid postanesthetic recovery, such as propofol, desflurane, and sevoflurane, may be advantageous because they permit a more rapid return to the patient's preoperative state. The possibility of coexisting hepatic dysfunction from tacrine and velnacrine may also influence the choice of a halogenated, volatile anesthetic. If an anticholinergic is required, glycopyrrolate, which does not cross the blood–brain barrier may be preferable to atropine or scopolamine. In theory, an anticholinergic drug that enters the brain could exacerbate the dementia. The patient's preoperative drug list should be reviewed for the possibility of interaction with anesthetics.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a degenerative disease of motor cells (anterior horn cells) throughout the central nervous system. Progression of the disease is relentless, and death usually follows within 3–5 years of diagnosis. Upper and lower motor neurons are involved almost exclusively, although lower motor neurons are affected first.²²⁸ The cause of ALS is unknown, but proposed causes include a slow viral infection, glutamate excitotoxicity, free radical stress, immune dysfunction, impaired neural protein repair, and altered axonal transport.²²⁹ Although the similarity between ALS and poliomyelitis is striking, data indicate that the incidence of ALS in postpoliomyelitis patients is actually decreased.²³⁰

The signs and symptoms of ALS reflect the upper and lower motor neuron dysfunction. Frequently reported initial manifestations are atrophy, weakness, and fasciculation of skeletal muscles, often beginning in the intrinsic muscles of the hand. Computed tomographic scanning of muscles demonstrates a symmetric atrophy of muscle and replacement of muscle tissue with fat.²³¹ As the disease progresses, the atrophy and weakness involve most skeletal muscles, including those of the tongue, pharynx, larynx, and chest. Pulmonary function studies demonstrate a decrease in vital capacity, maximal voluntary ventilation, and diminished expiratory muscle function.^{232,233} Serial pulmonary function testing may be useful for determination of prognosis and intervention options.²³⁴ In rare instances the initial presentation of ALS may be acute respiratory failure.²³⁵ Eventually, respiratory failure develops in all patients with ALS, and mechanical ventilation of the lungs is necessary. Patients with ALS have evidence of autonomic dysfunction manifested as an increased resting heart rate, orthostatic hypotension, and elevated resting levels of norepinephrine and epinephrine. There is usually a decreased R–R interval variation on the ECG and a decreased heart rate response to the administration of atropine.²³⁶ The cause of death in patients with ALS is usually respiratory failure. Sudden death from circulatory collapse frequently occurs in ventilator-dependent patients with ALS.²³⁷

Management of Anesthesia

Neuromuscular transmission is markedly abnormal in patients with ALS.²³⁸ Consequently, these patients can be very sensitive to nondepolarizing muscle relaxants. As with other patients with lower motor dysfunction, ALS patients should be considered vulnerable to hyperkalemia in response to the administration of succinylcholine. Bulbar involvement with dysfunction of pharyngeal muscles predisposes patients with ALS to pulmonary aspiration. The need for postoperative ventilatory support is highly likely for these patients. There is no evidence that a specific anesthetic drug or combination of drugs is best for patients with ALS. Subclinical autonomic dysfunction can produce severely exaggerated decreases in cardiovascular function in response to anesthetics.²³⁹

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease is one of three disorders that constitute the class of diseases known as the human spongiform encephalopathies. The other two diseases in this group are kuru and Gerstmann-Strausler syndrome. Pathologically, these disorders are characterized by vacuolation of brain tissue and neuronal loss. Creutzfeldt-Jakob disease is caused by an unusual infectious agent—a prion. A prion is a small proteinaceous infectious agent. Prions are resistant to alcohol, formalin, ionizing radiation, proteases, and nucleases, but can be inactivated by heat (autoclaving), phenol, detergents, and extremes of pH.²⁴⁰ Creutzfeldt-Jakob disease is an almost unique disease in that the incubation time is long (years), and there is an absence of fever and inflammation. There has been considerable concern in recent years about the potential transmission of prions from animals (cows) to man. Though much less common, Creutzfeldt-Jakob disease, like multiple sclerosis, is known for its diverse clinical presentations and varied neurologic signs.²⁴¹

The typical clinical characteristics include subacute dementia, myoclonus, and EEG changes. The EEG pattern is relatively characteristic, with diffuse, slow activity, and periodic complexes. Because of the dementia and wide array of presenting symptoms, patients with Creutzfeldt-Jakob disease are often misdiagnosed as having psychiatric disorders. There is no specific therapeutic drug for Creutzfeldt-Jakob disease.

Management of Anesthesia

Creutzfeldt-Jakob disease is transmissible. There are reports of cases developing after accidental inoculation and surgery.^{242,243} The transmission of Creutzfeldt-Jakob disease has been linked to contaminated dural graft material, corneal transplants, and administration of pooled human growth hormone.^{244,245} Although there have been no documented reports of transmission of Creutzfeldt-Jakob disease by blood transfusion, donor restrictions have been proposed.^{246,247} Because of the transmissibility of the disease, appropriate precautions should be taken to protect other patients and health care providers. The Creutzfeldt-Jakob prion is not inactivated by 3–10% formalin and 70% alcohol. Sodium hypochlorite (bleach) 0.05% and sterilization with steam or ethylene oxide will destroy the infectious agent.²⁴⁸

Although reported anesthetic experience with patients with Creutzfeldt-Jakob disease is limited, certain speculations and recommendations seem warranted. Patients with degenerative neurologic diseases are prone to aspirate gastric contents because they have impaired swallowing function and decreased activity of laryngeal reflexes. Therefore, appropriate anti-aspiration maneuvers are indicated during anesthesia. Because lower motor neuron dysfunction also occurs in these patients, the use of succinylcholine should be avoided. The autonomic and peripheral nervous systems may also be involved, which may result in abnormal cardiovascular responses to anesthesia and vasoactive drugs.^{249,250}

ANEMIAS

The causes of anemia are numerous (Table 19-9). Anemias can be classified as nutritional deficiency anemias, hemolytic anemias, hemoglobinopathies, and hemoglobin deficiency syndromes (thalassemias).

| |
|--|
| NUTRITIONAL |
| Iron deficiency |
| Vitamin B ₁₂ deficiency |
| Folic acid deficiency |
| HEMOGLOBINOPATHIES |
| Hemoglobin S (sickle cell) |
| HEMOLYTIC |
| Spherocytosis |
| Glucose-6-phosphate dehydrogenase deficiency |
| Pyruvate kinase deficiency |
| Immune-mediated |
| Drug-induced ABO incompatibility |
| THALASSEMIAS |
| Thalassemia major (Cooley's anemia) |
| Thalassemia intermedia |
| Thalassemia minor |

Table 19-9. TYPES OF ANEMIA

Regardless of the cause of the anemia, compensatory physiologic mechanisms develop to offset the decreased oxygen-carrying capacity of the blood. Typically, in an otherwise healthy person, symptoms do not develop from anemia until the hemoglobin level decreases below $7 \text{ g} \cdot \text{dL}^{-1}$. Symptoms are highly variable and depend on other concurrent disease processes. Physiologic compensation includes increased plasma volume, increased cardiac output, and increased levels of red blood cell 2,3-diphosphoglycerate (Table 19-10). Because elderly patients with chronic anemia have an increased plasma volume, transfusion of whole blood to these patients may result in congestive heart failure. Similarly, the myocardial depressant effects of anesthetics may be exaggerated in patients with increased cardiac output at rest as compensation for anemia.

| |
|---|
| Increased cardiac output |
| Increased red blood cell 2,3-diphosphoglycerate |
| Increased P ₅₀ |
| Increased plasma volume |
| Decreased blood viscosity |

Table 19-10. COMPENSATORY MECHANISMS TO INCREASE OXYGEN DELIVERY WITH CHRONIC ANEMIA

Concern about the transmission of blood-borne infectious diseases such as human immunodeficiency virus has greatly influenced the perioperative use of blood products and has radically altered recommendations for perioperative blood transfusion not only in normal patients, but also in patients with chronic anemia. Traditional hematocrit levels that previously triggered the need for preoperative blood transfusion have been challenged. Currently, there is no universally accepted hematocrit level that mandates blood transfusion. The patient's physiologic status and coexisting diseases must be factored into a highly subjective decision.²⁵¹

Nutritional Deficiency Anemias

The three primary causes of nutritional deficiency anemia are iron deficiency, vitamin B₁₂ deficiency, and folic acid deficiency. Chronic illness, as well as poor dietary intake, can result in nutritional deficiency anemia.

Iron deficiency anemia produces the typical microcytic, hypochromic red blood cell. Iron deficiency anemia may be an absolute deficiency secondary to decreased oral intake or a relative deficiency caused by a rapid turnover of red blood cells (e.g., chronic blood loss, hemolysis). Measuring the hemoglobin and serum ferritin levels is a rapid and effective mechanism for differentiating true iron deficiency anemia from other causes.²⁵² Severe iron deficiency anemia can result in respiratory distress, congestive heart failure, thrombocytopenia, and neurologic abnormalities.^{253,254} and ²⁵⁵

Megaloblastic anemia can be caused by vitamin B₁₂ (cobalamin) deficiency, folate deficiency, or refractory bone marrow disease.²⁵⁶ Absorption of vitamin B₁₂ by the gastrointestinal tract depends on production of intrinsic factor, a glycoprotein produced by gastric parietal cells. Atrophy of the gastric mucosa causes vitamin B₁₂

deficiency and megaloblastic anemia. Chronic gastritis and gastric atrophy in some patients are caused by autoantibodies to gastric parietal cells.²⁵⁷ In addition to megaloblastic anemia, vitamin B₁₂ deficiency can interfere with myelination and produce significant nervous system dysfunction.²⁵⁸ In adults this is usually manifest by a peripheral neuropathy secondary to degeneration of the lateral and posterior columns of the spinal cord. The neuropathy is evidenced by symmetric paresthesias with loss of proprioception and vibratory sensation, especially in the lower extremities. Administration of parenteral vitamin B₁₂ reverses both the hematologic and neurologic changes in adults. Congenital vitamin B₁₂ deficiency, however, produces severe neurologic changes that can only be partially reversed with therapy. The coexisting neuropathy of vitamin B₁₂ deficiency must be considered when regional anesthesia or peripheral nerve blocks might be used. The clinical significance of the effects of nitrous oxide on vitamin B₁₂ metabolism is controversial. Nitrous oxide inactivates the vitamin B₁₂ component of methionine synthetase; certainly, prolonged exposure to nitrous oxide results in megaloblastic anemia and neurologic changes similar to those that occur with pernicious anemia.²⁵⁹ Relatively short exposures to nitrous oxide have also been reported to produce megaloblastic changes.^{260,261} and ²⁶² Whether the duration of exposure to nitrous oxide obtained during the course of a normal anesthetic produces such changes in humans has not been established. The issue of nitrous oxide causing postoperative neurologic dysfunction is extremely controversial and case reports of neuropathy linked to intraoperative nitrous oxide exposure have increased in recent years.^{263,264,265} and ²⁶⁶ Whether these reports influence the future use of nitrous oxide is not yet clear.

Folic acid deficiency also produces megaloblastic anemia. Although peripheral neuropathy may occur, it is not as common as with vitamin B₁₂ deficiency. The administration of folic acid during early pregnancy markedly reduces the risk of neural tube defects in infants.²⁶⁷ Causes of folic acid deficiency include alcoholism, pregnancy, and malabsorption syndromes. Methotrexate, phenytoin, and ethanol are among the drugs known to interfere with folic acid absorption.

Hemolytic Anemias

The normal life span of an erythrocyte is 120 days. Abnormalities in the erythrocyte, however, may result in the premature destruction of red blood cells (hemolysis). Causes of hemolytic anemia include structural erythrocyte abnormalities, enzyme deficiencies, and immune hemolytic anemias.

Hereditary Spherocytosis

Spherocytosis, elliptocytosis, pyropoikilocytosis, and stomatocytosis are the four types of hereditary red blood cell membrane defects resulting in abnormally shaped red blood cells.

Hereditary spherocytosis is the most common of the red blood cell membrane defects producing hemolysis. Spherocytosis is a disorder of the proteins (spectrin) of the red blood cell cytoskeleton in which the red blood cell is more rounded, more fragile, and more susceptible to hemolysis than the normal, biconcave red blood cell. As a result of this increased fragility, the spleen destroys the abnormal red blood cells and a chronic anemia ensues. Cholelithiasis from chronic hemolysis and elevation of the serum bilirubin occur frequently in patients with hereditary spherocytosis. Patients with hereditary spherocytosis may have hemolytic crises accompanied by anemia, vomiting, and abdominal pain. These crises may be triggered by infection or folic acid deficiency.²⁶⁸

Hereditary spherocytosis is treated by splenectomy, which is usually delayed until the patient is 6 years old or older.²⁶⁹ Splenectomy before that age is associated with a high incidence of bacterial infections, especially those secondary to pneumococcus. Before splenectomy, most patients require a folic acid supplement owing to excessive utilization of folic acid for red blood cell production. Transfusion is rarely necessary for patients with hereditary spherocytosis.

There are no special considerations during anesthesia for patients with hereditary spherocytosis. Preoperative transfusion is not necessary because adequate compensatory mechanisms for chronic anemia have developed in these patients.

Glucose-6-phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzymopathy in humans and afflicts 400 million people worldwide.²⁷⁰ An estimated 1% of the African-American male population in the United States is affected by this disorder. African black, Asian, and Mediterranean populations are also susceptible to G6PD deficiency. In patients with G6PD deficiency, G6PD activity decreases by 50% during the 120-day life span of the red blood cell. G6PD initiates the hexose monophosphate shunt. This shunt produces nicotinamide-adenine dinucleotide phosphate (NADPH). Without NADPH, the red blood cell is susceptible to damage by oxidation. A deficiency of G6PD results in decreased levels of reduced glutathione when the red blood cell is exposed to oxidant compounds. This increases the rigidity of the red blood cell membrane and accelerates clearance of these stiff cells from the circulation. In severe forms of G6PD deficiency, oxidation produces denaturation of globin chains and causes intravascular hemolysis.²⁷¹

There are a number of drugs that accentuate the destruction of erythrocytes in patients with G6PD deficiency, including analgesics, antibiotics, sulfonamides, and antimalarials (Table 19-11). There is considerable variability in the hemolytic response to drugs; many drugs (e.g., aspirin) induce hemolysis only in very high doses.²⁷² Patients with G6PD deficiency are unable to reduce methemoglobin produced by sodium nitrate; therefore, sodium nitroprusside and prilocaine should not be administered. Characteristically, the crisis begins 2–5 days after drug administration. The hemolytic episode is usually self-limited because only the older red blood cells are affected.²⁷³ Bacterial infections can also trigger hemolytic episodes. Presumably, oxidant compounds produced by active white blood cells may hemolyze susceptible red blood cells.

| | |
|----------------------|----------------|
| Phenacetin | Nalidixic acid |
| Aspirin (high doses) | Isoniazid |
| Penicillin | Primaquine |
| Streptomycin | Quinine |
| Chloramphenicol | Quinidine |
| Sulfacetamide | Doxorubicin |
| Sulfanilamide | Methylene blue |
| Sulfapyridine | Nitrofurantoin |

Table 19-11. DRUGS THAT PRODUCE HEMOLYSIS IN PATIENTS WITH GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Glutathione synthetase is another enzyme of the hexose monophosphate shunt, and deficiency of this enzyme may also produce anemia.

Anesthetic drugs have not been implicated as hemolytic agents; however, early postoperative evidence of hemolysis might indicate a G6PD deficiency syndrome.

Pyruvate Kinase Deficiency

Pyruvate kinase is a glycolytic enzyme of the Embden-Meyerhof pathway. This pathway converts glucose to lactate and is the primary pathway for adenosine triphosphate synthesis in the red blood cell. A deficiency of pyruvate kinase produces a potassium leak from erythrocytes, increasing their rigidity and enhancing destruction in the spleen. Pyruvate kinase deficiency is responsible for 95% of the deficiency syndromes in the Embden-Meyerhof pathway, whereas deficiency of glucose phosphate isomerase accounts for 4%. Clinically, these patients exhibit anemia, premature cholelithiasis, and splenomegaly. The degree of anemia varies from a very mild anemia that does not require transfusion to a severe, transfusion-dependent anemia. Splenectomy may be beneficial for patients with severe anemia. The clinical features resemble those of patients with spherocytosis. There are no special considerations for anesthesia other than those for any patient with chronic anemia.

Immune Hemolytic Anemia

The immune hemolytic anemias are characterized by immunologic alteration in the red blood cell membrane and are caused by drugs, disease, or erythrocyte sensitization.

There are three types of immune hemolytic anemia: autoimmune hemolysis, drug-induced immune hemolysis, and alloimmune hemolysis (erythrocyte sensitization).²⁷⁴ Autoimmune hemolytic anemia includes warm and cold antibody hemolytic anemia. Cold autoimmune hemolytic anemia is of special concern to the anesthesiologist because of the likelihood that the cold operating room environment and hypothermia that are used during cardiopulmonary bypass may initiate a hemolytic crisis. Cold hemagglutinin disease is caused by IgM autoantibodies that react with the I antigen of red blood cells.²⁷⁵ Maintaining a warm environment is essential for prevention of hemolysis.²⁷⁶ Plasmapheresis to reduce the titer of cold antibody is recommended before hypothermic procedures such as cardiopulmonary bypass. Collagen vascular diseases, neoplasia, and infections produce immune hemolytic anemias by a variety of mechanisms, including warm and cold antibody-mediated hemolysis.

There are three types of drug-induced immune hemolysis: autoantibody type, hapten-induced type, and immune complex type. Hemolysis induced by a response to α -methyl-dopa is of the autoimmune type mediated by an IgG antibody that does not fix complement. The hapten-induced type is characteristic of the response to penicillin and other antibiotics. The immune complex type of reaction can occur after the administration of quinidine, quinine, sulfonamides, isoniazid, phenacetin, acetaminophen, cephalosporins, tetracycline, hydralazine, and hydrochlorothiazide.

The classic example of alloimmune hemolysis (erythrocyte sensitization) is hemolytic disease of the newborn produced by Rh sensitization. An Rh-negative mother with Rh antibodies produces hemolysis in an Rh-positive fetus. Differences in fetal and maternal ABO groups may also cause hemolysis. This is, however, unusual because A and B antibodies are of the IgM class and do not readily cross the placenta.

Hemoglobinopathies

There are more than 300 different hemoglobinopathies described in the literature. Fortunately, most are quite rare and may never be encountered by an anesthesiologist during his or her career. Of the hemoglobinopathies, the most common in the United States are the sickle cell diseases. An estimated 8–10% of African-Americans have the sickle cell trait, and 1 in 400 has sickle cell anemia.

Sickle Cell Disease

Hemoglobin S is a variant hemoglobin produced by substitution of valine for glutamic acid in the sixth position of the β chain. When hemoglobin S deoxygenates, a gel structure is formed that produces structural changes in the red blood cell. The kinetics of the gel formation by hemoglobin S is complex, and factors such as rapidity of deoxygenation may determine how the gel polymerizes and deforms the red blood cell. Low oxygen tension and acidosis exaggerate sickle cell formation. Consequently, any condition that causes a decrease in oxygen tension (e.g., arterial hypoxemia) or decreased blood flow may produce a sickling of red blood cells. Sickling begins at oxygen tensions less than 50 mm Hg and becomes most pronounced when the arterial oxygen tension decreases to 20 mm Hg. Local factors can also influence sickling. Systemic oxygenation may be adequate, but vascular occlusion may produce stasis with localized hypoxemia and initiate sickling. Similarly, if sickling occurs, increasing systemic oxygenation may not reverse the sickling if arteries supplying the area are occluded. It is certainly better to prevent sickling rather than treat it. The likelihood of sickling is directly related to the amount of hemoglobin S in the blood.

The definitive diagnosis of sickle cell disease is made with hemoglobin electrophoresis. This test not only detects hemoglobin S but also reveals any other type of hemoglobin present. Although there are several variants of hemoglobin S disease, the most common are SS (sickle cell anemia), SA (sickle cell trait), SC, and S-thalassemia. In sickle cell anemia, 70–98% of the hemoglobin is S, and the remainder is hemoglobin F (fetal). In patients with SA, 10–40% of the hemoglobin is hemoglobin S. Red blood cells with hemoglobin S and C are less likely to sickle than those with SS, but more likely to sickle than SA cells.

Clinical Manifestations. The patient with SA usually has a normal life expectancy and few complications with the hemoglobinopathy. Hemoglobin levels are normal, and sickling occurs only under extreme physiologic conditions. Although the risk of anesthesia is small, there have been some reports of death in the perioperative period. Of the 514 patients with SA who received general anesthesia reported in the literature, there have been 5 deaths.^{277,278} Not all of the deaths could be attributed to sickle cell trait, however.

Patients with SS are the most severely affected of those with sickle cell hemoglobinopathies. Clinical manifestations include chronic anemia and chronic hemolysis. Infarction of multiple organs is produced by occlusion of vessels with deformed erythrocytes.

There are two patterns of pulmonary complications in patients with sickle cell disease: sickle cell lung disease and acute chest syndrome. Sickle cell lung disease is characterized by generalized pulmonary fibrosis with hypoxemia and ultimately cor pulmonale, which is a significant cause of mortality in patients with SS disease. Sickle cell patients with acute chest syndrome have fever, chest pain, dyspnea, cough, and tachypnea and may suffer acute pulmonary hypertension and death.²⁷⁹ Cardiac dysfunction, characterized by decreased ventricular filling and reduced ejection fraction, in conjunction with pulmonary disease produces decreased exercise tolerance.²⁸⁰ Because of the slow blood flow and decreased local oxygen tension, the renal medulla is particularly vulnerable to infarction and necrosis. Papillary necrosis secondary to medullary ischemia occurs frequently, and there is an inability to concentrate urine. Glomerular filtration declines with age and nephrotic syndrome is common.²⁸¹ Renal transplantation may be required.²⁸² By the time the patient with sickle cell anemia is 6 years old, the spleen is virtually nonexistent because of repeated infarctions. The absence of splenic function increases the patient's vulnerability to bacterial infection. Chronic hemolysis of erythrocytes produces an elevated serum bilirubin level and results in a high incidence of cholelithiasis in patients with SS disease. Repeated cerebral infarction from large cerebral vessel occlusion and hemorrhage can produce neurologic dysfunction.²⁸³ Priapism also occurs with increased frequency in patients with sickle cell disease.

The clinical manifestations of SC disease are intermediate in severity between SA and SS hemoglobinopathies. Anemia is mild, with hemoglobin concentrations of 10–11 g · dl⁻¹. Sickle cell crises are less common in patients with SC disease than in those with SS. Pulmonary dysfunction secondary to upper respiratory tract infections, pneumonia, and pulmonary embolization is relatively common in patients with SC disease. There are at least 40 other variants of the S hemoglobinopathy, some of which are quite rare. Hemoglobin SA, SS, and SC are the three most frequently encountered variants (Table 19-12).

| | Hemoglobin SS | Hemoglobin SC | Hemoglobin SA |
|--|---|---|-----------------------------------|
| Hemoglobin level (g · dl ⁻¹) | 7-8 | 8-12 | 12-15 |
| Life expectancy (years) | 30 | Slightly reduced | Normal |
| Tendency for sickling | ++++ | ++ | + |
| Clinical features | Vaso-occlusive crises Splenic infarction Priapism Spleen atrophy | Vaso-occlusive crises Renal infarction Splenomegaly Splenomegaly | Few, under physiologic conditions |

Table 19-12. COMMON HEMOGLOBIN S VARIANTS

Treatment. Although the exact molecular defect of S hemoglobin has been known for 50 years, no definitive or corrective therapy is available. Supportive therapy has improved, increasing survival, so that many patients with SS disease live until their late 40s.

The best therapy is prevention of sickling. Maintenance of good systemic oxygenation and hydration to ensure good tissue perfusion is essential. Transfusion with normal adult hemoglobin (AA) to dilute the hemoglobin S erythrocytes and decrease blood viscosity may be indicated. A variety of techniques aimed at reversing the sickling process have been attempted, but with little success. Because reversal of the sickling process is so difficult, prevention becomes essential. The administration of hydroxyurea has been shown to increase the production of hemoglobin F, which is a potent inhibitor of polymerization of hemoglobin S. Treatment with hydroxyurea has been shown to decrease the frequency and severity of painful crises, the incidence of acute chest syndrome, and the need for transfusion.²⁸⁴ Bone marrow transplantation and transplantation of cord blood stem cells have also been efficacious.^{285,286}

There are three forms of clinical crises in patients with sickle cell anemia: vaso-occlusive (painful) crises, aplastic crises, and splenic sequestration crises. Vaso-occlusive crises are characterized by sickling, venous thrombosis, organ infarction, and severe pain. Pain may be secondary to infarction of bone and muscle.²⁸⁷ Pain management is an important aspect of the care of patients during a vaso-occlusive crisis. Aplastic crises produce dramatic decreases in erythropoiesis and

hematocrit level. Splenic sequestration crises occur in children less than 6 years of age.²⁸⁸

Management of Anesthesia. Because arterial hypoxemia and vascular stasis are powerful stimuli for sickling, it is imperative that the risk of these be minimized during anesthesia and the postoperative period. Patients with sickle cell anemia are at increased risk for perioperative complications including acute chest syndrome, sickling crises, infection, and intractable pain. Optimal perioperative management requires that the anesthesiologist, surgeon, and hematologist interact closely.²⁸⁹ Surgical diseases that occur with increased frequency in patients with sickle cell anemia include cholelithiasis, peptic ulceration, ischemic colitis, and leg ulcers. Laparoscopic surgical techniques have reduced morbidity in patients with sickle cell disease.^{290,291}

Preoperative sedation should not depress ventilation. During surgery and the postoperative period, the inspired oxygen concentration should be increased to maintain or increase the arterial oxygen tension as reflected by continuous monitoring using pulse oximetry. Although regional anesthesia is often used for these patients, the administration of supplemental oxygen may still be indicated. Regional anesthesia may produce compensatory vasoconstriction and decreased oxygen delivery to nonblocked areas, making red blood cells in those areas vulnerable to sickling. Circulatory stasis can be minimized with adequate hydration and anticipation of intraoperative volume loss to avoid acute hypovolemia. The use of extremity tourniquets is controversial. There are no definitive studies documenting the safety or danger of tourniquet use. Some authors recommend that a tourniquet not be used for patients with hemoglobin S because of the potential dangers, whereas other authors suggest that a tourniquet can be used if it is critical to the success of the operation.²⁹² The environmental temperature should be controlled to maintain normothermia. Fever increases the rate of gel formation by S hemoglobin. Although hypothermia retards gel formation, the decreased temperature also produces peripheral vasoconstriction. Consequently, normothermia is desirable. Preoperative transfusion to reduce hemoglobin S levels to 30–40% has been demonstrated to reduce perioperative complications in patients with sickle cell anemia.^{293,294} The decision for preoperative transfusion will depend upon the patient's preoperative condition and the extent of the surgical procedure. Precise guidelines for preoperative transfusion of the sickle cell patient have not been developed and consultation with a hematologist is helpful.²⁹⁵ There is evidence that autotransfusion can be used successfully if an exchange transfusion to dilute the number of hemoglobin S red blood cells is performed before anesthesia.²⁹⁶

Although inhaled, halogenated anesthetics accelerate precipitation of hemoglobin S *in vitro*, the clinical significance of this finding is not known. Maintenance of perfusion and oxygenation is more critical than is the type of anesthesia. Because of low peripheral blood flow, hypothermia, and acidosis, cardiopulmonary bypass is especially dangerous for patients with sickle cell disease.²⁹⁷

Close monitoring of the sickle cell patient during the postoperative period for pulmonary complications and aggressive treatment with supplemental oxygen are necessary as hypoxemia may be the primary trigger of acute chest syndrome.²⁹⁸ Acute chest syndrome during the early postoperative period produces significant morbidity and mortality. Pain management of the patient with sickle cell disease during a sickling crisis or in the postoperative period can be challenging. A variety of techniques including opioids (morphine), non-narcotic analgesics, and epidural analgesia have been used.^{299,300}

Although patients with SA are at less risk than patients with hemoglobin SS, the same perioperative precautions applied to patients with SS should also be used for those with SA. The patient with SC hemoglobin is also at risk during anesthesia and should be treated accordingly.³⁰¹

Thalassemia

Thalassemia represents a number of inherited disorders that result in the production of abnormal globin chains. Although there are four globin chains (a, b, g, d), the a and b thalassemias are the most common. The abnormal globin chains precipitate in the red blood cell, leading to their destruction in the bone marrow and the peripheral blood. The anemia results in increased erythropoietin production, extramedullary erythropoiesis, and splenomegaly.³⁰² A wide variety of clinical phenotypes are manifest, from very mild to very severe anemia.³⁰³ b Thalassemia major, or Cooley's anemia, is usually fatal. b Thalassemia minor produces a mild hemolytic anemia and iron deficiency. b Thalassemia intermedia is an intermediate form of thalassemia but usually does not require transfusion. a Thalassemia produces a mild hemolytic anemia. The incidence of thalassemia is highest in the Mediterranean area, the Middle East, India, and Southeast Asia.

Transfusion therapy is essential but often produces iron toxicity with resultant myocardial siderosis, which can markedly reduce ventricular function. Cardiac iron toxicity is a significant cause of mortality in patients with thalassemia. Treatment consists of the administration of iron chelators such as desferrioxamine and deferiprone.^{304,305} Hepatic fibrosis as a result of iron toxicity may also occur.

Management of Anesthesia. Anesthetic considerations depend on the severity of the anemia. If the patient is transfusion-dependent, careful evaluation of hepatic and cardiac function is warranted because of the potential for iron toxicity. When an anesthetic is selected, the likelihood of cardiomyopathy and hepatic dysfunction must be considered in addition to the effects of the anemia. Extramedullary hematopoiesis can produce hyperplasia of the facial bones and make direct laryngoscopic examination difficult.³⁰⁶ Extradural spinal cord compression and massive hemothorax from extramedullary hematopoiesis have been reported in patients with thalassemia.^{307,308}

COLLAGEN VASCULAR DISEASES

A number of diseases are classified as the collagen vascular or connective tissue diseases (Table 19-13). The four most common disorders of this group are rheumatoid arthritis, systemic lupus erythematosus (SLE), scleroderma, and polymyositis. Although many such patients can be categorized as having discrete disease syndromes, many others with collagen vascular diseases are considered to have overlap syndromes (also termed mixed connective tissue diseases) with features of different collagen vascular diseases, and cannot be conveniently classified. The etiology of the collagen vascular diseases is unknown, although current theories have implicated the immune system, with pathologic effects on small blood vessels. Although all of these diseases have localized features involving the joints, each has diffuse systemic effects as well. Both the localized and systemic alterations in these patients are significant in the management of anesthesia.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic inflammatory disease characterized by a symmetric polyarthropathy and significant systemic involvement. Many theories about the etiology of rheumatoid arthritis have been proposed, but none thoroughly explains all the aspects of rheumatoid arthritis. An inflammatory response with complex cell interactions produces destruction of synovial tissue. The initiator of this destructive process may be an antigen that initiates cellular and humoral responses in genetically susceptible individuals. The presence of rheumatoid factor (IgM) in 75% of patients with rheumatoid arthritis and the type of cellular response to inflammation certainly suggests an autoimmune process. However, the inability to identify a single etiology of rheumatoid arthritis suggests multiple etiologies for rheumatoid arthritis that may also include adrenal cortical dysfunction and infection.^{309,310} The pathologic changes of rheumatoid arthritis begin with cellular hyperplasia of the synovium, followed by invasion of the synovium by lymphocytes, plasma cells, and fibroblasts. Ultimately, the cartilage and articular surfaces are destroyed.

The hands and wrists are involved first, particularly the metacarpophalangeal and proximal interphalangeal joints. In the lower extremity the knee is involved most frequently. Compression of lower extremity peripheral nerves by the deformed knee can produce paresis and sensory loss over the lower leg. The upper cervical spine may be affected by the arthritic process in nearly 80% of patients with rheumatoid arthritis. Plain radiographs of the cervical spine demonstrate bony changes such as atlantoaxial subluxation and odontoid fracture.^{311,312} MRI, however, demonstrates the impact of these bony changes on the spinal cord. Spinal cord impingement may

be clearly demonstrated by cervical MRI. The degree of cord compression does not correlate well with the patient's symptoms, and asymptomatic patients may have a high degree of spinal canal stenosis (Fig. 19-4).³¹³ Although a very rare event, spinal cord damage after laryngoscopy and tracheal intubation has been reported.³¹⁴ Intradural spinal cord compression by a rheumatoid nodule has also been reported.³¹⁵ Rheumatoid arthritis commonly affects the joints of the larynx, resulting in limitation of vocal cord movement and generalized erythema and edema of the laryngeal mucosa that may progress to airway obstruction,^{316,317,318} and ³¹⁹ In addition to cervical spine and laryngeal changes, arthritic changes in the temporomandibular joint also occur. All of these abnormalities can seriously complicate laryngoscopy and tracheal intubation.

Figure 19-4. Magnetic resonance imaging of the cervical spine in a patient with rheumatoid arthritis. Although the patient had no neurologic symptoms, there is severe spinal stenosis in the upper cervical spine.

Extra-articular and systemic manifestations of rheumatoid arthritis are diverse (Table 19-14). Pericarditis occurs in nearly one third of patients with rheumatoid arthritis and can produce chronic constrictive pericarditis or pericardial tamponade.³²⁰ Although cardiac tamponade develops in only a small proportion of patients with rheumatoid arthritis, rheumatoid arthritis is more likely to produce tamponade than SLE. Ventricular dysfunction can result from myocarditis and coronary arteritis. Other cardiovascular effects of rheumatoid arthritis include dysrhythmias secondary to development of rheumatoid nodules in the cardiac conduction system, and aortitis, producing aortic root dilation and aortic insufficiency. Pulmonary changes are common and include pleural effusions, pulmonary nodules, interstitial lung disease, obstructive lung disease, and restrictive lung disease.³²¹ Several of the antirheumatic drugs cause pulmonary dysfunction as well. Renal failure is a common cause of death in patients with rheumatoid arthritis. There are several causes of renal dysfunction. Renal dysfunction may be secondary to vasculitis, amyloidosis, or drugs used to treat the disease such as analgesics and cyclosporine. There may also be a direct effect of the rheumatoid process that produces subclinical renal dysfunction that is subsequently aggravated by drugs and vasculitis.³²²

Table 19-14. EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Neurologic complications of rheumatoid arthritis include peripheral nerve compression (carpal tunnel syndrome) and cervical nerve root compression. Mononeuritis multiplex is presumed to be caused by deposition of immune complexes in blood vessels supplying the affected nerves. Rheumatoid vasculitis may also affect cerebral blood vessels, producing a cerebral necrotizing vasculitis.³²³

Mild anemia is present in almost all patients with rheumatoid arthritis. The anemia may be secondary to the rheumatoid process or may result from side effects of drug therapy. Felty's syndrome is the clinical complex of rheumatoid arthritis, leukopenia ($<2000 \text{ cells} \cdot \text{mL}^{-1}$), and hepatosplenomegaly.

A large number of drugs have been used for the treatment of rheumatoid arthritis. Analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin, ibuprofen, indomethacin, naproxen, piroxicam, sulindac, and tolmetin have been used extensively. Methotrexate has proved so highly successful as an antirheumatic drug that it is now considered to be a first-line drug. Other drugs known to alter the immune response include hydroxychloroquine, sulfasalazine, azathioprine, penicillamine, cyclosporine, and gold. Newer drugs aimed at modulating the immune response include drugs that inhibit tumor necrosis factor (TNF) (etanercept) and disrupt T-cell proliferation (leflunomide).^{324,325} Specific cyclo-oxygenase-2 (COX-2) inhibitors such as celecoxib and rofecoxib have anti-inflammatory and analgesic effects but produce fewer gastrointestinal side effects. Because of the adverse side effects produced by the long-term administration of steroids, treatment with corticosteroids is reserved for those patients who fail to respond to treatment with first- and second-line drugs.³²⁶ Many drugs used for the treatment of rheumatoid arthritis cause anemia, thrombocytopenia, and hepatitis (Table 19-15). Surgical procedures such as synovectomy, tenolysis, and joint replacement are performed to relieve pain and restore joint function.

| Drug | Effects |

Table 19-15. ADVERSE EFFECTS OF DRUGS USED TO TREAT COLLAGEN VASCULAR DISEASES

Management of Anesthesia

Because rheumatoid arthritis is a multisystem disease and the clinical manifestations are so diverse, individualized preoperative evaluation is important in the identification of systems that may be affected.³²⁷

The joint effects of rheumatoid arthritis, including arthritic changes in the temporomandibular joints, cricoarytenoid joints, and cervical spine can render rigid, direct laryngoscopy and tracheal intubation very difficult.³²⁸ The mobility of these joints should be evaluated before surgery so that a plan for tracheal intubation can be

formulated. Because atlantoaxial instability is relatively common, flexion of the neck may compress the spinal cord. Neck pain radiating to the occiput may be the first symptom of cervical spine involvement.³²⁹ Patients with rheumatoid arthritis with symptoms or evidence of cervical cord compression can be fitted with a soft cervical collar preoperatively to minimize the risk of overmanipulation of the neck during surgery.³³⁰ Many patients with rheumatoid arthritis, however, are asymptomatic. Preoperative imaging of the cervical spine (radiography, MRI) may be indicated if the degree of cervical involvement is not known.³³¹ It is not clear whether routine cervical spine radiography is indicated for elective surgical procedures.³³² Although there have been no documented reports of spinal cord damage in patients with rheumatoid arthritis undergoing tracheal intubation for elective surgery, alleged neurologic damage after laryngoscopy has been the source of litigation against anesthesiologists. Consequently, it is important that any preoperative evidence of neurologic dysfunction be documented before surgery. To minimize the risk of neurologic damage during tracheal intubation, awake fiberoptic laryngoscopy may be the best means of performing tracheal intubation in patients with significant rheumatoid arthritis of the cervical spine. Because many patients with rheumatoid arthritis undergo repeated anesthetics, it is quite helpful if the technique of airway management is clearly documented in the patient's medical record. However, progression of the rheumatoid process may alter joint function to the extent that neck motion may diminish with time and render a previously successful intubation technique useless. Cricoarytenoid arthritis may be recognized by erythema and edema of the vocal cords. Involvement of the cricoarytenoid joints reduces the size of the glottic inlet and necessitates the use of a smaller than predicted tracheal tube. Exaggerated postextubation edema and stridor may also occur.

The degree of cardiopulmonary involvement by the rheumatoid process influences the selection of the type of anesthesia. Functional evaluation of the lungs and heart is necessary if the clinical history suggests dysfunction. It may be difficult to determine if the dysfunction is secondary to rheumatoid arthritis or to more common causes of cardiopulmonary disease such as arteriosclerosis or smoking. The need for postoperative ventilatory support should be anticipated if severe pulmonary disease is present.

Medications that the patient is receiving influence the management of anesthesia. Corticosteroid supplementation may be necessary during the perioperative period. Aspirin and other anti-inflammatory drugs interfere with platelet function, and clotting may be abnormal. Many rheumatoid medications suppress red blood cell formation and anemia is common. Drug-induced hepatic dysfunction may be present, which can influence the choice of anesthesia.

Restriction of joint mobility necessitates careful positioning of the patient during the operation. The extremities should be positioned to minimize the risk of neurovascular compression and additional joint injury. Preoperative evaluation of joint motion helps determine how the extremities should be positioned.

Rheumatoid arthritis is a multisystem disease. The potential joint disabilities have been well documented in the medical literature and are often obvious. More significant and less evident are the effects on the spinal cord, heart, lungs, kidneys, and liver. The type and severity of systemic dysfunction must be considered when planning an anesthetic for the patient with rheumatoid arthritis.³³⁰

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease with diverse clinical and immunologic manifestations. The precise etiology of SLE is unknown, but appears to be a complex interaction between genetic susceptibility and hormonal and environmental factors.³³³ Patients with SLE produce autoantibodies primarily to DNA but also to RNA polymerase, cardiolipin, and ribosomal phosphoproteins.³³⁴ Some of the clinical manifestations of SLE may be a result of the production of an autoantibody highly specific for a single protein within an organ.³³⁵

The clinical manifestations of SLE are very diverse. The most common presenting features of SLE are polyarthritis and dermatitis. The arthritis is oligoarticular and migratory. The classic malar rash is present in only one third of SLE patients. Renal disease is a common cause of morbidity and mortality in patients with SLE. Proteinuria, hypertension, and decreased creatinine clearance are the usual manifestations of SLE nephritis. Of patients with SLE, 10–20% develop end-stage renal disease and require dialysis or transplantation. Recurrent nephritis in the grafted kidney reduces the success of renal transplant in SLE patients.^{336,337} Central nervous system involvement occurs in up to 50% of patients with SLE and is a result of vascular abnormalities. Central nervous system manifestations include seizures, stroke, dementia, psychosis, and peripheral neuropathy.³³⁸ The cranial MRI is an excellent diagnostic technique for SLE brain lesions and may also demonstrate the effects of therapy.³³⁹

Systemic lupus erythematosus produces a diffuse serositis that manifests as pleuritis and pericarditis. Although 60% of SLE patients have a pericardial effusion, cardiac tamponade is uncommon. Cardiac tamponade may, however, be the presenting symptom of SLE.^{340,341} and ³⁴² Cardiomyopathy, cardiac conduction abnormalities, reduced ventricular function, and coronary arteritis can occur in patients with SLE.³⁴³ A noninfectious endocarditis (Libman-Sacks endocarditis) often affects mitral valve function and can produce mitral insufficiency. Effective treatment of SLE has improved patient survival, but has increased the likelihood of ischemic heart disease. Pulmonary effects of SLE include pleural effusion, pneumonitis, pulmonary hypertension, and alveolar hemorrhage.^{344,345} There is a high correlation of pulmonary hypertension with Raynaud's phenomenon in patients with SLE.³⁴⁶ Patients with SLE are susceptible to infection, which may present as pneumonitis or adult respiratory distress syndrome. Pulmonary function studies in patients with SLE demonstrate a restrictive lung disease pattern and a decreased diffusion capacity.³⁴⁷ Patients with SLE may have cricoarytenoid arthritis that can manifest as hoarseness, stridor, or airway obstruction.^{348,349} and ³⁵⁰

Nearly one third of patients with SLE have detectable anti-phospholipid antibodies and may have thromboembolic complications. Other potentially serious manifestations of SLE include peritonitis, pancreatitis, bowel ischemia, protein-losing enteropathy, and lupoid hepatitis.³⁵¹

There is no specific etiologic therapy for SLE. Despite the diverse effects of SLE and the lack of specific therapy, current regimens have improved survival.³⁵² Most therapy for SLE is directed at altering T- and B-cell activity with immunosuppressants (corticosteroids) or cytotoxic drugs (cyclophosphamide, azathioprine, cyclosporine). Bone marrow transplantation for the treatment of SLE is under investigation.³⁵³ Nonsteroidal anti-inflammatory drugs (NSAIDs) are the first line treatment for arthritis; however, these drugs can cause renal dysfunction. The antimalarials, hydroxychloroquine and chloroquine, are administered for the treatment of arthritis if treatment with NSAIDs is unsatisfactory. The antimalarials may alter lysosome function and interfere with the induction of autoimmunity.³⁵⁴ An individual patient's therapy will depend upon the severity of the disease and the specific organ system affected. Therapeutic regimens for SLE change frequently and continue to develop.³⁵⁵ The potential for side effects from any of the drugs used for the treatment of SLE is significant and treatment can result in morbidity.³⁵⁶

Drug-induced lupus may be caused by procainamide, quinidine, hydralazine, methyldopa, captopril, enalapril, clonidine, isoniazid, or minocycline. Drug-induced lupus may be caused by reactive drug metabolites and autoreactive T cells.³⁵⁷ The clinical manifestations of drug-induced lupus are generally mild and include arthralgia, fever, anemia, and leukopenia. These effects typically resolve within 4 weeks of discontinuation of the drug, although some patients have significant morbidity.³⁵⁸

Management of Anesthesia

Careful preoperative evaluation of the patient with SLE is necessary because of the diverse systemic effects of the disease. Signs and symptoms of cardiopulmonary dysfunction must be recognized preoperatively.³⁵⁹ Preoperative chest radiography, echocardiography, or pulmonary function testing may be necessary if the clinical history suggests dysfunction. Anesthesia management is influenced not only by the degree of organ dysfunction, but also by the drugs used to treat SLE. Although there are no specific contraindications to a particular type of anesthetic, myocardial dysfunction will certainly influence the choice of anesthetic agents and types of intraoperative monitors. It has been demonstrated that patients with SLE are at risk for postoperative infections and pulmonary complications.³⁶⁰ Because renal dysfunction is so common in patients with SLE, renal function should be quantified preoperatively if there is any suggestion of a recent change in renal function. Although minor abnormalities in liver function are present in many patients with SLE, these changes are not usually significant. However, a fatal lupoid hepatitis, characterized by prolonged jaundice, hyperglobulinemia, and hepatosplenomegaly, develops in some patients.

Arthritic involvement of the cervical spine is unusual in patients with SLE. Consequently, tracheal intubation is not usually difficult. However, the potential for laryngeal involvement and upper airway obstruction requires clinical evaluation of laryngeal function.³⁶¹ Should postextubation laryngeal edema or stridor occur, the intravenous administration of corticosteroids is effective for alleviation of symptoms.

Drugs administered to the patient for treatment of SLE may also influence the management of anesthesia. Patients receiving corticosteroids may require intraoperative administration of corticosteroids. Cyclophosphamide inhibits plasma cholinesterase and may produce a prolonged response to succinylcholine or mivacurium.

Scleroderma

Scleroderma (systemic sclerosis) is an autoimmune collagen vascular disease affecting the skin, joints, and visceral organs. Vascular endothelium is damaged by autoantibodies to endothelial cells or immune mediators, resulting in increased vascular permeability, leakage of serum proteins, lymphatic obstruction, and ultimately tissue fibrosis. The fibrotic process is accelerated by an increase in collagen production.^{362,363} This widespread reactivity explains the diverse clinical manifestations of scleroderma. The manifestations are observed most readily in the skin, which becomes thickened and swollen. Eventually, the skin becomes atrophic and small arteries are obliterated. The skin becomes fibrotic and taut and produces severe restriction of joint mobility. Raynaud's phenomenon is the presenting feature of 70% of

patients with scleroderma. Vasospasm occurs in blood vessels that are already narrowed by intimal proliferation and fibrosis.³⁶⁴

The same pathologic process that affects the vascular system in the skin affects small blood vessels in other organs as well. Lung involvement occurs in 80% of patients with scleroderma and is characterized by interstitial fibrosis, pulmonary hypertension, and an impaired diffusing capacity.³⁶⁵ These changes, in conjunction with the effects of chronic aspiration pneumonitis, produce a restrictive lung disease. Treatment of the pulmonary effects of scleroderma include supplemental oxygen, vasodilators, captopril, and immunosuppressants.³⁶⁶ Myocardial fibrosis occurs in 70–80% of patients with scleroderma, although only 25% have clinical symptoms. Patients with clinical cardiac symptoms have a very poor prognosis.^{367,368} Degeneration of contractile myocardium and conducting tissue results in decreased contractility and cardiac dysrhythmias.³⁶⁹ The administration of nifedipine to patients with myocardial involvement from scleroderma may improve myocardial perfusion and performance. Pericarditis with effusion is very common in patients with scleroderma.³⁷⁰

Renal dysfunction is relatively common in patients with scleroderma. This dysfunction is secondary to pathologic changes in the renal vasculature similar to the changes in the digital arteries that produce Raynaud's phenomenon. Renal dysfunction can be so severe that a scleroderma renal crisis develops with hypertension, retinopathy, and a rapid deterioration in renal function.

Gastrointestinal motility is decreased and is very pronounced in the esophagus. The frequent episodes of gastroesophageal reflux and aspiration pneumonitis exacerbate pulmonary dysfunction.³⁷¹ Cimetidine is very effective for the treatment of epigastric pain secondary to hyperacidity. Although metoclopramide increases esophageal motility, the high incidence of side effects from metoclopramide limits its usefulness for chronic administration. Involvement of the colon and small intestine may result in pseudo-obstruction.³⁷²

Currently, therapy for scleroderma is limited to the relief of specific organ dysfunction, generalized immunosuppression (cyclophosphamide, cyclosporine, prednisone), and decreasing collagen production (penicillamine, interferon). Although the administration of these drugs may produce some improvement, it also introduces the risk of significant side effects.

Management of Anesthesia

Scleroderma, like other collagen vascular diseases, is a multiorgan disease with many systemic manifestations. Consequently, the altered organ systems must be thoroughly evaluated so that a logical plan for anesthesia can be selected. There are no specific contraindications to the use of any type of anesthesia, although the selection must be guided by the degree of organ dysfunction.

Tracheal intubation can be quite difficult.³⁷³ Fibrotic and taut facial skin can markedly hinder active and passive mouth opening and severely restrict mobility of the temporomandibular joints. Awake flexible fiberoptic laryngoscopy and tracheal intubation may be required; tracheostomy may be necessary in severely affected patients.³⁷⁴ Orotracheal intubation is preferable to nasotracheal intubation because of the fragility of the nasal mucosa and the propensity for severe nasal hemorrhage.

The patient with scleroderma is at risk for aspiration pneumonitis during the induction of anesthesia owing to the high incidence of gastroesophageal reflux. Appropriate measures to minimize the risk of acid aspiration, such as the use of histamine-2 blockers and oral antacids, may be indicated.

Chronic arterial hypoxemia is often present because of restriction of lung expansion and impaired oxygen diffusion. Consequently, controlled mechanical ventilation with an increased inspired oxygen concentration is usually necessary. Compromised myocardial function and decreased coronary vascular reserve often necessitate the use of invasive cardiovascular monitoring because the response to inhaled anesthetics may be exaggerated. Venous access can be difficult and a venous cutdown or central venous catheterization may be necessary. Muscle involvement may increase the sensitivity to muscle relaxants and short-acting neuromuscular blockers should be used.

Regional anesthesia may be administered to patients with scleroderma, although there are reports of prolonged responses to local anesthetics.^{376,377} The anesthesiologist is often consulted as to the efficacy of sympathetic blockade for the treatment of vasospasm secondary to Raynaud's phenomenon. Stellate ganglion block may, however, produce deleterious effects on contralateral blood flow in patients with scleroderma.³⁷⁸ Long-term intrathecal pain management can be helpful for intractable ischemic limb pain.³⁷⁹

Polymyositis/Dermatomyositis

Polymyositis is a noninfectious inflammatory myopathy affecting skeletal muscle. Dermatomyositis is a type of inflammatory myopathy associated with a characteristic skin rash. The other type of inflammatory myopathy is inclusion body myopathy. Pathologically, the myopathic processes in these three diseases are different. Polymyositis is a cell-mediated immune response against muscle fibers. Cytotoxic T cells enter muscle cells and destroy the muscle fiber. Muscle from patients with polymyositis reveals inflammation and fatty replacement. In dermatomyositis, a complement-mediated reaction attacks and destroys endomysial capillaries, resulting in muscle ischemia and muscle cell death.³⁸⁰

Common presenting symptoms of polymyositis are muscle pain, tenderness, and proximal muscle weakness. Patients with dermatomyositis have a skin rash characterized by a purplish discoloration of the eyelids (heliotrope rash), periorbital edema, erythematous lesions on the knuckles, and a sun-sensitive erythematous rash on the face, neck, and chest.³⁸¹ Although the pathogenic processes of polymyositis and dermatomyositis are different, the changes in the lungs and heart produced by these two diseases are similar. Of patients with polymyositis or dermatomyositis, 50% have evidence of pulmonary disease, including interstitial lung disease, bronchopneumonia, and alveolitis. Aspiration pneumonitis is one of the most common complications of polymyositis and undoubtedly contributes to the pathologic changes in the lungs.³⁸² These changes produce a restrictive lung disease pattern and decreased diffusing capacity.^{383,384} Myocardial fibrosis can result in congestive heart failure and cardiac dysrhythmias.^{385,386 and 387}

The most effective treatment for polymyositis and dermatomyositis is the administration of corticosteroids. Patients that do not respond to corticosteroids are treated with immunosuppressants such as methotrexate, azathioprine, cyclosporine, or chlorambucil. Antimalarials may be effective for treatment of the skin rash associated with dermatomyositis.^{388,389} Immunoglobulin therapy and total body irradiation have been recommended for patients resistant to other forms of therapy.

Management of Anesthesia

Mobility of the temporomandibular joints and cervical spine is usually adequate in patients with polymyositis. However, some patients have restricted mobility that can make direct laryngoscopy difficult. Adequate mouth and neck mobility must be ascertained before induction of anesthesia. Awake flexible fiberoptic laryngoscopy and tracheal intubation may be required for those patients with restricted neck mobility and inadequate mouth opening.

Dysphagia and gastroesophageal reflux are very common and there is an increased likelihood of aspiration pneumonitis.³⁹⁰ Appropriate precautions to avoid aspiration of gastric contents should be taken during the perioperative period. Gastrointestinal perforations, which necessitate surgery, are relatively common in patients with polymyositis.³⁹¹

Although the typical electromyographic changes of polymyositis suggest the potential for hyperkalemia after succinylcholine, succinylcholine has been administered to patients with polymyositis without complication.³⁹² Prolonged neuromuscular blockade has been reported after the administration of vecuronium in a patient with polymyositis.³⁹³ This prolonged response may be secondary to the myopathy or an interaction between the nondepolarizing muscle relaxant and immunosuppressants.³⁹⁴ The reported experience with anesthesia for patients with polymyositis and dermatomyositis is very limited, and generalizations from a few case reports must be interpreted with caution. It should be anticipated that considerable individual variation in response to muscle relaxants will occur. It would seem prudent to avoid the administration of succinylcholine if possible, and to use shorter-acting muscle relaxants such as mivacurium or rapacuronium. Because of the preoperative muscle weakness, postoperative ventilatory support may be necessary.

The degree of cardiopulmonary dysfunction influences the choice of anesthesia and selection of intraoperative monitors. Further preoperative evaluation of cardiopulmonary function may be required if the clinical history suggests a deterioration in cardiac or pulmonary function.

SKIN DISORDERS

Most primary diseases of the skin are localized and cause few systemic effects or complications during the administration of anesthesia. Two skin disorders, however, can result in complications during anesthesia—the blistering diseases, epidermolysis bullosa and pemphigus.

Epidermolysis Bullosa

Epidermolysis bullosa is a rare skin disorder that may be inherited or acquired. Patients with heritable forms have an abnormal collagen that is insufficient in anchoring different skin layers together.³⁹⁵ The acquired forms are autoimmune disorders in which autoantibodies are produced that destroy the basement membrane of the skin and mucosa.³⁹⁶ Regardless of the etiology, the end result is the loss or absence of normal intercellular bridges and separation of skin layers (Fig. 19-5). The separation of the skin layers results in intradermal fluid accumulation and bullae formation. Even minor skin trauma produces skin blisters. Lateral shearing forces applied to the skin are especially damaging because of skin separation. Pressure applied perpendicular to the surface of the skin is not as hazardous.

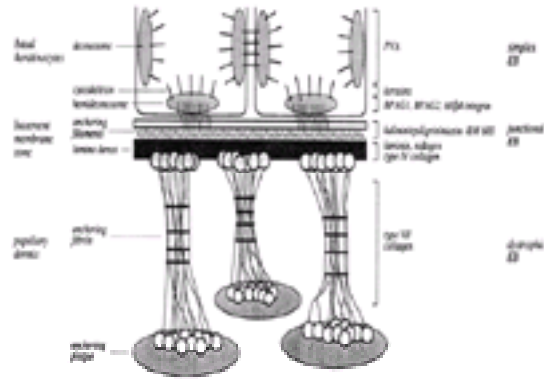

Figure 19-5. The ultrastructure of the zones of the skin. The diagram demonstrates where skin separation occurs in the different types of epidermolysis bullosa. (Reproduced with permission from Uitto J, Christiano AM: Molecular genetics of the cutaneous basement membrane zone. *J Clin Invest* 90:687, 1992; copyright of the American Society for Clinical Investigation.)

Although there are 25 subtypes of epidermolysis bullosa, these disorders can be conveniently categorized into three groups depending on where the actual skin separation occurs: epidermolytic (epidermolysis simplex), junctional, and dermolytic (epidermolysis bullosa dystrophica).³⁹⁷ Although serious complications from skin and mucosal loss can occur with any form of epidermolysis, the simplex form is generally benign. Patients with the junctional form rarely survive beyond early childhood. Laryngeal involvement is unusual, but is most likely to occur with the junctional type.^{398,399}

Epidermolysis bullosa dystrophica produces severe scarring of the fingers and toes, with pseudosyndactyly formation and underlying bone deformities such as ankylosis of the interphalangeal joints and resorption of the metacarpals and metatarsals (Fig. 19-6). Involvement of the esophageal mucosa is present in most patients, resulting in dysphagia and esophageal strictures that contribute to poor nutrition.⁴⁰⁰ Anemia and hypoalbuminemia from chronic infection and malnutrition are common. Secondary infection of bullae with *Staphylococcus aureus* or β -hemolytic streptococci is common. Severe anemia and cardiomyopathy develop as a result of malnutrition.^{401,402} Mitral valve prolapse has also been reported in patients with epidermolysis bullosa.⁴⁰³

Figure 19-6. Epidermolysis bullosa. (A) Bullous lesion of the finger of a neonate with epidermolysis. (B) Hands of an older child with epidermolysis showing progression to produce severe scarring and pseudosyndactyly. (Courtesy of James E. Bennett, M.D., Division of Plastic Surgery, Indiana University School of Medicine, Indianapolis, IN.)

Glomerulonephritis may be secondary to streptococcal infection. Albumin loss secondary to nephritis, in combination with albumin loss into bullous skin lesions, can produce hypovolemia that further impairs renal function.⁴⁰⁴ In addition to chronic skin infection, there is an increased propensity to neoplastic degeneration. Hypoplasia of tooth enamel results in carious degeneration of the teeth and the need for extensive dental restorations. Other diseases associated with epidermolysis bullosa include porphyria cutanea tarda, amyloidosis, multiple myeloma, diabetes mellitus, and hypercoagulation. Patients with epidermolysis bullosa rarely survive beyond the third decade of life.

Medical therapy for epidermolysis bullosa has not been very successful. Corticosteroids have been used without much benefit. Phenytoin, which inhibits collagenase, may produce a favorable response in some patients, but long-term studies have not been encouraging.⁴⁰⁵ Surgical therapy is directed at preserving and improving hand function.

Management of Anesthesia

It is critical that trauma to the skin and mucous membranes be avoided or minimized in patients with epidermolysis bullosa. Trauma from adhesive tape, blood pressure cuffs, tourniquets, and adhesive ECG electrodes can cause bullae formation.⁴⁰⁶ The blood pressure cuff must be padded with a loose cotton dressing. Intravascular catheters should be anchored with sutures or a gauze dressing rather than adhesive tape. Trauma from a face mask may be reduced by gentle application against the skin. Lubrication of the mask and the patient's face can be quite helpful for reducing trauma. Use of upper airway instruments, including oropharyngeal and nasopharyngeal airways, should be kept to a minimum because squamous epithelium lining the oropharynx and esophagus is susceptible to bullous formation. Frictional trauma to the oropharynx may result in formation of large intraoral bullae, airway obstruction, and extensive hemorrhage from denuded mucosa.^{407,408}

Laryngeal involvement in patients with epidermolysis bullosa is extremely rare. However, when tracheal intubation is performed, the laryngoscope and tracheal tube should be well lubricated to reduce friction against the oropharyngeal mucosa.⁴⁰⁹ Scarring of the oral cavity can produce microstomia and immobility of the tongue, which increases the difficulty of tracheal intubation.^{410,411} Flexible, fiberoptic laryngoscopy may be required.⁴¹² Insertion of an esophageal stethoscope should be avoided because it may lead to the formation of intraoral and esophageal bullae. Although the safety of tracheal intubation has been established for patients with the dystrophic form of epidermolysis bullosa, it has not yet been established for infants with the junctional form. The junctional form affects all mucosa, including the respiratory epithelium.⁴¹³ However, the types of surgical procedures (intra-abdominal) required in infants with the junctional form, usually mandate tracheal intubation.

Surgical procedures for patients with epidermolysis bullosa are usually peripheral and involve the hands. Ketamine is very useful for anesthesia for such superficial procedures because it provides good analgesia and usually does not require supplemental inhalation anesthesia. There are, however, no contraindications to inhalation anesthesia. Regional anesthesia, including spinal, epidural, and brachial plexus anesthesia, has been used successfully for patients with epidermolysis bullosa.^{414,415}

Porphyria cutanea tarda, often associated with epidermolysis bullosa, does not have the same implications for anesthesia as acute intermittent porphyria.

Despite all the potential complications with anesthesia for patients with epidermolysis bullosa, appropriate intraoperative management is associated with surprisingly few complications.⁴¹⁶

Pemphigus

Pemphigus is a vesiculobullous disease that may involve extensive areas of the skin and mucous membranes. Pemphigus is an autoimmune disease, as evidenced by the finding that patients with pemphigus have circulating antibodies that bind to the surface of epithelial cells. These autoantibodies are highly specific and result in the excessive production of proteolytic enzymes that disrupt cell adhesion, leading to separation of epithelial layers. Drugs such as penicillamine, captopril, phenobarbital, piroxicam, propranolol, levodopa, and cephalosporins can cause a drug-induced pemphigus.⁴¹⁷

There are several types of pemphigus including pemphigus vulgaris, pemphigus foliaceus, pemphigus vegetans, pemphigus erythematosus, and paraneoplastic pemphigus. Pemphigus vulgaris is the most common type and the most clinically significant for the anesthesiologist because of the occurrence of oral lesions. Oral lesions occur in 50–70% of patients with pemphigus vulgaris and usually precede the onset of skin lesions. Lesions of the pharynx, larynx, esophagus, conjunctiva, urethra, cervix, and anus can develop.⁴¹⁸ Extensive oropharyngeal lesions may make eating painful to the extent that malnutrition occurs. Skin denudation and bullae formation can result in significant fluid and protein losses and the risk of secondary bacterial infection is great. As with epidermolysis bullosa, lateral shearing forces are more likely to produce bullae than pressure exerted perpendicular to the skin surface. Treatment with corticosteroids and immunosuppressants is highly effective. The administration of immunosuppressants such as azathioprine, cyclophosphamide, methotrexate, and mycophenolate reduces the risk of steroid-induced side effects.⁴¹⁹

Paraneoplastic pemphigus is an autoimmune disease associated with a number of malignant tumors, especially lymphomas and leukemias. IgG autoantibodies are produced that react with desmosomal proteins. Some patients with paraneoplastic pemphigus develop fatal bronchiolitis obliterans and respiratory failure.^{420,421}

Pemphigus foliaceus (superficial pemphigus) is a less severe form of pemphigus in which skin separation occurs near the epidermal surface; the oral mucosa is not affected. Pemphigus foliaceus can be fatal if untreated. Pemphigus vegetans is histologically similar to pemphigus vulgaris and involves the axillae, groin, skin flexures, and the oral cavity. Pemphigus erythematosus (Senechal-Usher syndrome) is a superficial form of pemphigus with erythematous hyperkeratotic lesions over the nose and malar areas; the oral cavity is not involved.

Management of Anesthesia

Preoperative drug therapy and the extreme fragility of the mucous membranes are the primary concerns for the management of anesthesia in patients with pemphigus. Corticosteroid supplementation will be necessary during the preoperative period. Management of the upper airway and tracheal intubation should be performed as described for patients with epidermolysis bullosa. Ketamine and regional anesthesia have been used successfully for patients with pemphigus.^{422,423 and 424}

There are no specific contraindications to the use of any inhaled or intravenous anesthetic; however, potential side effects of treatment drugs and interactions with anesthetics must be considered. For example, methotrexate produces hepatorenal dysfunction and bone marrow suppression, and cyclophosphamide may prolong the effect of succinylcholine and mivacurium by inhibiting cholinesterase activity.

As a result of physiologic, metabolic, or anatomic changes, many inherited disorders have significant implications for anesthetic management. In this chapter we discuss the inherited disorders whose manifestations are enhanced or instigated by drugs usually used by anesthesiologists. In some cases, such as the porphyrias, the manifestations may be induced by agents other than anesthetics. In other enzymatic disorders, such as pseudocholinesterase abnormalities, it would be extremely unlikely for a patient to have any problems until he or she is exposed to the depolarizing neuromuscular blocking agent succinylcholine. Malignant hyperthermia (MH) or malignant hyperpyrexia is perhaps the most significant inherited disorder triggered by exposure to anesthetic drugs.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia was first formally described in 1960 in *Lancet*¹ by Denborough and Lovell and subsequently in *The British Journal of Anaesthesia*.² That first case report laid the foundation for much of our understanding of the clinical presentations of MH. The patient was a young man who claimed that several of his relatives had died without apparent cause during anesthesia. He was anesthetized with halothane and developed tachycardia, hot sweaty skin, peripheral mottling, and cyanosis. Early recognition and symptomatic treatment saved the patient. It therefore became apparent that this new syndrome had the following elements: patients were otherwise healthy unless exposed to an anesthetic agent; temperature elevation was a hallmark; a heritable or genetic component was present; and a high mortality rate was likely. In addition, with early recognition and treatment it was possible to abort the malignant effects of the syndrome.

In the 1960s other cases of MH were reported in increasing numbers, and a gene pool for MH was established in certain parts of the world. In addition, the association between porcine stress syndrome (PSS) or "pale soft exudative pork syndrome" and MH was described, thus providing an animal model for MH.³ Porcine breeds such as the Landrace, Poland China, and Pietrain show the classic presentations of MH on induction of anesthesia with potent inhalation agents and succinylcholine. During the 1970s, many more clinical presentations of MH were reported. The development of an *in vitro* diagnostic test was suggested by Kalow *et al* based on exposure of a skeletal muscle biopsy specimen to caffeine and then halothane.⁴ In 1975, Harrison reported that dantrolene could be effective in treating and preventing MH in pigs.⁵ By 1979, a sufficient number of cases were described showing that intravenous dantrolene could successfully reverse the human form of MH, and the drug was approved for use by the Food and Drug Administration (FDA). During that decade, studies of the pathophysiology of MH were also performed. By the late 1970s, it was apparent that MH most likely resulted from metabolic alterations in skeletal muscle. In the 1980s, lay organizations in the U.S., Canada, and Great Britain were formed to disseminate information to patients affected by MH as well as to enhance awareness of the syndrome among physicians. The manifestations of MH and its association with other muscle disorders were studied. Application of the muscle biopsy diagnostic halothane–caffeine contraction test was standardized and a registry for MH was created in the U.S. in the late 1980s. In addition, a variety of other tests for diagnosing MH were introduced, many of which subsequently were found to be of little or no validity.

A major step forward occurred in 1985, when the Lopez group directly demonstrated an increased intracellular concentration of calcium ion in muscle from MH-susceptible pigs and humans.⁶ The intracellular calcium concentration dramatically increased during an MH crisis and was reversed by the administration of dantrolene.

In the 1990s sophisticated molecular biologic techniques were first applied to identify the genes associated with MH susceptibility. It is anticipated that better understanding of the genetic substrate of the pathophysiology of MH will result in a less invasive diagnostic test than the contracture tests used at present. In the 1990s epidemiologic information helped to differentiate MH from other life-threatening anesthetic complications. It was appreciated that some deaths in children formerly attributed to MH were really the result of destruction of muscle cells that occurred during anesthesia with volatile agents and succinylcholine in patients with unrecognized myopathies.⁷

Clinical Presentations

As our knowledge of MH has grown, the definition of MH has changed. At first MH was thought in all cases to be a heritable syndrome consisting of an extremely elevated body temperature, skeletal muscle rigidity, and acidosis associated with a high mortality rate. However, we have now begun to concentrate on the definition of MH in terms of its underlying pathophysiologic characteristics. MH is a hypermetabolic disorder of skeletal muscle with varied presentations, depending on species, breed, and triggering agents. An important pathophysiologic process in this disorder is intracellular hypercalcemia. Intracellular hypercalcemia activates metabolic pathways that, if untreated, result in adenosine triphosphate depletion, acidosis, membrane destruction, and cell death. Although a heritable component is present in many cases, it is not invariably apparent from patient family history. In addition, disorders that may have symptoms and signs similar to those of MH, such as neuroleptic malignant syndrome, may not have an inherited basis.

Classic Malignant Hyperthermia

Malignant hyperthermia may present in several ways. In almost all cases, the first manifestations of the syndrome occur in the operating room. However, MH also may occur in the recovery room or (rarely) even on return to the patient floor. In the classic case, the initial signs of tachycardia and tachypnea result from sympathetic nervous system stimulation secondary to underlying hypermetabolism and hypercarbia. Because most patients who receive general anesthesia are paralyzed, tachypnea usually is not recognized. Shortly after the increase in heart rate, an increase in blood pressure occurs, often associated with ventricular dysrhythmias induced by sympathetic nervous system stimulation from hypercarbia or caused by hyperkalemia or catecholamine release. Thereafter, muscle rigidity or increase in muscle tone may become apparent. Increase in body temperature, climbing at a rate of 1–2°C every 5 minutes follows. With the increase in metabolism, the patient may "break through" the neuromuscular blockade. At the same time, the CO₂ absorbent becomes activated and warm to the touch (because the reaction with CO₂ is exothermic). The patient will display peripheral mottling and, on occasion, sweating and cyanosis. Blood gas analysis usually reveals hypercarbia and respiratory and metabolic acidosis without marked oxygen desaturation. Elevation of end-tidal CO₂ is one of the earliest signs of MH. On the other hand, vigorous hyperventilation may mask such hypercarbia and delay the diagnosis.⁸ A mixed venous sample will show even more dramatic evidence of CO₂ retention and metabolic acidosis.⁹

Hyperkalemia, hypercalcemia, lactacidemia, and myoglobinuria are characteristic. Increase in creatine kinase (CK) levels is dramatic, often exceeding 20,000 units in the first 12–24 hours. Death results unless the syndrome is promptly treated. Even with treatment and survival, the patient is at risk for life-threatening myoglobinuric renal failure and disseminated intravascular coagulation. Another significant clinical problem is recrudescence of the syndrome within the first 24–36 hours.¹⁰

If succinylcholine is used during induction of anesthesia, an acceleration of the manifestations of MH may occur such that tachycardia, hypertension, marked temperature elevation, and dysrhythmias are seen over the course of 5–10 minutes. However, it is important to note that a completely normal response to succinylcholine may be present in some MH-susceptible patients. A potent inhalation agent apparently is necessary to trigger the syndrome in these cases.

Review of case reports of MH suggests that the syndrome becomes apparent most frequently shortly after anesthesia induction, particularly when succinylcholine is used, and at the end of the procedure as the patient is emerging from anesthesia.

Masseter Muscle Rigidity

Rigidity of the jaw muscles after administration of succinylcholine is referred to as *masseter muscle rigidity* (MMR) or *masseter spasm*. The association of this phenomenon with MH was underlined by many case reports of MMR preceding MH.^{11,12} Although MMR probably occurs in patients of all ages, it is distinctly most common in children and young adults. Several studies have shown a peak age incidence at 8–12 years of age. Characteristically, anesthesia is induced by inhalation with halothane or sevoflurane, after which succinylcholine is administered. Snapping of the jaw or rigidity on opening of the jaw is seen. However, this rigidity can be overcome with effort and usually abates within 2–3 minutes. A peripheral nerve stimulator usually reveals flaccid paralysis. However, increased tone of other muscles also may be noted. Repeat doses of succinylcholine do not relieve the problem. Tachycardia and dysrhythmias are not infrequent. Only in rare cases does frank MH supervene immediately after MMR. More commonly (if the anesthetic is continued with a triggering agent), the initial signs of MH appear in 20 minutes or more. If the anesthetic is discontinued, the patient usually recovers uneventfully. However, within 4–12 hours, myoglobinuria occurs and CK elevation is detected.

Muscle biopsy with caffeine–halothane contracture testing has shown that approximately 50% of patients who experience MMR are also susceptible to MH.^{13,14} Therefore, most authorities recommend that anesthesia (if elective in nature) be discontinued and surgery postponed after an episode of MMR. With the introduction of end-tidal CO₂ monitoring, the availability of dantrolene, and enhanced understanding of MH, some have questioned the advice that all anesthetics must be discontinued after MMR. Instead, they recommend continuation with nontriggering anesthetics and the use of end-tidal CO₂ monitoring. The issue of whether to give dantrolene after an episode of MMR is also unresolved. Dantrolene is most useful only when there is a clear diagnosis of MH. When MMR is accompanied by rigidity of chest or limb, MH is more likely to follow than after isolated jaw rigidity.^{15,16}

The differential diagnosis of MMR consists of the following: (1) myotonic syndrome, (2) temporomandibular joint dysfunction, (3) underdosing with succinylcholine, (4) not allowing sufficient time for succinylcholine to act before intubation, (5) increased resting tension after succinylcholine in the presence of fever or elevated plasma epinephrine. A variety of reports have shown that succinylcholine increases jaw muscle tone in patients with normal muscle.¹⁷ This normal agonistic effect of succinylcholine, further increased by temperature¹⁸ and epinephrine in the presence of halothane, may account for some cases of MMR. The pathophysiology of jaw muscle tone increase is unknown. One reason for the high incidence of positive biopsy results and the low incidence of clinical MH after MMR may relate to selection of patients with marked muscle rigidity for biopsy. Such patients may be at greater risk for MH.¹⁴

Signs of temporomandibular dysfunction as well as myotonia should be sought following the MMR episode. If rigidity precluding laryngoscopy occurred without temporomandibular joint dysfunction, the patient should be evaluated by a neurologist for the presence of occult myopathy and counseled regarding the need for a muscle biopsy and diagnostic contracture test to evaluate MH susceptibility. It is incumbent upon the anesthesiologist to alert the patient to the possibility that MH may follow in subsequent procedures.

The incidence of MMR is debatable. This sign may occur in as many as 1 in 100 children anesthetized with halothane and given succinylcholine.¹⁹ A retrospective study based on the information supplied to the Danish Malignant Hyperthermia Registry found that the incidence of MMR was 1 in 12,000 (including adults and children).²⁰ A prospective study found MMR in 1 of 500 children who received halothane followed by intravenous succinylcholine.²¹

Our advice regarding MMR is as follows:

1. When it occurs, the anesthesiologist should, if at all possible, discontinue the anesthetic and postpone surgery. If end-tidal CO₂ monitoring and dantrolene are available and the anesthesiologist is experienced in managing MH, he or she may elect to continue with a nontriggering anesthetic.
2. After episodes of MMR, the patient should be observed carefully for a period of 12–24 hours for myoglobinuria and signs of MH. Administration of 1–2 mg · kg⁻¹ of dantrolene should be considered.
3. The family should be informed of the episode of MMR and its implications.
4. Creatine kinase levels should be checked 6, 12, and 24 hours after the episode. If the CK level is still grossly elevated at 12 hours, additional samples should be drawn until it begins to return to normal.
5. If the CK level is greater than 20,000 IU in the perioperative period and a concomitant myopathy is not present, the diagnosis of MH is very likely.²² If contracture test results are within normal limits after an episode of MMR, we currently do not recommend that other family members undergo testing, but advise that succinylcholine be avoided in future anesthetics for that patient.

A study by Littleford *et al*²³ has shown that acidosis and rhabdomyolysis occur after anesthesia if continued with an inhalation agent after MMR, although fulminant MH may not occur. MMR has been documented most frequently in association with succinylcholine, although it may occur after induction with any anesthetic agent, intravenous or inhalation, before succinylcholine administration.²⁴ As such, many pediatric anesthesiologists avoid the use of succinylcholine except on specific indication. It is also of interest that a thiobarbiturate induction will greatly decrease the incidence of MMR.²⁵

Late Onset of MH and Myoglobinuria

Malignant hyperthermia may occur not only in the operating room, but also in the early postoperative period, usually within the first few hours of recovery from anesthesia. The characteristic tachycardia, tachypnea, hypertension, and dysrhythmias indicate that an episode of MH may be about to follow. Isolated myoglobinuria in the postoperative period should also alert the anesthesiologist that a problem has occurred. Myoglobinuria may occur without an obvious increase in metabolism.²⁶ Succinylcholine may cause rhabdomyolysis in patients who have other muscle disorders that may not be clinically obvious on cursory examination.^{7,27,28} It may result from interactions of succinylcholine with other drugs such as inhibitors of cholesterol formation.²⁹ The presence of myoglobinuria mandates that the patient be referred to a neurologist for further investigation.

Myodystrophies Exacerbated by Anesthesia: Relation to Malignant Hyperthermia

Patients suffering from *muscular dystrophy* are at risk to develop hyperkalemic cardiac arrest after administration of succinylcholine. In some muscle diseases hyperkalemia has been noted after volatile agents only. These adverse events were first believed to represent a form of MH.^{30,31} It now appears that the pathophysiology of the hyperkalemic episodes and MH is different. Case reports collected by the Malignant Hyperthermia Association of the United States (MHAUS) and the North American MH Registry indicate that when an apparently healthy child experiences a sudden unexpected cardiac arrest on induction of anesthesia, once hypoxemia and ventilatory problems are ruled out, hyperkalemia should be considered. Of 29 patients with such a presentation, 60% died. In 50% there was evidence of undiagnosed myopathy (usually muscular dystrophy).⁷ The treatment of hyperkalemic arrests includes administration of calcium chloride, glucose, insulin, bicarbonate, and hyperventilation.

In 1993 and in 1994 the package insert for succinylcholine was modified to warn against routine use of succinylcholine in children. Of course, in special circumstances, such as airway emergencies and full stomach, succinylcholine may still be appropriate. Some pediatric anesthesiologists are comfortable with the administration of short-acting nondepolarizing neuromuscular blockers in these situations.

Central core disease is an unusual myopathy characterized by muscle weakness. It is probably inherited in a recessive manner. Many cases of MH have been reported in patients with central core disease. Therefore, precautions regarding MH must be taken for all patients with central core disease.^{32,33}

The *myotonias* are a varied set of disorders. Patients with any of these disorders will display muscle contractures after succinylcholine. Only one myotonic disorder (myotonia fluctuans) has been linked to MH susceptibility by the halothane–caffeine contracture test.³⁴

King or King-Denborough syndrome is a rare myopathy characterized by cryptorchidism, markedly slanted eyes, low-set ears, pectus deformity, scoliosis, small stature,

and hypotonia. Several patients with this disorder have been diagnosed as MH-susceptible both clinically and by muscle biopsy.^{35,36}

Other Conditions Associated with MH

Skeletal abnormalities such as *osteogenesis imperfecta*³⁷ and the Schwartz-Jampel³⁸ syndrome, *myotonia*, have been associated with signs of MH. Metabolism is increased in patients with *osteogenesis imperfecta* because of the bone disease. Fever during anesthesia is common in these patients. The Schwartz-Jampel syndrome is an autosomal recessive myotonic-like condition with osteoarticular deformities. In both these conditions, association with MH is sporadic. Despite a few well-documented cases of MH in patients with *osteogenesis imperfecta*, we (and others³⁹) have not confirmed MH susceptibility in three cases of *osteogenesis imperfecta* tested with the halothane-caffeine contracture test. But we have found typical contractures in one other muscle biopsy from a patient with *osteogenesis imperfecta*.

Pheochromocytoma may be mistaken for MH because of its presentation by tachycardia, hypertension, and fever during anesthesia. However, pheochromocytoma does not predispose to MH.⁴⁰ Thyrotoxicosis could also be mistaken for MH. Carbon dioxide production is lower in these endocrine disorders than in MH. Hypertension is greater in pheochromocytoma than in thyrotoxicosis, and even less in MH. Neither endocrine crisis is associated with as much rigidity as MH. Metabolic acidosis was not present during thyrotoxicosis and not as great during pheochromocytoma as during MH. Thyroid crisis did not trigger MH even in susceptible pigs.⁴¹

Malignant Hyperthermia Outside the Operating Room

The concern that MH may occur outside the operating room without mediation of drugs in humans has been expressed repeatedly. This concern derives from the often-repeated observation that an MH-like syndrome can occur in certain pig breeds in response to stressful situations. However, documented cases of fulminant MH occurring without drug intervention in humans have not been convincing. Gronert *et al* have described a patient who had episodic fevers and whose muscle biopsies tested positive for MH.⁴² The fevers were controlled by dantrolene. Reports have shown that some patients who suffered from heatstroke are MH-susceptible, but many questions still remain.

Concerning the relationship of heat syndromes and MH, some also believe that MH-susceptible patients are likely to die suddenly,⁴³ but the evidence is not convincing. Detailed information usually is not available regarding the medical history of young people who die suddenly and unexpectedly. Was there evidence of a recent infection? What were the results of previous medical treatments, drug levels, and other tests? Studies of sudden death in young people have found that infection and unrecognized cardiac disease account for more than half the causes of such death. Often, the symptoms of such problems either are mild and unrecognized or are ignored. About 10% of sudden unexpected deaths in healthy young adults result from a cerebral bleed, 25% from asthma and epilepsy, and about 15% from undetermined causes.

A great deal of debate and very few data characterize the discussions regarding sudden death and MH. A more widespread, easier-to-use diagnostic test and a better understanding of the pathophysiologic characteristics of MH are necessary to resolve this issue.

Neuroleptic Malignant Syndrome and Other Disorders

The symptoms and signs of the *neuroleptic malignant syndrome* include fever, rhabdomyolysis, tachycardia, hypertension, agitation, muscle rigidity, and acidosis.⁴⁴ The mortality rate is unknown, but may be as high as 20%. Dantrolene is an effective therapeutic modality in many cases of neuroleptic malignant syndrome. Therefore, it is not unusual for an anesthesiologist to be consulted in the management of patients with this disorder.

Although the resemblance of neuroleptic malignant syndrome to MH is striking, there are significant differences between the two. MH is acute, whereas neuroleptic malignant syndrome often occurs after longer term drug exposure. Phenothiazines and haloperidol or any of the newer potent antipsychotic agents alone or in combination are usually triggering agents for neuroleptic malignant syndrome. Sudden withdrawal of drugs used to treat Parkinson's disease may also trigger neuroleptic malignant syndrome. Electroconvulsive therapy (ECT) with succinylcholine does not appear to trigger the syndrome.⁴⁵ Also, neuroleptic malignant syndrome does not seem to be inherited, and there are no case reports of it in family members who have had an episode of MH.

Many believe that the changes in neuroleptic malignant syndrome are a reflection of dopamine depletion in the central nervous system by psychoactive agents. In support of this theory, therapy with bromocriptine, a dopamine agonist, is often useful in treatment of neuroleptic malignant syndrome. Therefore, although there appear to be similarities between MH and neuroleptic malignant syndrome,⁴⁶ a common pathophysiology is not readily apparent. From an anesthesiologist's viewpoint, it is best to monitor patients with neuroleptic malignant syndrome as though they were susceptible to MH. However drugs such as succinylcholine have been used for ECT without problems in MH patients.

Drugs That Trigger Malignant Hyperthermia

It is clearly established that the potent inhalation agents, including sevoflurane, desflurane, isoflurane, halothane, methoxyflurane, cyclopropane, and ether, may trigger MH. Succinylcholine and decamethonium are also triggers. The status of many other drugs is less clear. [Table 20-1](#) indicates the drugs we believe to be safe and those that are unsafe.

| Safe Drugs | Unsafe Drugs |
|-------------------|--|
| Alfentanil | All inhalation agents (except nitrous oxide) |
| Antibiotics | Succinylcholine |
| Antihistamines | Potassium salts |
| Atracurium | |
| Barbiturates | |
| Benzodiazepines | |
| Droperidol | |
| Ketamine | |
| Local anesthetics | |
| Opioids | |
| Nitrous oxide | |
| Pancuronium | |
| Propofol | |
| Propofol | |
| Vasopressors | |
| Venocurium | |

Table 20-1. SAFE VERSUS UNSAFE DRUGS IN MALIGNANT HYPERTHERMIA

Local Anesthetics

Based on studies indicating that amide or ester local anesthetics do not trigger MH in susceptible swine and that amide local anesthetics do not trigger MH in susceptible humans, it seems clear that all local anesthetics are safe for MH-susceptible patients.^{47,48} Preliminary studies of local anesthetics during an MH crisis (*e.g.*, for dysrhythmia control) do not show an exacerbation of MH by amide local anesthetics.

Catecholamines

Although plasma catecholamine concentration increases during an MH crisis, such an elevation is usually secondary to metabolic and cardiovascular changes. Vasopressors and other catecholamines are not involved in triggering MH.⁴⁹ Therefore, these drugs should be used as necessary but only with simultaneous treatment of the MH crisis.

Nondepolarizing Relaxants

Although curare is a suspected trigger of MH,⁵⁰ vecuronium, rocuronium, atracurium, pancuronium, and all other nondepolarizing drugs are considered safe to use in patients with MH.

Anticholinesterases

Clinical studies have shown that anticholinesterase–anticholinergic combinations are safe for reversal of nondepolarizing relaxants in MH-susceptible patients.⁵¹

Phenothiazines and Drugs Used to Treat Psychoses

Phenothiazines increase intracellular calcium ion concentration and may cause contractures *in vitro* in muscle from MH-susceptible patients.⁵² Phenothiazines also induce the related neuroleptic malignant syndrome. Therefore, although there have been several reports that phenothiazines are effective in managing temperature fluctuations during recovery from MH, these compounds should be used cautiously in MH-susceptible patients. As of 1999 none of the more than 300 records of fulminant MH in the North American MH Registry included administration of phenothiazines, butyrophenones (droperidol), thioxanthenes, or heterocyclics (haloperidol) prior to the appearance of MH (personal communication from M. G. Larach).

Other Drugs

Digoxin, quinidine, and calcium salts do not induce MH in the swine.⁵³ Therefore, it is reasonable to assume that they are safe to use in clinical situations. However, potassium salts can trigger MH. This results from a depolarization of the muscle membrane, leading to muscle contracture. Neither ketamine nor propofol is an MH trigger.⁵⁴

Incidence and Epidemiology

Although the incidence of reported episodes of MH has increased, the mortality rate from MH has declined. In part these two trends reflect a greater awareness of the syndrome, earlier diagnosis, and better therapy. The incidence of MH varies from country to country, based on differences in gene pools. In the upper midwest of the United States, for example, there are many families containing large numbers of MH-susceptible people. In contrast, other areas of the country and parts of the world have rarely reported MH. The overall incidence is said to be 1 in 50,000 anesthetics administered in adults and 1 in 15,000 anesthetics administered in children. Results of large-scale studies of operative mortality are in general agreement with this figure. For example, a study in Great Britain revealed 3 cases of MH in 100,000 administered anesthetics.⁵⁵ Even now, the best epidemiologic study of MH was done in the mid-1980s by Ording.²⁰ Based on information supplied to the Danish Malignant Hyperthermia Registry comprising the reported incidence of MH in Denmark (population approximately 5 million), this study revealed fulminant MH in approximately 1 in 250,000 administered anesthetics. However, if the definition of MH is expanded to include abortive cases of MH and is further refined to include only cases in which inhalation anesthetics and succinylcholine were used, the incidence was as high as 1 in 4000 anesthetic administrations.²⁰

A more recent study by Bachand and colleagues examined the incidence of MH in the province of Quebec, Canada, where many families had been biopsied. They traced the pedigrees of the patients to the original immigrants from France. They found an incidence of MH susceptibility in 0.2% of the population. However, that represented only five extended families.⁵⁶

Currently, the consensus is that the mortality from MH is approximately 10%. However, the epidemiologic characteristics of MH are very difficult to define for the following reasons:

1. Widespread diagnostic testing for MH is difficult to apply.
2. The clinical diagnosis of MH is often questionable.
3. Triggering of MH even in susceptible patients may not occur on an individual anesthetic exposure. In some cases, susceptible patients have received triggering agents for up to 13 anesthetics without any problems, only to have MH triggered on the subsequent anesthetic. Investigation of the Danish Malignant Hyperthermia Registry found the MH genotype to be expressed in only 34–54% of anesthetic exposures.⁵⁷
4. Registries of MH cases do not capture all data. There is a paucity of data concerning the frequency of use of anesthesia in the general population.

Inheritance of Malignant Hyperthermia

Many of the reasons that limit our understanding of the epidemiologic characteristics of MH also limit our accurate assessment of its inheritance. It would seem that studies of the animal model would clarify the issue of inheritance, but this has not been the case. MH in most pig breeds is inherited in an autosomal recessive fashion.⁵⁸ Variabilities in clinical presentation and the fact that MH is not regularly apparent on exposure to triggering agents, even in those who are susceptible, result in great difficulty in assessing the inheritance of MH in humans. The inheritance of MH in humans has been described as autosomal dominant, multifactorial, autosomal dominant with variable penetrance, and multigenetic.⁵⁹

Our studies, as well as anecdotal reports from other diagnostic centers, have supported the concept of autosomal dominant inheritance by a single gene with variable penetrance. Representative examples of such clinical documentation of autosomal dominance are as follows:

1. A 34-year-old man died of the classic MH syndrome. Although his father had a history of ptosis, he had MH-negative results on muscle biopsy. His mother was too ill to have a biopsy performed. A maternal cousin was found to be MH-susceptible on the contracture test, as was his maternal uncle.
2. A 4-year-old child developed masseter rigidity during anesthesia with succinylcholine, with a postepisode CK level of 8000 IU. Her two siblings had negative muscle biopsy results; however, her mother had MH-positive results. None of the children had had anesthesia previously.
3. An 8-year-old boy developed masseter rigidity with CK level elevation after receiving succinylcholine. His father stated that his own father had died of hyperthermia during surgery years previously. The father was MH-susceptible on contracture testing.

Studies of large families have also documented an autosomal dominant pattern.⁵⁶ We therefore advise patients that siblings and children of MH-susceptible patients have a 50% risk for this disorder. Although baseline CK determinations may be of no value in screening for MH, relatives of MH-susceptible patients with an elevated CK level (without recent trauma or muscle disorder) have a higher than 80% chance of being susceptible. However, relatives with a normal CK level may also be susceptible.

Diagnostic Tests for Malignant Hyperthermia

Development of the *In Vitro* Contracture Test

In 1970, Kalow *et al* demonstrated that isolated muscle from MH-susceptible patients was unusually sensitive to caffeine when exposed *in vitro*.⁴ Shortly thereafter, Ellis and coinvestigators demonstrated that muscle from MH-susceptible patients also had a more sensitive than normal contracture response to halothane.⁵⁹ Subsequent studies suggested that specific cutpoints for the halothane and caffeine responses could be adopted for diagnosing MH.⁶⁰ The European MH Group (EMHG)^{61,62} and North American MH Group (NAMHG)^{63,64,65} separately have standardized protocols for contracture testing. Treatment of muscle biopsy specimens in a tissue bath with either halothane or caffeine has come to be the standard test for diagnosing MH susceptibility.^{66,67,68,69,70}

Other tests have been proposed to differentiate patients with MH from those who are normal. Some tests use skeletal muscle biopsy specimens, whereas others employ blood elements such as platelets or white blood cells to determine susceptibility. Most of these tests have been proven to be of either questionable or no value in determining MH status. These tests have been reviewed elsewhere,^{66,67,68,70} and only the currently acceptable or potentially useful tests are addressed in this chapter.

Halothane–Caffeine Contracture Test

The contracture test has also been reviewed elsewhere.^{66,67,68,70} However, this test is constantly undergoing refinement, and the newer developments are emphasized in this chapter. Although some procedures and interpretations differ between the EMHG and NAMHG protocols, the following steps are similar. Skeletal muscle (1–3 g) is usually biopsied from the vastus lateralis muscle. Strips of muscle weighing 100–200 mg and measuring 15–30 mm (±25 mm preferred) in length by 2–3 mm in width by 2–3 mm in thickness are carefully isolated and mounted in a standard muscle bath apparatus (Fig. 20-1). The tissue bath contains a modified Krebs solution at 37°C bubbled with O₂ and CO₂ (95%/5%), and the resting tension is adjusted to the optimum length for maximal twitch tension (usually about 2 g). The bundles are stimulated supramaximally with pulses of frequency 0.1–0.2 Hz with 2-msec pulses to verify viability. After a 15–60-min equilibration in which the preparation is oxygenated with O₂/CO₂ (95%/5%), halothane is added to the gas phase, either as a bolus dose or in incrementally increasing concentrations (Fig. 20-2). The concentration of halothane is verified by gas chromatography. A second set of muscle strips is equilibrated and subsequently exposed to incrementally increasing

concentrations of caffeine-free base (see Fig. 20-2). It is recommended that the caffeine strips be tested early in the procedure because they tend to be more sensitive to instability over time.⁷¹ Testing is usually completed within about 5 hours of biopsy to ensure adequate viability of the muscle preparations. Owing to time constraints, it is essential that the biopsy be performed at or within about 1 hour of the testing laboratory. Usually a histologic evaluation accompanies the contracture test to examine whether the subject has a muscle disorder other than MH.

Figure 20-1. Diagram of the muscle bath apparatus used for contracture testing for diagnosing MH susceptibility.

Figure 20-2. Muscle strips weighing approximately 150 mg and stimulated supramaximally are exposed to 3% halothane or incremental doses of caffeine. (A) A 3-g contracture is recorded from this strip from an MHS patient after exposure of the muscle to 3% halothane (*top*); a normal response to 3% halothane (*bottom*). (B) Contractures noted after exposure to 0.5, 1, and 2 mM caffeine in MHS muscle (*top*); no contracture response to the same caffeine concentrations. Twitch height augmentation is normal following caffeine addition (*bottom*).

Interpretation of the Halothane–Caffeine Contracture Test. Two protocols have been adopted for use over the past decade. These protocols were initiated to standardize procedures so that the results from groups of laboratories could be pooled for analysis. Also, a uniform approach was necessary to standardize the phenotype derived from the contracture test for use in genetic analysis.

The EMHG was the first to meet and establish testing standards.^{61,62} Halothane is added incrementally by this protocol (0.5, 1.0, 2.0%) with the preparation exposed to each concentration for 3 minutes. In practice, the EMHG requires estimating the time that the expected concentration in the tissue bath is reached (0.11, 0.22, 0.44 mM, respectively) and the 3-minute exposure for each concentration begins after that time is reached. A response indicative of MH susceptibility is based on a contracture threshold (>0.2 g) at a halothane concentration $\leq 2\%$ in either of the two muscle strips tested. Caffeine is also added incrementally in concentrations of 0.25, 0.5, 1.0, 1.5, 2.0, 3.0, and 4.0 mM. Each caffeine concentration is maintained until the contracture plateau is reached, or for 3 minutes, whichever is sooner. A positive response is a contracture threshold (>0.2 g) at a concentration of caffeine of 2 mM or less in either of two strips tested.

In the NAMHG protocol⁶³ a bolus dose of halothane 3% is added to the gas phase for each of three muscle strips and the maximum contracture within 10 minutes is recorded. A positive response is a contracture >0.7 g tension to halothane 3% and a negative response is <0.5 g. An equivocal response to halothane (MH-equivocal, or MHE) is between 0.5 and 0.7 g.⁶⁴ As with the EMHG protocol, caffeine is added incrementally, but the concentrations are 0.5, 1.0, 2.0, 4.0, 8.0, and 32 mM; the interval at each concentration is 4 minutes or contracture plateau, whichever is sooner; and three muscle strips are tested. A positive response is a contracture >0.3 g (determined by the specific laboratory) to 2 mM caffeine. The magnitude of contracture at 2 mM caffeine is believed to be more specific and is used as the primary means for interlaboratory comparisons. Also, a response to caffeine 2 mM of <0.2 g is negative, and a response between 0.2 and 0.3 g is MHE.

The interpretations of the outcomes of the halothane and caffeine tests differ between the EMHG and NAMHG protocols. The EMHG protocol requires a positive response to halothane and a positive response to caffeine for a diagnosis of MH-susceptible (MHS). If the outcomes of both tests are negative, then the subject is diagnosed as MH-normal (MHN). If only the caffeine test is abnormal, the patient is considered MHE to caffeine (MHEc). If only the halothane test is abnormal, the patient is considered MHE to halothane (MHEh). The NAMHG protocol differs in that the subject is considered MH positive (MH+ or MHS) if either the response to halothane or the response to caffeine is abnormal. The patient is diagnosed as normal (MH- or MHN) if neither test is positive. As with the EMHG protocol, MHE subjects are treated as positive by the NAMHG.

Sensitivity and Specificity of the Halothane–Caffeine Contracture Test. Three published studies have examined the outcome of the EMHG protocol in patients with a history of fulminant MH. In the first study,⁷² of the seven patients with a personal history of fulminant episodes, five were diagnosed as MHS, and two as MHE; all 13 controls (low-risk subjects) were diagnosed as MHN. In a second study⁷³ the four patients with a personal history of fulminant episodes were all diagnosed as MHS. In the third study, using the combined data from the EMHG,⁷⁴ 33 of the 38 patients with a personal history of fulminant MH were MHS and the remaining five were MHE. Sixty-eight of the 73 normal controls were MHN, one was MHEh, and four were MHEc.

The NAMHG protocol was examined in 120 control (low-risk) subjects and 32 patients with a high likelihood of having a fulminant MH episode using data pooled from ten diagnostic centers.⁶⁵ Using cutpoints of 0.7 g for halothane (3%) and 0.3 g for caffeine (2 mM), the NAMHG protocol was found to have sensitivity of 88% and specificity of 81% in humans. Lowering the cutpoint for halothane (3%) to 0.5 g with the cutpoint for caffeine (2 mM) of 0.3 g increased the sensitivity to 97% and specificity to 78%.^{64,74} Thus, the finding of a positive result by this definition on either or both of the halothane or caffeine contracture tests is the most sensitive definition of MH susceptibility used in North America. In a study specifically using normal vastus lateralis there were no false-positive responses to caffeine (2 mM) or halothane (3%) in 16 patients.⁷⁶

Studies also have been conducted in swine.^{77,78} Based on 19 control and 27 MH-susceptible Yorkshire/Duroc swine, the sensitivity of 96% (one false negative) and specificity of 95% (one false positive) were estimated for the NAMHG protocol, using cutpoints of 0.7 g for halothane (3%) and 0.3 g for caffeine (2 mM).⁷⁷

When the outcome of either the NAMHG or EMHG protocols is compared to the outcome of the other in humans, the diagnoses are similar, but not necessarily identical.^{73,79} However, in the one study with patients with personal histories of fulminant episodes, all four were diagnosed as MHS by the EMHG protocol and MH+ by the NAMHG protocol.⁷³ In a comparison of the NAMHG and EMHG halothane testing protocols, the outcomes of the two protocols were identical in nine of ten MH and three of four control pigs.⁷⁸ The one negative test to halothane by the EMHG protocol was accompanied by a positive test to caffeine, making the diagnosis MHEc by the EMHG protocol; the pig would be treated as if MH-susceptible. In a study of 84 patients referred for diagnostic testing the two protocols produced similar diagnoses.⁷⁹ At a different testing center there was agreement between the diagnoses reached by these two protocols in 87% of 156 patients and 17 controls.⁸⁰ The divergence in opinion occurred in patients whose contracture results were near the cutoff rather than in those with strongly positive or unquestionably negative results. Taking the final information conveyed to the patient into account (*e.g.*, for EMHG, MHE is clinically treated as MHS), it is not clear that one protocol is significantly better than another. Both protocols and their interpretations are prone to small numbers of false positives. However, the initial patient selection for diagnostic testing reduces this possibility.⁸¹ The more important function of the test is to decrease the possibility of a false diagnosis that MH exists in families that do not carry the causative gene, as would happen if all relatives of a proband were assumed to be susceptible. The EMHG protocol reduced the number of marginal responders, which

may make the remaining diagnoses slightly more accurate for use in genetic studies.⁷⁹

Other Contracture Tests.

Ryanodine. An additional contracture test using the plant alkaloid ryanodine was recently proposed for inclusion in the EMHG protocol because the ryanodine receptor (the Ca²⁺ release channel of skeletal muscle) was believed to be the only cause of MH. It was reasoned that this test would afford maximum specificity for MH, and early studies supported this concept.^{79,82,83,84,85} The NAMHG has adopted the same protocol used by the EMHG to provide a common denominator for data interchange between groups.

The basic testing conditions for ryanodine are similar to those described for halothane and caffeine testing. High-purity ryanodine is employed. A bolus of ryanodine (1 μM) is added to the bath and the time to onset of contracture, time to 0.2-g contracture, time to 1-g contracture, and the time and amplitude of maximum contracture are recorded. Discrimination was improved by using the time to initial contracture and time to development of a 10-mN (1 g) contracture.⁸⁶ Variability between laboratories currently prevents recommendation of specific diagnostic guidelines for this test.⁸⁶

4-Chloro-*m*-cresol. 4-Chloro-*m*-cresol (4-CmC) is a potent activator of ryanodine receptor-mediated Ca²⁺ release. Cumulative administration of 25, 50, 75, 100, 150, and 200 μmol · l⁻¹ 4-CmC produced concentration-dependent contractures. Contractures developed earlier and to a greater magnitude in muscle from patients identified as MHS by the EMHG protocol than in normal muscle.⁸⁷ The accuracy of this test for MHS is 100% compared to the EMHG protocol at a threshold of 75 μmol · l⁻¹ 4-CmC.⁸⁸ However, muscle defined as MHEh by the EMHG protocol reacts to 4-CmC as does normal muscle.⁸⁹ Thus the utility of the 4-CmC contracture test is not well defined.

Pitfalls in the Contracture Test

Ideally, each laboratory should derive specimens from patients who are clearly and unequivocally normal and those who are clearly and unequivocally MH-susceptible to verify that cutpoints for MH susceptibility are diagnostic within the laboratory. Unfortunately, because of the variation in presentation of MH and the confusion with signs associated with non-MH causes, it is not always possible to have complete agreement on the MH status of a patient based on a clinical history, even among experts in the field. This problem has made estimates of sensitivity and specificity difficult.

A clinical grading scale has been developed to address concerns for objectively evaluating the clinical episode.^{75,90} The scale was developed with the input of 11 internationally recognized experts in the clinical aspects of MH. This scale lacks sensitivity, because incomplete recording of necessary data or early termination of the crisis would not yield scores indicative of MH, even if an episode had occurred. The scoring system also is designed to avoid overweighting duplicative indicators representing the same processes. The value of the grading scale is mainly in identifying those subjects with the most convincing episodes of MH for subsequent evaluation of the sensitivity and specificity of the diagnostic tests. The clinical grading scale is useful in evaluating clinical episodes in those cases in which the subject is rated a 6 (almost certainly MH), but lower scores should not be considered for actual diagnosis. We would even encourage the practice of sending patients rated 6 for diagnostic testing, because these individuals are rare and essential for the continuing evaluation of the sensitivity and specificity of the halothane-caffeine contracture test and the new ryanodine test. Additionally, these subjects may prove to be important for inclusion in the genetic studies of MH.

One of the main problems in MH testing is that, on halothane-caffeine testing, two separate groups may not be discernible; rather, a continuum of responses is observed.^{87,91} Susceptibility is determined by a response above or below a certain threshold. Addition of a ryanodine component to the contracture test may improve the specificity of this test for those in whom abnormal function of the ryanodine channel is responsible for MH susceptibility. But this may not be the case for all MH-susceptibles. In addition, there may be variability between individual strips from the same muscle biopsy specimen.^{22,67,70,92,93,94} At present the cause for this variation is not understood, but both protocols require testing multiple muscle strips to halothane and caffeine.

There have been a few incidents in which patients who were diagnosed as nonsusceptible by contracture testing subsequently experienced clinical episodes highly suggestive of MH; and in one case, the estimated false-negative rate was 4 out of 171 subjects (2%).^{95,96} The interpretation of these studies is controversial, and not all investigators are convinced that these are valid cases of MH. In contrast, two studies have reported 16 MHN patients receiving triggering agents on 23 occasions⁹⁷ and 13 MHN patients receiving triggering agents on 26 occasions,⁹⁸ all without complications. Unfortunately, studies like these are difficult to conduct because they require large patient populations and tracking of subjects diagnosed several years before the actual study. Such studies are also rare in the literature because they are negative findings and more difficult to publish than studies of false-negatives. Until more data are gathered, it is difficult to put the occasional false-negative diagnosis into proper perspective.

Variability seems to exist between families in the magnitude of contracture.⁹⁹ This may be due to the inheritance of different genetic defects. Although some investigators have suggested using different cutpoints for different families,¹⁰⁰ this would be impractical because of the need for testing large numbers of family members to establish these cutpoints. Because relatively few normal controls exceed the standards established by the two protocols,^{65,72,74,76} the larger magnitude of contractures observed in some MH families over others⁹⁹ may be of interest more in studies of pathophysiology and genetics than in diagnosis.

Until such time as all the basic biochemical defects of MH are uncovered, the contracture test will always be subject to some differences in interpretation. However, the halothane-caffeine contracture test is currently the only method of MH diagnosis that has been standardized and has had sensitivity and specificity confirmed in any manner by multiple centers throughout the world.

Tests with More Limited Usefulness in Malignant Hyperthermia Diagnosis

Alternative tests that have not gained acceptance within the EMHG or NAMHG have been reviewed elsewhere.^{66,67,68,70} These tests include lymphocyte tests, platelet aggregation, skinned fiber tests, adenosine triphosphate depletion, erythrocyte osmotic fragility, and others. The tests discussed below have at least some usefulness in some cases of MH.

Elevated resting CK values are associated with MH susceptibility in a few families. However, many subjects susceptible to MH do not have elevated CK values, making this method of diagnosis relatively insensitive.⁶⁸ Also, several muscle disorders are associated with resting CK values, making this test nonspecific.⁶⁸ Nevertheless, the only identifiable muscle disorder in many cases of elevated CK levels is MH.¹⁰¹ The most important application of elevated CK levels is in those families in which at least a few members have undergone diagnostic contracture testing, and in these subjects elevated CK levels cosegregate with MH susceptibility. In this instance, other family members can tentatively be diagnosed by CK levels. We caution that this method of diagnosis is only tentative and should be confirmed by contracture testing. Elevated CK values also may be useful in preliminarily identifying key family members to be referred for contracture testing and in identifying MH in children too young to undergo contracture testing.

The use of resting CK values for general screening for MH is neither sensitive nor specific, but there is a relationship between high postoperative CK values associated with MMR and the probability for diagnosis as MH-susceptible by the contracture test.^{14,22,67} Although it is not a perfect indicator of MH susceptibility,¹⁰² the chances are about 80% that a CK value >20,000 after MMR will yield a positive diagnosis by contracture testing.^{14,22} A relatively normal CK postoperatively does not rule out the possibility of an acute MH reaction during that anesthetic.¹⁰³

Intracellular pH and levels of inorganic phosphate, phosphocreatine, adenosine triphosphate, phosphomonoesterase, and phosphodiesterases can be measured noninvasively by nuclear magnetic resonance (NMR) spectrometry. Alterations in the ratio of inorganic phosphate to phosphocreatine, phosphocreatine recovery rates, and other parameters are observed in MH-susceptible patients using NMR.^{104,105,106,107} Special equipment and personnel are necessary to perform this test, and diagnosis by this method is restricted to just a few centers. As with elevated CK values, several other muscle disorders would give a false-positive diagnosis of MH, making analysis for muscle disorders mandatory. A negative finding should still be confirmed by the *in vitro* contracture test.

Blood tests using genetic screening are included here not because they are currently useful, but to allow for future developments in genetic screening. Neither we nor other investigators¹⁰⁸ advise genetic testing in its current state. As discussed in greater detail under pathogenesis and etiology, the cause-effect relationships of the defects and MH have not been satisfactorily established.

The utility of genetic tests for diagnosing malignant hyperthermia is discussed in more detail in the section on pathogenesis. In a few families where a specific mutation has been identified in the ryanodine receptor gene that correlates with an abnormal contracture response to halothane or caffeine, it is possible to determine MH susceptibility by screening the DNA of relatives for that mutation. If the mutation is present, the patient may be considered to be at risk to MH. But if it is not present, the patient cannot be presumed to be MH-negative.¹⁰⁹ We believe that, as the molecular genetics of MH are unraveled, molecular genetic testing will replace the more

invasive diagnostic tests. At present, however, this prospect is remote.

Treatment of Malignant Hyperthermia

Malignant hyperthermia is a treatable disorder. If it is diagnosed early and treated promptly with proper continuing observation, the mortality rate should be close to zero. All institutions in which anesthetic agents are administered should have dantrolene available [36 ampules (720 mg) is recommended] and have a plan of management.

The Acute Episode

The following steps should be taken immediately when MH is diagnosed:

1. Administration of all inhalation agents and succinylcholine should be discontinued.
2. Hyperventilation with 100% oxygen should be instituted at high flow rates, and assistance should be secured. (It is usually helpful to have a cart available containing the agents for treatment of MH.)
3. Assistance should be obtained in mixing dantrolene. The present preparation of dantrolene is poorly soluble. Each ampule containing 20 mg should be mixed with 50 ml of sterile distilled water (not saline solution). Initial intravenous therapy should be started with a minimum dose of $2.5 \text{ mg} \cdot \text{kg}^{-1}$ with repeat doses as needed.¹⁰⁹ It is often recommended that the maximum dose of dantrolene be $10 \text{ mg} \cdot \text{kg}^{-1}$, but more should be given as dictated by clinical circumstances.
4. Titration of dantrolene and bicarbonate to heart rate, body temperature, and PaCO_2 is the best clinical guideline of therapy.
5. In fulminant cases in which significant metabolic acidosis is present, $2\text{--}4 \text{ mEq} \cdot \text{kg}^{-1}$ bicarbonate should be given.
6. If it is not already available, a capnometer should be obtained so that CO_2 excretion can be followed.
7. If at all possible, the anesthesia circuit and CO_2 absorbent should be changed because residual inhalation anesthetics may contaminate the anesthesia circuit. If not, very high flows, $>10 \text{ l} \cdot \text{min}^{-1}$, of oxygen should be used.
8. Dysrhythmia control usually follows hyperventilation, dantrolene therapy, and correction of acidosis. Calcium channel blockers should not be used in the acute treatment of MH. Several studies have shown that verapamil can interact with dantrolene to produce hyperkalemia and myocardial depression.^{110,111} Lidocaine can be safely used to treat dysrhythmias during an MH crisis.
9. Body temperature elevation should be managed by packing the patient with external ice packs and by use of gastric, wound, and rectal lavage. Gastric lavage is the quickest, most practical means for rapid temperature control. Some have recommended peritoneal dialysis and others, cardiopulmonary bypass. Cooling should be stopped when body temperature reaches approximately 38°C to avoid hypothermia.
10. Although arterial blood gas determinations are useful for assessing acidosis, central mixed venous blood gas determinations (or, if not available, femoral venous blood gas readings) serve as a better guideline for therapy.
11. Hyperkalemia should be managed in the usual fashion. If hyperkalemia is associated with significant cardiac effects, calcium should be given. During therapy of MH, hypokalemia frequently results. However, potassium replacement should be undertaken very cautiously, if at all, because potassium may retrigger a MH episode.

Management After the Acute Episode

After the acute episode, the clinician should be concerned about three complications of MH:

1. Recrudescence of MH. Although most cases of MH resolve promptly with therapy, some cases are difficult to control. As many as 25% of patients may experience acute recrudescence within hours of the first episode.¹¹²
2. Disseminated intravascular coagulation.¹¹³ Disseminated intravascular coagulation has often been described in cases of MH, probably resulting from release of thromboplastins secondary to shock and/or release of cellular contents on membrane destruction. The usual regimen for treatment of disseminated intravascular coagulation should be followed.
3. Myoglobinuric renal failure. CK elevations may not occur for 6–12 hours after a MH episode and should be followed as a rough guide for therapy. However, myoglobinuria classically occurs within 4–8 hours of the episode; therefore, bladder catheterization is recommended.

The guidelines for the dose and duration of dantrolene therapy after resolution of acute MH are empirical. It would seem prudent to continue dantrolene, $1 \text{ mg} \cdot \text{kg}^{-1}$ every 6 hours intravenously, for at least 24–36 hours. Some recommend conversion of dantrolene therapy from intravenous to oral form ($4 \text{ mg} \cdot \text{kg}^{-1}$ per day or more) with continuation for several days.

Significant muscle weakness may follow MH, resulting from muscle destruction along with dantrolene administration; this should be managed symptomatically.

A variety of other electrolyte changes may occur, such as hypocalcemia and hyperphosphatemia. Sodium and chloride changes may occur secondary to fluid shifts during the acute episode. All these changes usually respond to control of the acute episode.

Dantrolene

In 1979, intravenous dantrolene was approved by the FDA for treatment of MH. Until that time, the primary use of dantrolene was in the management of spasticity. Dantrolene is a unique muscle relaxant. Unlike neuromuscular blocking agents (whose site of action is at the nicotinic receptor of the neuromuscular junction) or the nonspecific relaxants (which modulate spinal cord synaptic reflexes), dantrolene acts within the muscle cell itself by reducing intracellular levels of calcium. Most likely, this results from a reduction of calcium release by the sarcoplasmic reticulum or inhibition of excitation-contraction coupling at the transverse tubular level. It has now been demonstrated that during a MH episode, dantrolene reduces intracellular calcium levels. Therefore, dantrolene is a specific and effective agent in the treatment of MH. In the usual clinical doses, dantrolene has little effect on myocardial contractility.¹¹⁴

Studies have also indicated that doses of neuromuscular blocking agents need not be changed significantly after dantrolene administration. However, the drug should be used cautiously in patients with neuromuscular disease.¹¹⁵

The serum level of dantrolene required for prophylaxis against MH is about $2.5 \mu\text{g} \cdot \text{mL}^{-1}$. The half-life of intravenous dantrolene, which is the only form recommended, is approximately 12 hours. However, the therapeutic level of dantrolene usually persists for 4–6 hours after a usual intravenous dose of $2.5 \text{ mg} \cdot \text{kg}^{-1}$.¹¹⁶ Therefore, dantrolene should be supplemented at least every 6 hours after a clinical episode. Some muscle weakness may persist for 24 hours after dantrolene therapy is discontinued. Nausea and phlebitis are other complications of acute dantrolene administration. Hepatotoxicity has been demonstrated only with long-term use of oral dantrolene. Prophylaxis for MH should be carried out with intravenous or oral dantrolene ($5 \text{ mg} \cdot \text{kg}^{-1}$ per 24 hours) in those rare situations where prophylaxis is desired.¹¹⁷

Management of the Patient Susceptible to Malignant Hyperthermia

Because of an increasing awareness of MH and more widespread use of diagnostic tests, it is not unusual for an anesthesiologist to be confronted with a MH-susceptible patient or a patient who has a family history of MH. The management of such patients should be carefully planned.

In the preoperative interview, the anesthesiologist should try to obtain sufficient information regarding previous episodes of MH and their documentation. The anesthesiologist should allow adequate time to reassure patients and their families that he or she is familiar with MH and its implications and that appropriate prophylaxis and therapy will be instituted as necessary. It may be worth mentioning that there have been no deaths from MH in previously diagnosed MH-susceptible patients when the anesthesia team was aware of the problem. Some believe that anxiety may predispose a patient to MH and therefore recommend that anxiolytic agents be included in the premedication. Standard premedicant drugs such as opioids, benzodiazepines, ataractics, barbiturates, and antihistamines do not cause problems in MH-susceptible patients when administered in appropriate doses; however, we do not recommend phenothiazines for premedication. Anticholinergics are also used routinely.

Dantrolene need not be given preoperatively if nontrigger agents are used and end-tidal CO_2 and core temperature are monitored. Dantrolene must be immediately available in the operating room, and equipment for rapid measurement of blood gases and electrolytes should be available.

The anesthesia machine is prepared by draining or removing vaporizers, changing tubing and CO_2 absorbent, and flowing oxygen at $10 \text{ l} \cdot \text{min}^{-1}$ for 20 minutes.¹¹⁸

Obviously, iced solutions and adequate supplies of dantrolene must be available in the vicinity of the operating room when MH-susceptible patients are anesthetized.

Exhaled CO₂ should be monitored because the earliest sign of MH is an increase in CO₂ production and excretion.¹¹⁹ In the absence of capnography, blood gas monitoring is recommended. Arterial and central venous monitoring is recommended for MH-susceptible patients, as dictated by the surgical procedure. Body temperature should be monitored by nasopharyngeal, rectal, or esophageal routes in all patients for all surgical procedures. Skin temperature, although acceptable, is not as desirable because it may lag core temperature.¹²⁰

If possible, a regional, local, or major conduction anesthetic should be used with either amide or ester local anesthetics. If not possible, intravenous induction of anesthesia followed by nitrous oxide, oxygen, and nondepolarizing relaxant with opioid supplementation is recommended. Other induction agents that have not been implicated in MH are midazolam, diazepam, droperidol, and propofol.

Neuromuscular blocking agents such as pancuronium, vecuronium, atracurium and cisatracurium, rocuronium, and mivacurium are safe, according to animal and human studies. We routinely reverse nondepolarizing relaxants with anticholinesterase and anticholinergic agents.

Many thousands of safe anesthetics have been administered with nitrous oxide in MH-susceptible patients. Two cases have been reported in which early signs of MH have been documented despite the use of a safe anesthetic technique.¹²¹ Therefore, even under the most controlled circumstances, the anesthesiologist should be alert to the early signs of MH.

We do not continue dantrolene after operation if there are no signs of MH. However, the patient must be observed closely for 4–6 hours. MH has not occurred after surgery when dantrolene pretreatment and safe anesthetic techniques were used. The patient may be discharged on the same day as surgery if indicated.

The same precautions should be taken for the obstetric patient as for the routine surgical patient. We are not convinced that the stress of labor may precipitate MH, and we recommend well-conducted epidural anesthesia for labor and delivery without dantrolene pretreatment but with careful monitoring of vital signs. If an emergency cesarean section with general anesthesia is necessary, alternatives to succinylcholine should be used. In the very acute situation, anesthesia should be induced and dantrolene administration should be considered thereafter. The maternal:fetal partition ratio for dantrolene is probably 0.4.¹²² Dantrolene has not been reported to produce significant problems for the fetus or newborn, but existing data are very scanty.

Malignant Hyperthermia in Species Other Than Pigs and People

Malignant hyperthermia has been reported sporadically in many species. Clinical episodes have been documented in cats, dogs, and horses. Capture myopathy is a syndrome characterized by temperature elevation, rhabdomyolysis, acidosis, and death in wild animals (e.g., zebra, elk).¹²³ This also has been suggested to be an MH variant.

Medicolegal Aspects

In this era of malpractice actions, it is not surprising that MH cases have been the subject of malpractice suits. Because MH may be considered an inborn genetic problem with a relatively fixed associated mortality that may go unrecognized before a patient's exposure to triggering agents, it may be used as a "cover" for other problems.

Fever, opisthotonic posturing, and neurologic abnormalities may accompany hypoxic brain injury, and because of their similarity to MH, MH may be incorrectly implicated in the differential diagnosis. Furthermore, after cardiac arrest from any cause, CK and potassium levels may be significantly elevated. We do not know of data concerning the incidence of litigation after the occurrence of MH.

Some have stated that, with the advent of dantrolene, there should be no deaths from MH; this is probably unrealistic because the syndrome may be truly explosive in some cases and impossible to control with current therapy. Also, we are not completely familiar with all factors that lead to MH, including which drugs may trigger it and the proper dose of dantrolene needed to prevent recrudescence. Nevertheless, certain common themes underlie the basis for litigation in MH:

1. Failure to obtain a thorough personal history in regard to anesthetic problems and a family history of any unexplained perioperative problems.
2. Failure to monitor temperature continuously with an electronic temperature monitoring device. Several jury trial cases have been lost by the defense because the patient's temperature was not monitored. Intraoperative temperature monitoring is now considered a "standard of care" in the U.S. by the legal profession, despite the failure of the American Society of Anesthesiologists to recommend routine temperature monitoring during administration of all general anesthetics.
3. Failure to have adequate supplies of dantrolene on hand with a plan of management of MH.
4. Failure to investigate unexplained increases in body temperature and increased skeletal muscle tone (especially after succinylcholine administration) when associated with increased heart rate and dysrhythmias.

Several examples of medicolegal cases involving these principles are described below:

1. Increased heart rate developed in a 35-year-old man during a bowel resection for regional enteritis. His oral temperature by mercury thermometer was 37°C. The oral thermometer was left in place and the anesthesia continued with halothane and nitrous oxide. Toward the end of the procedure, there was a rapid increase in heart rate followed by an increase in body temperature. Despite cooling and administration of procainamide (this episode occurred in the predantrolene era) and other appropriate medical therapy, disseminated intravascular coagulopathy eventually developed and the patient died. The plaintiff won the case when it was tried by jury primarily because continuous electronic temperature monitoring was available and was not used.
2. A young female patient had shoulder surgery with isoflurane–nitrous oxide–oxygen. Again, temperature was not monitored continuously. At the end of the procedure, premature ventricular beats and increasing end-tidal carbon dioxide were noted. The patient had a cardiac arrest as the dysrhythmia was being treated. As the drapes were being removed, the patient felt warm. A temperature probe revealed a reading of nearly 42°C. The patient was diagnosed as having an acute episode of MH. Dantrolene was administered an hour later. The patient developed DIC over the next day and died. The case was settled out of court.
3. A 26-year-old woman was undergoing a breast augmentation in a plastic surgeon's office using general anesthesia with isoflurane. Toward the end of the procedure, her heart rate increased as did end-tidal carbon dioxide and skin temperature. Dantrolene was not available and the patient was sent to a nearby emergency room. By the time dantrolene was given, her temperature was about 43°C. She developed DIC and died. The case is under litigation.
4. Symptoms of bowel obstruction developed in a middle-aged man. He was taken to a local hospital, and anesthesia was administered with nitrous oxide–oxygen–halothane and succinylcholine. His temperature was not monitored, but an unexplained tachycardia (140–160 beats · min⁻¹) was present throughout the 2-hour procedure. On arrival in the intensive care unit after the operation, the patient was slightly hypotensive. Invasive monitoring was started. Despite marked metabolic and respiratory acidosis, a P_{aCO_2} of 100 mm Hg, and a recorded temperature of nearly 42°C, MH was not diagnosed. A cooling blanket and antibiotics failed to arrest the decrease in the patient's blood pressure, which eventually led to cardiac arrest. A judgment against the physicians and hospital of \$4.5 million was reached.

There have been several malpractice cases filed against anesthesiologists in which cardiac arrest and death occurred after succinylcholine was used in patients with an undiagnosed myopathy. The usual outcome is an out-of-court settlement.

The message is clear. All facilities where general anesthesia is administered (including hospitals, outpatient surgery centers, physician offices, dental offices) should have a full supply of dantrolene available. All patients undergoing general anesthesia should have standard monitoring, including end-tidal carbon dioxide and, except for brief cases, body temperature.

Patient Support Services

To answer the needs of patients and families who wished to learn more about MH and of those families whose relatives have died from MH, support groups were founded in several countries (e.g., the Malignant Hyperthermia Association [of Canada] and the Malignant Hyperthermia Association of the United States). Both groups serve as a repository of information about MH, provide names of physicians knowledgeable about MH and the location of MH diagnostic centers, and simply lend an ear to those with MH who have questions. Both organizations have an advisory committee of physicians but are run by volunteers who usually have a personal connection with MH. Both organize annual meetings for physicians and nonphysicians. The Malignant Hyperthermia Association of the United States publishes a quarterly newsletter, *The Communicator*, with excerpts from the medical literature, explanatory articles, questions and answers, and related information. In addition, a hotline has been organized so that a physician with an urgent question about MH can be placed in contact with a knowledgeable specialist. Approximately 30–40 calls a month are handled by this hotline.

The address of the Malignant Hyperthermia Association of the United States is 32 S. Main St., P.O. Box 1069, Sherburne, NY 13815. The phone number is

1-800-98MHAUS. The hotline number is 1-800-MHHyper. The Web site address is <http://www.mhaus.org>.

The address of the Malignant Hyperthermia Association of Canada is Room 314, Elizabeth Wing, Toronto General Hospital, 101 College Street, Toronto, Ontario M5G1L7.

In 1989, the North American MH Registry was formed. Based in Pittsburgh, Pennsylvania (Children's Hospital of Pittsburgh, 412-692-5464), the Registry will eventually be the repository for patient- and family-specific information for MH-susceptible patients. The Registry was merged with MHAUS in 1992.

Physicians who want to provide patient services for MH must prepare for lengthy discussions about the disorder, because patients usually have very limited information.

Pathogenesis and Etiology

With the clinical complexities of MH as a background, the equally complex pathophysiology and etiology can be more easily explored. Several major developments have contributed to the present understanding of MH. The first was the recognition that the syndrome is genetically transmitted.² This finding is significant because it suggests that a rigorous application of modern molecular genetics will lead to the identification of mutations in specific proteins causing the disorder. A second finding was a greater sensitivity of biopsied skeletal muscle from MH-susceptible patients to halothane or caffeine.¹²⁴ This was the basis for an *in vitro* diagnostic test and studies of the mechanisms underlying MH. The third was the recognition of similarities between human MH and porcine stress syndrome.¹²⁵ This animal model was used to elucidate the role of altered Ca^{2+} regulation in MH and led to the finding that a mutation in the ryanodine receptor may be a causative factor in some families with MH.¹²⁶ Fourth, MH has been identified as a heterogeneous disorder.^{127,128} Heterogeneity may account for some variability in presentation and forces investigators to consider the role of a final common pathway resulting from a mutation in any one of several different proteins. Fifth, the finding that pigs or human subjects with MH do not always trigger in response to adequate triggering agents, has suggested that a modulator influences the expression of the syndrome.^{129,130}

Experimental Models for Malignant Hyperthermia

Although MH is rare in humans, breeding pigs for leaner meat and better musculature has resulted in the appearance of the MH gene (or genes) in relatively high frequency in a number of herds (e.g., Poland, China, Landrace, Pietrain). This has been a major concern for breeders because the meat from pigs with MH is not marketable. A syndrome in pigs undergoing anesthesia is similar to the MH syndrome in humans. However, the porcine syndrome can also be elicited in the absence of anesthetics, by factors such as heat and stress. Although pigs administered MH-triggering anesthetics have provided a model for human MH, there is no evidence that a human stress syndrome completely analogous to the porcine stress syndrome (PSS) exists in the majority of patients. However, some evidence is accumulating for an association between exertional heat stroke and MH.^{131,132,133} A single genetic defect in the ryanodine receptor has been associated with porcine MH, and this specific mutation is found in a small percentage of humans with MH. The mode of inheritance in swine (autosomal recessive)¹³⁴ is different from that in humans (autosomal dominant). The porcine model has been extensively exploited in studies of MH. Reports of MH exist, but are rare, in horses, dogs, and cats. Of these, only the dog has been proposed as a model of human MH.¹³⁵ The pattern of inheritance in the dog appears to be autosomal dominant, yet there are some differences between the anesthesia-elicited canine and human MH syndromes.

Understanding the Malignant Hyperthermia Defect: Necessary Concepts

A hypothesis explaining MH must account for the puzzling clinical observations surrounding this disorder. Most importantly, the large majority of these patients function normally in the absence of anesthetics. Therefore, the defect should not significantly interfere with normal muscle physiology. The defect, at least in humans, appears to be expressed significantly only in skeletal muscle. The expression of the syndrome shows a large variability among individuals. For example, 30% of patients have had up to three uneventful anesthetics.^{136,137} A spectrum of presentations can occur, ranging from relatively minor intraoperative complications to rapid temperature rise, muscle rigidity, acidosis, dysrhythmias, and death. Some cases have a greater latency to onset and are not made manifest until several hours postoperatively. MH does not always occur in response to triggering agents. This is a well-established observation in human MH^{136,137} and similar observations have been reported in swine. Young PSS-susceptible pigs experience a period of several weeks during which they cannot be triggered.^{138,139} Also, while most investigators would agree that PSS is a more consistently triggered syndrome than the human MH syndrome, even adult swine occasionally do not respond to adequate triggering agents in either a barnyard challenge with halothane alone¹⁴⁰ or prolonged halothane,¹⁴¹ or halothane and succinylcholine challenge.¹²⁹ The term "MH" may, in fact, be a misnomer, as sometimes patients show no signs of temperature elevation. Finally, many cases do not exhibit rigidity, which is sometimes incorrectly considered a hallmark sign of the syndrome. The large variability among individuals may be explained by different genes causing MH in different families or by other predisposing factors being expressed differently in different patients or families.¹⁴² The function of many different proteins has been reported to be altered in MH skeletal muscle. Thus, it is reasonable to assume that systems other than those directly involved in Ca^{2+} regulation are secondarily altered in MH and these may play a crucial role in modifying the response to triggering agents. The involvement of secondary systems would explain the high variability in the phenotype.

Skeletal Muscle: Site of the Malignant Hyperthermia Defect

The MH and PSS defects are expressed in skeletal muscle, as evidenced by the *in vitro* contracture test for MH susceptibility. Results regarding other tissues are more controversial, especially in humans, and are not considered in detail in this chapter. The defects are expressed in Type I and Type II fibers.¹⁴³ While the distributions and amounts of protein in whole skeletal muscle¹⁴⁴ and in isolated sarcoplasmic reticulum¹⁴⁵ appear to be normal by electrophoretic analysis, down-regulation of specific proteins, including the ryanodine receptor¹⁴⁶ and dihydropyridine receptor,¹⁴⁷ has been reported. Additionally, the expression of subtypes of the sodium channel is altered in MH muscle.^{148,149,150} The gross distribution of lipids in MH muscle is close to normal,¹⁵¹ but subtle differences have been reported.^{152,153} The detection of protein and lipid alterations depends on the methodologies employed and, in some cases, is an artifact of the methodology.

Acidosis is highly characteristic of human MH and the PSS on *in vivo* challenge with triggering agents. These findings are confirmed by a marked decrease in pH in *in vitro* incubates of porcine MH skeletal muscle.¹⁵⁴ However, in human MH skeletal muscle incubated *in vitro*, the pH decrease is much less and is similar for MH and control human muscle. Based on the *in vitro* contracture response to halothane, the MH lesion and possible modifying factors are not uniformly expressed in the skeletal muscle mass.¹⁵⁵

Altered Calcium Regulation: The Common Final Pathway

Ultimately, the main problem in skeletal muscle is a lack of control of myoplasmic Ca^{2+} concentration during anesthesia,^{6,156} which may be manifest clinically as muscle rigidity. Ca^{2+} levels are controlled by a complex interaction of Ca^{2+} release from the terminal cisternae, the adenosine triphosphate-driven Ca^{2+} pumps at the sarcoplasmic reticulum and sarcolemma, $\text{Na}^+/\text{Ca}^{2+}$ exchange, several Ca^{2+} buffering proteins (calsequestrin, parvalbumin) and mitochondrial Ca^{2+} regulation (Fig. 20-3). Although several of these systems may become involved as the MH syndrome progresses, the difficulty in Ca^{2+} regulation appears to originate in the Ca^{2+} release mechanism in the terminal cisternae. The Ca^{2+} release mechanism could be made sensitive to anesthetics by any of several possibilities, including: a mutation in the skeletal muscle calcium release channel, termed the ryanodine receptor (*ryr1*); a protein directly coupled to *ryr1* (e.g., dihydropyridine receptor); or an altered modulator of *ryr1* function (e.g., fatty acids). The target of succinylcholine is not clear at this time, but is presumed to be the acetylcholine receptor. Opening of the acetylcholine receptor depolarizes the muscle by opening the voltage-dependent sodium currents, which have altered function in MH. Depolarization leads to Ca^{2+} release from the sarcoplasmic reticulum. Dantrolene antagonizes Ca^{2+} release from the sarcoplasmic reticulum and can lower elevated Ca^{2+} levels and reverse an episode of MH.⁶

Figure 20-3. Excitation-contraction coupling and MH. The action potential generated at the endplate region of the neuromuscular junction is propagated down the

sarcolemma (muscle plasma membrane) by the opening of voltage-dependent Na^+ channels (1). The action potential continues down into the t-tubules (2) to the dihydropyridine receptors (3). The dihydropyridine receptors in skeletal muscle function as voltage sensors and are coupled to the Ca^{2+} release channels (4). Through this coupled signaling process, the Ca^{2+} release channels are opened, some of the available terminal cisternae Ca^{2+} stores (5) are released, and the levels of myoplasmic Ca^{2+} are elevated. The Ca^{2+} then diffuses to the myofibrils (6) and interacts with the troponin/tropomyosin complex associated with actin (thin lines) and allows interaction of actin with myosin (thick lines) for mechanical movement. The Ca^{2+} diffuses away from the myofibrils and this Ca^{2+} signal is terminated by an ATP-driven Ca^{2+} pump (7), which pumps Ca^{2+} into the longitudinal sarcoplasmic reticulum (8). The Ca^{2+} diffuses from the longitudinal sarcoplasmic reticulum to the terminal cisternae, where it is concentrated for release by Ca^{2+} binding proteins. Na^+ entering during the action potential is subsequently extruded from the cell by the Na^+/K^+ -ATPase (9) and possibly through $\text{Na}^+/\text{Ca}^{2+}$ exchange (10). This latter process would elevate intracellular Ca^{2+} and could result from delayed inactivation of Na^+ currents. A major form of energy for supplying cellular ATP for the ion pumps and numerous other energy consuming processes is fatty acids (FA) derived from the serum (dietary FA), or from intramuscular triglyceride (TG) stores. Therefore, a defect in the intracellular Ca^{2+} regulating processes (increased Ca^{2+} release or decreased Ca^{2+} uptake), or a defect in the sarcolemma could account for an increase in myoplasmic Ca^{2+} .

Presence or Absence of a Malignant Hyperthermia-Associated Defect Within Skeletal Muscle Organelles

Sarcolemma. The sarcolemma (Fig. 20-3) maintains the membrane potential of the muscle cell and acts as a permeability barrier to ions, including Na^+ , K^+ , Cl^- , and Ca^{2+} . Skeletal muscle, in most cases, does not require extracellular Ca^{2+} for nerve- or electrically evoked contractility. In contrast, halothane-induced contractures^{155,156,157} and, to a lesser extent (depending on the species), caffeine-induced contractures¹⁵⁶ require extracellular Ca^{2+} . A loss of integrity in the sarcolemma could cause a large influx of Ca^{2+} from the extracellular medium. Also, opening specific Ca^{2+} channels (e.g., dihydropyridine receptors) in the sarcolemma would allow the entry of extracellular Ca^{2+} . However, the dihydropyridine receptors in skeletal muscle do not normally appear to act as Ca^{2+} channels in the same manner that they do in other tissues. There are reports of altered dihydropyridine receptor binding,^{146,147} diminished maximum sarcolemmal Ca^{2+} accumulation,¹⁵⁸ and adenosine triphosphate-stimulated Ca^{2+} uptake in PSS.¹⁵⁹ Also, there is an altered Na^+ current and distribution of Na^+ channel subtypes in MH muscle.^{148,149}

Terminal Cisternae: Ca^{2+} Release. The terminal cisternae of the sarcoplasmic reticulum are the sites of Ca^{2+} sequestration. They are coupled to the t-tubules through *ryr1* and the dihydropyridine receptor (see Fig. 20-3). Several investigators have reported a hypersensitive Ca^{2+} -induced Ca^{2+} release in terminal cisternae preparations from porcine MH muscle.^{129,160,161,162} Also observed for PSS Ca^{2+} -induced Ca^{2+} release are an enhanced rate of release from skinned fibers¹⁶³ and terminal cisternae preparations.^{164,165} The maximum amount of Ca^{2+} released is normal for PSS vesicles.¹⁶⁶ In the human MH population, the Ca^{2+} release process appears to be less dramatically affected than that in PSS muscle. For example, the threshold of Ca^{2+} -induced Ca^{2+} release in terminal cisternae-containing fractions is not altered in a human MH population.^{161,167} Although the alterations in Ca^{2+} release reported in swine cannot be observed in isolated heavy sarcoplasmic reticulum preparations from humans, abnormalities in Ca^{2+} release are observed when preparations containing additional cellular components are examined, such as skinned fiber preparations (Fig. 20-4). MH subjects have a greater than normal rate and hypersensitivity of Ca^{2+} -induced Ca^{2+} release¹⁶⁸ and Ca^{2+} release is hypersensitive to caffeine using the skinned fiber preparation.¹⁶⁹

Figure 20-4. Methods to examine Ca^{2+} regulation. (1) *Terminal cisternae.* Skeletal muscle can be homogenized and resealed portions of the terminal cisternae containing the Ca^{2+} release channel (*ryr1*) can be recovered by a series of centrifugation steps. These vesicles can take up Ca^{2+} from the bathing medium by means of the ATP-driven Ca^{2+} pump and can subsequently release Ca^{2+} by opening of *ryr1*. Ca^{2+} levels in the extravascular medium can be monitored spectrophotometrically by a number of dyes (usually metalochrome indicators such as arsenazo III or antipyrilazo III). Alternatively, $^{45}\text{Ca}^{2+}$ and filtration of the vesicles can be used. The amount of calcium released is usually determined by the decrease in radioactivity retained on the filters that contain the vesicles. Both the spectrophotometric and radioisotopic approaches allow monitoring of Ca^{2+} uptake and Ca^{2+} release, and these processes can be dissociated pharmacologically with the *ryr1* blocker, ruthenium red. The terminal cisternae method allows the overall response of a large population of channels to be examined and may best reflect the overall responsiveness of the muscle. (2) *Planar lipid bilayers.* It is possible to incorporate *ryr1* into artificial lipid bilayers (i.e., planar lipid bilayer) and monitor the Ca^{2+} current as electrical charge movement through one to several channels at a time. Although this method can provide very useful, detailed information on the opening and closing of individual *ryr1*s, it does not provide an indication of the overall responsiveness of the muscle in which both Ca^{2+} uptake and Ca^{2+} release are participating and in which many modulating substances are present. (3) *Skinned fibers.* A third approach involves skinned fiber preparations in which the sarcolemma is either removed mechanically or made permeable chemically, and the function of the sarcoplasmic reticulum (Ca^{2+} uptake and release) and myofibrils (actin and myosin) monitored by the contractile response of the fiber. This preparation has an interesting advantage in that type I and type II fibers can be distinguished. Also, the t-tubules seal completely, allowing the function of the dihydropyridine receptors and Na^+ channels to be examined. This method only examines one muscle fiber at a time, which might be a slight disadvantage in MH or PSS skeletal muscle, because the defect is not uniformly expressed throughout the tissue. (4) *Ca^{2+} electrodes and fluorescence dyes.* The cytoplasmic Ca^{2+} levels can be monitored in intact muscle either with fluorescence dyes or Ca^{2+} electrodes. The former can monitor a muscle mass, while the latter examines individual fibers. Both approaches can be used with muscle fibers or cell culture systems.

With respect to anesthetic action, the rate of halothane-induced Ca^{2+} release is abnormally high in PSS-susceptibles.^{162,170} In contrast, in human MH muscle¹⁷¹ and PSS muscle,¹⁷² the dose-response curves for halothane-induced Ca^{2+} release are normal when the amount of Ca^{2+} release is monitored. The concentration of Ca^{2+} in the assay medium greatly influences the rate and amount of Ca^{2+} release by halothane.^{162,163} Therefore, it is believed that the differences observed in halothane-induced Ca^{2+} release in PSS muscle are actually due to an acceleration in Ca^{2+} -induced Ca^{2+} release by halothane. Free calcium was determined (with fura-2) in voltage-clamped human muscle fibers.¹⁷³ The kinetics and voltage dependence of calcium release for MH muscle was normal; however, the maximal peak rate of Ca^{2+} release increased about threefold. Although resting Ca^{2+} concentrations are normal, human skeletal muscle cell cultures have a twofold greater than normal sensitivity to halothane.¹⁷⁴ There is no effect of temperature on the rate of halothane-induced Ca^{2+} release.^{170,176}

In heavy sarcoplasmic reticulum preparations (containing triads and sarcoplasmic reticulum), halothane at clinically relevant concentrations cannot induce a sustained net Ca^{2+} release if physiologic levels of adenosine triphosphate and Mg^{2+} are included. This ability to overcome the effects of halothane under approximate physiologic conditions is due to the enormous capacity of the Ca^{2+} pumping system.¹⁶⁷ Transient net Ca^{2+} release at lower than clinical concentrations of halothane has been reported for PSS terminal cisternae preparations.¹⁷⁵ The addition of fatty acids, even to vesicles isolated from normal muscle, markedly (~20–30-fold) decreases the concentration of halothane required for the sustained opening of the Ca^{2+} release channel in the presence of adenosine triphosphate and Mg^{2+} .¹⁶⁷ Under these conditions, fatty acids can cause a sustained Ca^{2+} release at clinical concentrations of halothane. Unlike studies of Ca^{2+} release in the absence of fatty acids,¹⁷⁶ there is an absolute temperature dependence (occurs at 37°C, not at 25°C) of the fatty acid enhancement of halothane-induced Ca^{2+} release,¹³⁰ which is consistent with the temperature dependence of halothane-induced contractures of MH muscle.^{155,177}

Mitochondria. Mitochondria oxidize a variety of substrates to generate the form of energy (adenosine triphosphate) most useful for driving cellular reactions. Defects in mitochondrial function do not appear to initiate the MH syndrome. The uncoupling of Ca^{2+} -stimulated, but not adenosine diphosphate-stimulated, mitochondrial succinate oxidation has been demonstrated in muscle from pigs and humans¹⁷⁸ susceptible to MH. It is essential that these studies are conducted at physiologic temperatures (37–40°C), since a defect in uncoupling of Ca^{2+} -stimulated mitochondrial succinate oxidation does not occur at room temperature. This temperature dependence of mitochondrial uncoupling deserves attention.

Longitudinal Sarcoplasmic Reticulum: Ca^{2+} Uptake. The longitudinal sarcoplasmic reticulum (Fig. 20-3) is primarily involved in removing Ca^{2+} from the myoplasm

through the adenosine triphosphate-driven Ca^{2+} pump. While earlier studies had suggested a defect in Ca^{2+} uptake might cause the loss of Ca^{2+} regulation associated with MH, subsequent studies have ruled out a role for the Ca^{2+} pump in causing MH.¹⁷⁰

Myofibrils. Relatively few studies have been conducted on myofibrils in MH. However, there is apparently no defect in the Ca^{2+} sensitivity of the fast or slow fibers of the contractile system from MH skeletal muscle.

Proteins or Systems Reported Altered in Malignant Hyperthermia Muscle

Calcium Release Channel of Skeletal Muscle (*ryr1*)

Skeletal muscle *ryr1* is encoded by a different gene (chromosome 19q13.1) than *ryr2* (chromosome 1), which is the cardiac muscle equivalent of *ryr1*. A third ryanodine receptor (*ryr3*) with a wide tissue distribution is distinct from *ryr1* and *ryr2*. *Ryr1* is the primary conduit through which the sarcoplasmic reticulum stores of Ca^{2+} are released to the sarcoplasm.¹²⁶ *Ryr1* is an extremely large homotetramer, having subunits of about 560,000 MW each. *Ryr1* has binding sites for the contracture-inducing plant alkaloid ryanodine¹⁷⁹ and the preservative 4-chloro-*m*-cresol.¹⁸⁰

A mutation in *ryr1* is the hypothesis with the most substantial support to explain human MH. This hypothesis originated with the identification of the Arg⁶¹⁵ Cys mutation in porcine MH muscle. The *ryr1* mutation hypothesis is supported by biochemical studies demonstrating abnormal binding of ryanodine to *ryr1* in human MH muscle under specific nonphysiologic conditions¹⁷⁹ and by physiologic studies showing subtle effects of halothane on isolated *ryr1* currents in human MH muscle.¹⁸¹ In theory, the addition of halothane opens a hypersensitive *ryr1*, Ca^{2+} regulation becomes unstable, and this leads to an uncontrolled release of Ca^{2+} to the myoplasm and the MH syndrome. The hypersensitivity of *ryr1* may be due to a reduced inhibitory effect of Mg^{2+} on *ryr1*, as demonstrated for PSS muscle.¹⁸² The hypothesis in which a defect in *ryr1* directly leads to the MH syndrome is attractive and simple to understand. In conflict with this hypothesis, the buffering capacity of the Ca^{2+} pump in the presence of adenosine triphosphate is able to sustain normal Ca^{2+} regulation in the presence of halothane in terminal cisternae preparations isolated from MH muscle.¹³⁰ It also is difficult to explain the intra- and interindividual variability in human MH and the occurrence of nonrigid MH with this direct cause-and-effect hypothesis. Supporting the notion of *ryr1*'s crucial role in MH, investigators have reported genetic linkage of the locus encoding *ryr1* with a positive contracture test (see [Using Molecular Biology to Understand Malignant Hyperthermia](#)). However, many other genes are encoded in that region that also could be involved in MH.¹⁸³ Furthermore, studies have identified genetic linkage to chromosomes other than that encoding *ryr1*, suggesting that MH is a heterogeneous disorder (see [Using Molecular Biology to Understand Malignant Hyperthermia](#)).

Unlike the hypersensitive Ca^{2+} release in porcine muscle,¹⁶⁰ Ca^{2+} regulation in human MH heavy sarcoplasmic reticulum fractions appears to be normal.¹⁶¹ However, using planar bilayer approaches capable of monitoring single *ryr1* channels, subtle changes in the function of *ryr1* have been observed in human MH muscle,^{181,184} similar in some respects to those in PSS muscle in planar bilayers.¹⁸⁵ These differences relate primarily to an increased probability of the MH *ryr1*'s being in an open state. While differences between normal and PSS-susceptibles have been reported in the absence of halothane or caffeine,¹⁸⁵ human MH muscle requires the presence of caffeine¹⁸⁴ or halothane¹⁸¹ to detect differences in *ryr1* function. In human MH muscle two populations of ion channels appear to be present—one halothane-insensitive and the other halothane-sensitive.¹⁸¹ The halothane-sensitive channels have an increased probability of opening in the presence of clinically relevant concentrations of halothane. The halothane-sensitive channels do not occur in muscle from all MH patients, and both types (or states) of channels can coexist in the same muscle biopsy,¹⁸¹ is the case with the K_d of ryanodine binding.¹⁷⁹

Whether these subtle differences in *ryr1* function in planar bilayers, or the differences in K_d of ryanodine binding, in human muscle reflect a different acylation or phosphorylation state of *ryr1* should be investigated.

In agreement with the altered function of the PSS *ryr1*, there has been a specific mutation identified (Arg⁶¹⁵ to Cys⁶¹⁵) in *ryr1* in PSS.¹⁸⁶ The mutation is on the cytoplasmic surface of *ryr1*.¹⁸⁷ The porcine mutation may account for the altered functional states of *ryr1* and ryanodine binding in PSS swine. However, the porcine mutation does not appear to account directly for the caffeine sensitivity of PSS muscle.¹⁸⁸ Approximately 50% of the families with human MH exhibit linkage to the gene encoding *ryr1*.^{127,189,190,191,192,193,194,195,196,197,198,200,201,202,203,204,205,206} In the few (2–4%) MH families in which the human equivalent (Arg⁶¹⁴ to Cys⁶¹⁴) to the PSS *ryr1* mutation has been identified, the evidence for this mutation as a direct cause–effect is not as compelling as in porcine muscle, as there is discordance between inheriting the mutation and the outcome of the diagnostic test.^{197,198} Also, not all subjects known to have the Arg⁶¹⁴ Cys mutation have exhibited the MH syndrome. A major reason for the attenuated effects of the *ryr1* mutation in human muscle is likely the dominant mode of inheritance versus recessive inheritance in the pig. Thus, normal copies of *ryr1* are expressed in human MH muscle, but not PSS muscle. The number of mutations in *ryr1* reported at scientific meetings to date is about 30, including Arg⁶¹⁴ Cys, and this number is constantly rising. Each of these mutations commonly is found in only one or two families. None has an overall frequency in MH families of 10% or greater.^{33,199,200}

There is a twofold greater than normal sensitivity to halothane in cell cultures from MH muscle.¹⁷⁴ However, a twofold increase in sensitivity to triggering agents in cell culture does not equate to the much greater sensitivity of MH muscle to halothane observed *in vivo*. Transfection of human MH skeletal muscle cell cultures with normal (wild-type) *ryr1* does not result in the MH-negative phenotype (judged by sensitivity of Ca^{2+} transients to halothane), whereas expression of a mutated *ryr1* (Arg¹⁶³ to Cys¹⁶³) in normal muscle cells causes hypersensitivity to halothane.¹⁷⁴ Transfection of nonmuscle cell lines with any one of 19 *ryr1* mutations increased the sensitivity of the cells to relatively high concentrations of halothane and caffeine.^{202,203} Therefore, there is evidence that cell cultures may be useful models for elucidating the mechanisms by which MH mutations enhance the sensitivity of muscle to triggering agents (see also [Sodium Channel](#)).

In summary, there are physiologic, biochemical, pharmacologic, and molecular genetic data supporting a mutation in *ryr1* as an important factor, and perhaps an initiating factor, in about 50% of the families with MH. The effects of the altered *ryr1* function on Ca^{2+} regulation determined *in vitro* are not as pronounced in humans as in swine, possibly owing to the dominant mode of inheritance in humans. It is highly probable that other systems come into play as modulators of the MH response. This may better explain the extreme intra- and interindividual variability in the human MH syndrome, which is in contrast to the more consistent response in MH swine.

Sodium Channel

Skeletal and cardiac muscle sodium channels are composed of two subunits (a, 220,000 MW; b, 40,000 MW). The a subunit forms the ion pore, allowing Na^+ to enter the cell, and the smaller b subunit can modify the kinetics of the ion flux.^{204,205} Sodium channels in skeletal muscle are of two, and possibly three,¹⁵⁰ subtypes. These subtypes can be differentiated by their sensitivity to tetrodotoxin (TTX), a toxin from the puffer fish that blocks the channel pore. The adult sodium channel (SkM1) is 90% blocked by a 100 nM concentration of TTX. The “embryonic” sodium channel (SkM2) in skeletal muscle is identical to the cardiac sodium channel, and is blocked by a 10- μM concentration of TTX in cell culture. A third channel is expressed following denervation, and this subtype is not antagonized by TTX, even at a 100- μM concentration. The adult sodium channel a subunit, encoded on chromosome 17,^{204,205} was formerly believed to be the only subtype expressed in normal, mature skeletal muscle. The embryonic sodium channel a subunit appears early in muscle differentiation and is encoded on chromosome 3. Each of the a subunits interacts with the same b subunit (b_1), encoded on chromosome 19.²⁰⁶ Recently, the sodium channels of normal human skeletal muscle (vastus lateralis) were shown to be composed of approximately 50% SkM1 and 50% SkM2.¹⁵⁰ Specific mutations in the a subunit of SkM1 have been implicated as the cause of other disorders of skeletal muscle, including the myotonic form of hyperkalemic periodic paralysis,^{205,207} paramyotonia congenita,²⁰⁸ and myotonia fluctuans.²⁰⁹ These disorders are well known to exhibit masseter muscle rigidity and whole body rigidity to agents associated with the MH syndrome,²¹⁰ although they lack the signs of acidosis characteristic of MH.

A role for altered sodium channel function is becoming more evident in human MH. The function of the sodium channel is abnormal in primary cultures of human MH skeletal muscle.²¹¹ There are two populations of sodium currents separated by their kinetics of inactivation (*i.e.*, closing of the channel). These are the normally inactivating and delayed inactivating fast sodium currents. There is a greater proportion of the slow inactivation of the Na^+ current in cultured human MH muscle¹⁴⁸ that would keep the sodium current active for a longer time (delayed inactivation). The consequence of this prolonged sodium current in MH muscle is a longer membrane depolarization and increased period of Ca^{2+} release from the terminal cisternae. The increased levels of intracellular Na^+ would have to be removed by Na^+/K^+ -adenosine triphosphatase activity. Additionally, the accumulation of Na^+ likely activates $\text{Na}^+/\text{Ca}^{2+}$ exchange and could account for the need for extracellular Ca^{2+} for *in vitro* halothane-induced contractures. Studies in swine also have suggested that halothane selectively affects either time-dependent Na^+ or K^+ currents in PSS muscle, in agreement with the findings in human MH muscle.²¹² A toxin from the sea anemone (ATX II) causing delayed inactivation of the sodium current, as found in human MH muscle cultures, enhances the response of normal muscle to halothane, caffeine, and ryanodine.²¹³ This finding supports a role for altered Na^+ channel currents in the response of MH muscle to triggering agents. Veratridine, also a sodium channel inhibitor, enhances the response of MH muscle to halothane.²¹⁴ Therefore, altered Na^+ currents may be important for at least some of the signs associated with MH. Those patients expressing sodium channel abnormalities may be more likely to exhibit certain signs, such as muscle rigidity.

The expression of sodium channel subtypes is also altered in MH skeletal muscle. SkM2 (embryonic form) appears to be down-regulated in MH, in cell culture systems, or in biopsies of vastus lateralis muscle.¹⁴⁹ This would lead to a predominance of SkM1 in MH muscle. SkM1 is more sensitive to halothane than SkM2.²¹⁵ There are

immunologically distinct differences between t-tubule Na⁺ channels and those on the surface membrane.²¹⁶ Therefore, the distribution of sodium channel subtypes within the t-tubules could be altered in MH. Preliminary studies have demonstrated that transfection of muscle cell cultures with cDNA encoding *ryr1*, and containing mutations associated with MH, causes down-regulation of SkM2.²¹⁷ Therefore, down-regulation of SkM2 in MH muscle appears to be the result of a sequence of events initiated by the MH mutation. While the significance of altered SkM1 and SkM2 expression is less clear than that of altered sodium channel function, an increase in the SkM1 subtype may increase the sensitivity to triggering agents.

Fatty acid production is elevated in MH (see [Elevated Fatty Acid Production](#)). Fatty acids modulate the expression of the skeletal muscle sodium channels from normal patients.¹⁴⁹ Intracellular injection of fatty acids into primary cell cultures of normal human skeletal muscle turns on inactive adult Na⁺ currents.²¹¹ In contrast, the adult Na⁺ channels in primary cultures of skeletal muscle from MH-susceptible humans are apparently already maximally active, even without injected fatty acid, and the intracellular injection of fatty acids has no further effect.²¹¹ Therefore, the sodium channel in MH cell cultures acts as if fatty acids are elevated, and this may account for the greater proportion of SkM1:SkM2 ratio in MH muscle. Based on the above results, the MH mutation may increase fatty acid production, which then decreases the expression of SkM2.

There also is evidence for linkage of MH to chromosome 17^{218,219} at or near the locus encoding the Na⁺ channel α subunit.²²⁰ In one family, a Gly1306Ala mutation in the sodium channel known to cause myotonia fluctuans cosegregated with MH susceptibility, as determined by contracture testing.²²¹ Two of these patients had whole body rigidity and/or masseter muscle rigidity to succinylcholine, although without metabolic acidosis. As with *ryr1*, it is not clear in most cases if the altered function reflects a primary defect in the Na⁺ channel protein, or if the function is altered indirectly by processes such as phosphorylation or acylation.²²²

In summary, changes in sodium channel expression or function could be the result of mutations within a sodium channel subtype, or a secondary effect of a primary mutation in another protein (e.g., *ryr1*). Also, second-messenger systems, such as fatty acids, may play a role in altered sodium channel function and expression. These changes in sodium channel function may be essential for the phenotypic expression of certain aspects of the MH syndrome, such as muscle rigidity.

Elevated Fatty Acid Production

Lipids are an important component of a cell, as they provide energy and structure (e.g., membranes) and participate in function. Several lipid metabolites, including fatty acids, serve second-messenger functions.²²⁴ Fatty acids are the major source of energy in the resting state of skeletal muscle and can also contribute up to 65% of the energy during exercise.²²⁴ Fatty acids provide about 70% of the energy in resting muscle. Therefore, fatty acid utilization is likely up-regulated in MH muscle to compensate for the energy consumed by the adenosine triphosphatases attempting to maintain Na⁺ and Ca²⁺ homeostasis. Intramuscular triacylglycerides have been reported as utilized during an MH crisis in swine.²²⁵

In addition to existing in a free form, fatty acids are esterified to phospholipids, triacylglycerides, diacylglycerides, monoacylglycerides, cholesterol esters, and many proteins. Free fatty acids are maintained at very low levels in a cell (since they are not only essential, but very toxic) and most of the "free" fatty acids actually are bound to fatty acid-binding proteins.²²⁶

Fatty acid production is elevated in mitochondrial fractions¹⁷⁸ and whole muscle homogenates²²⁷ from PSS and MH susceptibles. There is an age-related increase in fatty acid production in skeletal muscle that parallels an age-related increase in susceptibility to the PSS.¹³⁸ When only static levels of free fatty acids are examined, they are at normal levels in human MH¹⁵¹ and PSS muscle. However, the flux of fatty acids through β -oxidation can still be increased to a large extent in MH muscle without increasing the levels of free fatty acids. The fatty acid flux is derived from triacylglycerides, and this likely accounts for the low levels of triacylglycerides (or total neutral lipid) in biopsied MH or PSS skeletal muscle.^{167,228} The hormone-sensitive lipase (chromosome 19q13.1) has been suggested to be a gene candidate,¹⁸³ as this enzyme liberates fatty acids from triacylglyceride.

The effects of fatty acids on Ca²⁺ release from skeletal muscle sarcoplasmic reticulum are significant, but not dramatic, in the absence of anesthetics,^{229,230} and they are not mediated through *ryr1*.²³¹ However, the fatty acids act in synergy with halothane and decrease the amount of halothane required for sustained Ca²⁺ release by 20–30-fold!^{130,161} This fatty acid enhancement of halothane-induced Ca²⁺ release, in contrast with all other studies of Ca²⁺ release, exhibits the same temperature dependence (i.e., it occurs only at 37°C, not at 25°C) as halothane-induced contractures of skeletal muscle and is mediated through *ryr1*.¹³⁰ While the concentration of fatty acid required for this effect exceeds that of the normal unbound form, halothane can displace fatty acids from fatty acid-binding proteins.²³² Therefore, it is highly likely that sufficient concentrations of fatty acids could be achieved at the site of halothane action. If the production of free fatty acids is sustained by accelerated triacylglyceride breakdown and the fatty acids are shunted toward acylation of *ryr1* and the sodium channel, then this could lead to greatly elevated myoplasmic Ca²⁺ levels. In the case of *ryr1*, this would lead to a greater sensitivity to halothane [see [Calcium Release Channel of Skeletal Muscle \(*ryr1*\)](#)]. For the sodium channel, this would cause an increase in relative expression of SkM1:SkM2 (see [Sodium Channel](#)).

Phospholipase C and Inositol 1,4,5-Trisphosphate

Phosphatidylinositol phospholipids have become of interest in MH since one specific metabolite of phospholipase C action, IP₃, has been demonstrated to be elevated in human MH²³³ and PSS²³⁴ muscle, but not in MH human blood specimens.²³³ This product of the hydrolysis of the phospholipid, phosphatidylinositol 4,5-bisphosphate, causes Ca²⁺ release from intracellular stores.²³⁵ The elevation of all products of phosphatidylinositol hydrolysis is observed,²³⁵ and this suggests that phospholipase C activity may be elevated in MH. Activation of phospholipase C in skeletal muscle also elevates diacylglycerol and indirectly elevates free fatty acids by deacylation of the diacylglycerol. Diacylglycerol and fatty acids have diverse cell signaling effects.^{223,236} In addition to elevated IP₃ production, MH muscle is also hypersensitive to IP₃.²³⁷ Therefore, secondary involvement of this system could have multiple effects that together increase the sensitivity of Ca²⁺ release.

Antioxidant Defense

The antioxidant defense abnormality reported in PSS²³⁸ is especially interesting as it could be either the cause or the effect of accelerated fatty acid production. In either case, it provides a novel target site for prophylactic and therapeutic intervention.²³⁹ Observations supporting an antioxidant defense abnormality in PSS include the production in plasma of excess thiobarbituric acid reactive substances and conjugated dienes, which are nonspecific markers of peroxidation of unsaturated fatty acids.^{238,239} Despite an antioxidant defense abnormality, the levels of skeletal muscle antioxidants and antioxidant enzymes examined are normal. Excessive peroxidation could contribute to the loss of Ca²⁺ regulation in MH muscle. These studies have suggested that vitamin E may be an antagonist of the MH episode, although at least one study has suggested otherwise.²³⁹

Phosphorylation Activity

Higher than normal levels of phosphorylation and altered sensitivity to protein phosphatase inhibition have been reported in porcine MH muscle. Altered phosphorylation could be either a primary or secondary defect in MH. As a secondary defect, perhaps as a result of fatty acid and/or diacylglycerol activation of protein kinase C, such activity could play a modulatory role in MH, as suggested for fatty acids.

Molecular Biology and Malignant Hyperthermia

Modern molecular biology provides powerful approaches for identifying and understanding mutations in genetic disorders. These studies can be conducted with no prior knowledge of the actual proteins involved through a process termed reverse genetics. Using some of the techniques of reverse genetics (restriction fragment length polymorphisms and linkage analysis), it was determined that MH is a heterogeneous disorder.^{126,219,240} Linkage of MH (based on contracture test data) has been reported to markers on regions of chromosomes 1q,²⁴² 3q13.1,²⁴¹ 5p,²⁴² 7q21.1,²⁴⁰ 17q11.2-q24,^{218,219} and 19q13.1.^{190,193} The identification of a gene locus is only the first step in the process of reverse genetics. It then becomes much more difficult to narrow the large stretches of DNA identified by linkage down to a single gene and mutation(s) within that gene.

Once the actual genes have been identified, the proteins responsible may be elucidated and the pathophysiology understood. For example, based on the localization of the gene for Duchenne's dystrophy to the X chromosome, it was eventually determined that patients with this disorder did not manufacture a specific protein (dystrophin), which is now believed to be needed for the maintenance of muscle cell integrity. However, for MH the process of identifying the responsible genes could be a far greater task than that for Duchenne's muscular dystrophy for several reasons. First, since there are several chromosomes involved, each presumably with any of a number of specific mutations, we may never know when we have identified all causes of MH. Second, the mutations identified to date have all been point mutations, which are more difficult to identify than the large areas of deletion associated with Duchenne's muscular dystrophy. Third, the only way to phenotype individuals is by the *in vitro* contracture test, and many family members may choose not to undergo this procedure.

Two genetic findings have been repeatedly demonstrated and seem certain. First, chromosome 19q13.1 is linked to about 50% of the families with MH first demonstrated by the MacLennan¹²⁶ and McCarthy¹⁸⁹ groups. Second, more than one gene can cause MH.^{127,243} The number of reported mutations associated with MH in the most studied protein, *ryr1*, is approaching 30 (21 are published). In addition, four of these mutations (Arg163Cys,²⁴² Ile403Met,²⁴⁴ Arg2434His,²⁴⁵ Tyr522Ser²⁴⁶) have been associated with both central core disease (CCD) and MH. While early genetic studies had suggested 100% concordance of MH and CCD,^{243,244} other studies have found the relationship to be less clear.^{247,248}

A mutation associated with MH has been reported in the α_1 subunit of the human skeletal muscle, dihydropyridine-sensitive, L-type voltage-dependent calcium channel (dihydropyridine receptor). The Arg to His substitution at residue 1086 results from the nucleotide substitution of G3333A.²⁴⁹ One mutation (Gly1306Ala) has been described in the adult Na⁺ channel α subunit associated with myotonia fluctuans that correlates with the diagnosis of MH in a North American family.²²¹ The same mutation occurring in a German family did not correlate with a positive contracture test for MH.²⁰⁹ Perhaps coinheritance of a second factor is required for a positive diagnosis in some Na⁺ channel mutations.

There have been several reports of discordance between segregation of mutations identified in *ryr1* and the outcome of the *in vitro* contracture test for MH.^{197,198,250} This discordance is relatively rare and the reason for it is unknown. However, a study in swine has demonstrated that there is an excellent correlation between the contracture test outcome and the genetic susceptibility for MH. Nonetheless, it is still possible that a false diagnosis may occur, as the sensitivity and specificity of the diagnostic tests are not 100%.²⁵¹ Alternatively, the involvement of modulating factors in a positive contracture test, as demonstrated with the sodium channel,²¹³ may influence the diagnostic outcome.

In summary, none of the *ryr1*, Na⁺ channel, or dihydropyridine receptor mutations has been conclusively demonstrated as the direct cause of the human MH syndrome, while the Arg⁶¹⁵ Cys mutation in *ryr1* is almost certainly the cause of porcine MH. This discrepancy most likely is due to the recessive mode of inheritance in swine and dominant mode of inheritance in humans. The human MH syndrome appears to be highly dependent on modulators that are secondarily affected by the primary mutation. No single mutation accounts for the majority of MH, suggesting that a large percentage of MH may be due to spontaneous mutations. Strong evidence exists for the involvement of mutations in *ryr1* in human MH; however, some of the reported mutations could be polymorphisms unrelated to MH. Also, some of the mutations may have an association with MH, but cannot be causative on their own. These mutations may trigger a sequence of events that are dependent on the expression of modulating factors modifying the MH episode.

A Hypothesis to Explain Many Observations in Human Malignant Hyperthermia Muscle

Cause-effect relationships between the primary defect and the human MH syndrome are unclear. It is clear that the function or structure of several proteins is altered in MH skeletal muscle. Skeletal muscle from MH susceptible patients exhibits elevated fatty acid production. Fatty acid production is likely up-regulated as an energy source to pump excess Ca²⁺ out of the myoplasm (Fig. 20-4). Fatty acids modify the function of *ryr1*, especially the response to halothane, and expression of subtypes of the Na⁺ channel. These effects of fatty acids may play an important role as a modulator of the syndrome. We postulate that the pathophysiologic change during a MH crisis results from widespread alteration of protein function secondary to elevated utilization of fatty acids. Phospholipase C activity and protein phosphorylation are other systems that affect a wide variety of proteins and could play a role in modifying the expression of the MH syndrome.

The Future of Research in Malignant Hyperthermia

While molecular genetics has dominated the research in MH in recent years, a deeper understanding of the physiology and biochemistry of the interplay among *ryr1*, the Na⁺ channel, and fatty acid metabolism still is needed. DNA-based linkage analyses are no longer pursued to the same extent as in the early 1990s. Instead, the focus of recent molecular genetic studies has been on identifying new mutations in *ryr1*. Further linkage studies are necessary to identify other chromosomes linked to MH. Molecular genetic approaches may be the only hope for a diagnostic blood test. However, such a test will be restricted to the few families (less than 20% of families to date) in which a specific proven causative mutation is known to exist.

Summary

The defect for MH appears to be expressed only in skeletal muscle in humans, and the consequences of the defect are manifest in virtually all organelles in skeletal muscle. Any one of at least six different genes may cause MH, although the exact proteins remain to be identified in some cases. Mutations have been identified in *ryr1* and the dihydropyridine receptor. A mutation in a sodium channel subunit may be associated with some signs of MH, but this requires the expression of other factors. A disturbance in fatty acid metabolism, as a secondary effect, alters the function of several organelles and can lead to a hypersensitive *ryr1* response to halothane and altered Na⁺ channel subunit expression in skeletal muscle. The MH syndrome is the result of a complex and poorly understood interaction among several systems in skeletal muscle.

OTHER INHERITED DISORDERS

Inherited diseases affect every bodily organ and every physiologic and biochemical process. Some are mild and allow a relatively normal life span, whereas others are incompatible with extrauterine existence even for a few days. Adding to the complexity is a natural variability of genetic penetrance and expressivity even in a single family. All of these disorders have as a common feature an abnormality in one or more genes that affects the function of one or more enzymes. The metabolic basis of inherited diseases is the subject of several well-known books,²⁵² which may be consulted for an in-depth appreciation of our state of knowledge of many of these disorders.

Disorders of Plasma Cholinesterase

Plasma cholinesterase, *pseudocholinesterase*, or *nonspecific cholinesterase* is an enzyme with a molecular weight of 320,000 and a tetrahedral structure. It is found in plasma and most tissue but not in red blood cells. Pseudocholinesterase degrades acetylcholine released at the neuromuscular junction, as well as other choline and aliphatic esters.²⁵³ The half-life of pseudocholinesterase has been estimated to be 8–16 hours. It is very stable in serum samples and can be stored for long periods of time at -20°C with little or no activity loss. Cholinesterase is manufactured in the liver. Therefore, decreased plasma cholinesterase activity occurs in advanced cases of hepatocellular dysfunction.

Inherited variants of pseudocholinesterase are of interest to the anesthesiologist because the duration of action of succinylcholine, mivacurium, and (in some cases) ester-linked local anesthetics, as well as the toxicity of cocaine,²⁵⁴ is a function of the activity of this enzyme system. Prolonged apnea after succinylcholine, or mivacurium, administration occurs in patients who have very low absolute activity of pseudocholinesterase or have enzyme variants.²⁵⁵ These patients otherwise have no symptoms.

Many physiologic, pharmacologic, and pathologic factors can either increase or decrease the activity of this enzyme to a significant extent. However, it is only when there is a >75% decrease in the levels of the normal pseudocholinesterase that there is clinically evident prolongation of succinylcholine activity (see below). Table 20-2 lists some of the causes for variation in plasma cholinesterase activity.

| Category | Subcategory | Specific Factors |
|----------|-------------|---|
| Genetic | Deficiency | Atypical (A), Homozygous (A/A) |
| | Variant | Atypical (A), Heterozygous (A/a) |
| | Deficiency | Atypical (A), Homozygous (A/A) |
| | Variant | Atypical (A), Heterozygous (A/a) |
| | Deficiency | Atypical (A), Homozygous (A/A) |
| Acquired | Deficiency | Liver disease, Malnutrition, Alcoholism, Pregnancy, Burns, Trauma, Shock, Infection, Hemodialysis, Placental transfer |
| | Variant | Liver disease, Malnutrition, Alcoholism, Pregnancy, Burns, Trauma, Shock, Infection, Hemodialysis, Placental transfer |
| | Deficiency | Liver disease, Malnutrition, Alcoholism, Pregnancy, Burns, Trauma, Shock, Infection, Hemodialysis, Placental transfer |
| | Variant | Liver disease, Malnutrition, Alcoholism, Pregnancy, Burns, Trauma, Shock, Infection, Hemodialysis, Placental transfer |
| | Deficiency | Liver disease, Malnutrition, Alcoholism, Pregnancy, Burns, Trauma, Shock, Infection, Hemodialysis, Placental transfer |
| Drugs | Deficiency | Chlorpromazine, Chlorzoxazone, Ethacrynic acid, Ethanol, Fluorimazine, Halothane, Propofol, Thiopental |
| | Variant | Chlorpromazine, Chlorzoxazone, Ethacrynic acid, Ethanol, Fluorimazine, Halothane, Propofol, Thiopental |
| | Deficiency | Chlorpromazine, Chlorzoxazone, Ethacrynic acid, Ethanol, Fluorimazine, Halothane, Propofol, Thiopental |
| | Variant | Chlorpromazine, Chlorzoxazone, Ethacrynic acid, Ethanol, Fluorimazine, Halothane, Propofol, Thiopental |
| | Deficiency | Chlorpromazine, Chlorzoxazone, Ethacrynic acid, Ethanol, Fluorimazine, Halothane, Propofol, Thiopental |

Table 20-2. SOME CAUSES OF CHANGES IN CHOLINESTERASE ACTIVITY

Succinylcholine-Related Apnea

Succinylcholine is hydrolyzed by a two-step process, first to succinylmonocholine and then to succinic acid. It has been estimated that only about 5% of the injected drug reaches the end-plate region because of a combination of both hydrolysis and diffusion from the plasma. Urinary excretion and protein binding play unimportant roles in the disposition of the drug when plasma cholinesterase activity is normal. The rate of metabolism determines the duration of action of succinylcholine.

A variety of assay procedures are available for pseudocholinesterase activity. However, most involve the reaction of a thiocholine (e.g., butyrylthiocholine) with serum or plasma containing cholinesterase. The reaction product is coupled with 5,5'-dithiobis(2-nitrobenzoic acid) and forms a colored product that can be followed spectrophotometrically. The use of benzoylcholine, a specific substrate for plasma cholinesterase, avoids contamination of the assay for plasma cholinesterase by the esterase in red blood cells which is released when hemolysis occurs.

Kalow *et al* were the first to show that qualitative as well as quantitative differences in the pseudocholinesterase enzyme determine the duration of succinylcholine apnea.²⁵⁶ Kalow found that in certain persons displaying succinylcholine sensitivity, the local anesthetic dibucaine (Nupercaine) inhibited the hydrolysis of a benzylcholine substrate less than it inhibited the reaction in those displaying a normal response to succinylcholine. Thus, this atypical phenotype may be referred to as dibucaine-resistant. The percentage inhibition of the reaction was termed the *dibucaine number*. It was found to be constant for a person and did not depend on the concentration of the enzyme.

A discontinuous distribution of dibucaine numbers suggested an inheritance pattern based on alteration at a single gene locus (Table 20-3). Those with dibucaine numbers in the range of 80 would be homozygous normal with a normal response to succinylcholine, those with dibucaine numbers of 20 would be homozygous atypical with a marked prolongation of succinylcholine activity, and those with dibucaine numbers in the 60 range would be heterozygous and, in general, have a normal response to succinylcholine. This theory was substantiated by other workers.

| Genotype | Cholinesterase Activity | Dibucaine Number | Fluoride Number | Choline Number | Succinylcholine Number |
|----------|-------------------------|------------------|-----------------|----------------|------------------------|
| EaEa | 67-100 | 70-80 | 35-60 | 1-10 | 80-85 |
| EaEe | 16-25 | 30-50 | 30-50 | 40-80 | 4-10 |
| EaEe | 35-100 | 3-70 | 30-50 | 15-20 | 30-70 |
| EeEe | 25-40 | 70-80 | 4-8 | 30-30 | 0-10 |
| EeEe | 45-60 | 0-9 | 5-10 | 30-30 | 30-90 |
| EeEe | 0 | 0 | 3 | 5 | 0 |

Ea = normal enzyme gene; Ee = atypical enzyme gene; Ee = fluoride-resistant gene; Ee = silent gene.
Reprinted with permission from Vib-Mogensen J. Succinylcholine neuromuscular blockade in subjects homozygous for atypical plasma cholinesterase. *Anesthesiology* 55:291-193.

Table 20-3. BIOCHEMICAL CHARACTERISTICS OF SOME CHOLINESTERASE VARIANTS

Over the years, two other major allelic variants were discovered. In one case, the silent gene, the enzyme is not produced. In the other, there is a differential inhibition of cholinesterase activity by fluoride.²⁵⁷ In those with prolonged duration of succinylcholine activity with this genotype, fluoride ion inhibits the *in vitro* hydrolysis of substrate by the enzyme less than it does in normals. Thus the phenotype may be referred to as fluoride-resistant. A *fluoride number*, similar to a dibucaine number, is thereby created. Other variants exist.

When there is a question of succinylcholine sensitivity, the absolute activity of pseudocholinesterase should be determined as well as the dibucaine and fluoride numbers. In some cases, because of biologic variability or unusual combinations of genotype (e.g., combination of atypical and fluoride genes), it is helpful to use other inhibitors of the cholinesterase reaction in genotyping the patient. Bromide, urea, sodium chloride, and succinylcholine have been used to distinguish the various genotypes (see Table 20-3).

Molecular genetic techniques have been successfully applied to pseudocholinesterase variants. La Du's laboratory has identified a point mutation in the gene for human serum cholinesterase in which a nucleotide change leads to an alteration of a single amino acid (adenine to guanine) in the protein.²⁵⁸ This change apparently alters the affinity of atypical cholinesterase for choline esters. Other base pair alterations account for other atypical variants, including the K and J silent gene variants, which, while common, produce little to no clinical prolongation of succinylcholine action (Table 20-4).²⁵⁹

| | |
|------------|---------------------|
| Atypical | 70ASP→GLY |
| Silent | 117 GLY→Frame shift |
| Fluoride-1 | 243 THR→MET |
| Fluoride-2 | 390 GLY→VAL |
| K Variant | 539 ALA→THR |
| H Variant | 142 VAL→MET |
| J Variant | 497 GLU→VAL |

Table 20-4. STRUCTURAL CHANGES OF BCHE VARIANTS

The identification of the genetic defect offers the prospect that more accurate and precise diagnostic tests for atypical pseudocholinesterase variants will be offered soon.

The frequencies of occurrence of the various genes vary to some extent with ethnic background. For example, South African blacks²⁶⁰ and Eskimo populations have the silent gene much more frequently, patients with Huntington's chorea are more likely to have an Ee gene (fluoride-resistant) than are normal controls, and Israelis have a higher chance of having an atypical genotype than Americans. In European studies, the approximate percentages in the population of the genotypes are as follows: EuEu (96%), EuEa (2.5%), EuEe or EuEs (0.3%), EaEe (0.005%), EaEa (0.05%), and EeEe or EeEs (0.006%).²⁶¹

Patients homozygous for atypical, fluoride, or silent genes as well as those with the combination of atypical with fluoride, atypical with silent genes, or fluoride with silent genes should wear safety identification bracelets indicating that succinylcholine administration will lead to prolonged apnea. Relatives should be tested as well. There are only a few cholinesterase research units that investigate families and interpret results: Whittaker's in Great Britain, Hanel and Viby-Mogensen's in Denmark, and La Du's in the U.S. (University of Michigan, Department of Anesthesiology).

Clinical Implications of Pseudocholinesterase Abnormalities

Important questions for the anesthesiologist are: Which patients are at risk for development of an abnormal response to succinylcholine? What are the clinical characteristics of this response? and What are the treatment options?

Significant prolongation of succinylcholine's effects occurs in the following genotypes: EaEa, EeEe, EaEs, EeEa, and EsEs. The more common situations in which homozygote normals and heterozygotes are at risk are as follows: patients who have been receiving echothiophate eyedrops (up to 2 weeks after therapy is discontinued), patients who are undergoing plasmapheresis,²⁶² patients with severe liver disease, and patients (particularly heterozygotes) who have received

succinylcholine after reversal of nondepolarizing blockade with neostigmine.

Viby-Mogensen^{263,264} has studied the question of plasma cholinesterase apnea in detail. His cholinesterase unit found that 6.2% of patients who displayed apnea for 50–250 minutes after a “usual” dose of succinylcholine had an acquired deficiency of plasma cholinesterase. He then studied 70 patients who were genotypically normal for pseudocholinesterase and administered $1.0 \text{ mg} \cdot \text{kg}^{-1}$ of succinylcholine during a 50% nitrous oxide–oxygen–1% halothane anesthetic and followed the depression and return of thumb twitch. He found that there was indeed a relationship between the duration of apnea, the return of a full twitch response, and plasma cholinesterase activity.²⁶⁹ However, only moderate prolongation of apnea was found when cholinesterase was depressed by as much as 70%. Apnea is significantly prolonged only with extreme depression of cholinesterase activity.

In a second study with a similar protocol, he found that heterozygotes having one normal gene (e.g., EuEa, EuEf) had a normal response to succinylcholine, including typical fasciculations and a depolarizing type of block with train-of-four stimulations.²⁶³ However, heterozygotes without the usual gene (e.g., EaEf) had a prolonged response to succinylcholine, with apnea lasting as long as 24 minutes. Most showed typical fasciculations. Fade with train-of-four stimulations was the rule. It should be noted that others have found that heterozygotes with one normal gene display a prolonged response to succinylcholine under certain conditions. About 1 in 500 heterozygotes is prone to such a response.

Apnea lasts from 120 minutes to more than 300 minutes in homozygous atypical patients (EaEa) when they are given succinylcholine.²⁶⁴ The onset of neuromuscular block is similar to that in normals; however, there is fade in response to train-of-four stimulation. The other class of patients who regularly display prolonged apnea after succinylcholine administration comprises patients who are homozygous for the silent gene.

Treatment of Succinylcholine Apnea

The safest course of treatment after the patient fails to breathe within 10–15 minutes after succinylcholine administration is to continue mechanical ventilation until adequate muscle tone has returned. Two units of blood may contain adequate amounts of pseudocholinesterase to hydrolyze the succinylcholine,²⁶⁵ although blood transfusion is not recommended for routine treatment of succinylcholine-induced apnea.

The use of cholinesterase inhibitors in treating succinylcholine apnea is controversial. When given along with blood or plasma, the improvement is rapid and lasting. If they are administered alone before there is evidence of fade with train-of-four stimulation, there may be a transient improvement followed by intensification of the neuromuscular block. Remember that neostigmine inhibits the degradation of succinylcholine by plasma cholinesterase. The best chance for reversal of succinylcholine-related apnea in these situations occurs when no more than $0.03 \text{ mg} \cdot \text{kg}^{-1}$ of neostigmine is given 90–120 minutes after succinylcholine when a nondepolarizing type of blockade is present.

C5 Variant

An isoenzyme of pseudocholinesterase has been demonstrated whereby the hydrolysis of succinylcholine is increased, and therefore the duration of apnea is decreased after succinylcholine administration. The gene does not appear to be an allele of the Eu and Ea gene and is found infrequently in the population.²⁶⁶

Plasma Cholinesterase Abnormalities and the Metabolism of Local Anesthetics

Although the ester-linked local anesthetics (e.g., procaine, tetracaine, 2-chloroprocaine) are metabolized by pseudocholinesterase, prolongation of block and/or clinical toxicity of these local anesthetics in homozygous atypical patients has rarely been documented.^{267,268} Jatlow *et al* have shown delayed hydrolysis of cocaine *in vitro* with plasma from homozygote atypicals.²⁶⁹ They theorized that such persons may be at risk for toxic reaction from normal doses of cocaine.

Mivacurium Disposition and Plasma Cholinesterase. Despite being a nondepolarizing relaxant, mivacurium is metabolized to a significant extent by pseudocholinesterase. Although it is theoretically possible to reverse neuromuscular block in patients with atypical pseudocholinesterase who receive mivacurium, the few cases so far reported indicate that anticholinesterase agents may not be effective under such situations. These individuals should be managed in a manner similar to patients with the atypical enzyme who received succinylcholine.²⁷⁰ When abnormal plasma cholinesterase does not metabolize mivacurium as rapidly as expected, the neuromuscular blocker is cleared by the kidneys as curare is. The most rapid adequate recovery from mivacurium-induced block will be obtained when the plasma concentration of mivacurium has decreased to the level at which 3–4 responses to a train-of-four stimulation to the ulnar nerve are palpable. Then neostigmine should induce recovery as it would from blocker that was expected to be long-acting.

THE PORPHYRIAS

All the porphyrias result from a defect in heme synthesis. The heme pigments are tetrapyrroles that are the essential elements in hemoglobin, myoglobin, and the cytochromes, *i.e.*, compounds that are involved in the transport of oxygen, activation of oxygen, and the electron transport chain. Cytochrome P-450 is a hemoprotein intimately involved in the conversion of lipid-soluble nonpolar drugs to soluble polar compounds that may be excreted in the urine.

A complete deficiency of enzymes that are involved in heme synthesis is incompatible with life. However, a partial deficiency may lead to the accumulation of one or more of the molecular intermediates in heme production. Such an accumulation of precursors is responsible for the clinical manifestations of the porphyrias (in an as-yet unexplained manner).

The rate-limiting step in heme synthesis is the conjugation of succinyl-CoA with glycine to form D-aminolevulinic acid (the enzyme is aminolevulinic acid synthetase). In the porphyrias, there is a partial deficiency of enzymes subsequent to this initial step, which results in a stimulation of this reaction to form aminolevulinic acid. The result is overproduction of intermediate products before the deficient step (Fig. 20-5).

Figure 20-5. Biosynthesis of heme and sites of defects in certain porphyrias. (ALA = aminolevulinic acid; PGB = porphobilinogen; URO = uroporphyrinogen; COPRO = coproporphyrinogen; PROTO = protoporphyrinogen; PRO = protoporphyrin.) In intermittent acute porphyria, there is a partial deficiency of the enzyme at site 1. In hereditary coproporphyria, there is an enzyme deficiency at site 2. In variegate porphyria, the enzyme problem is at site 3. In porphyria cutanea tarda, there is a deficiency at site 4. (Reprinted with permission from Mees DL, Frederickson EL: Anesthesia and the porphyrias. *South Med J* 68:29, 1975.)

The porphyrias generally manifest after puberty. Inheritance is through an autosomal dominant pattern, but congenital erythropoietic porphyria is inherited as an autosomal recessive pattern.

A functional classification for the anesthesiologist is based on a division of the porphyrias into inducible and noninducible forms. The inducible porphyrias are those in which the acute symptoms are precipitated on drug exposure (Table 20-5).²⁷¹ These forms are acute intermittent porphyria, variegate porphyria, and hereditary coproporphyria. These porphyrias cause an acute neurologic syndrome and are therefore of interest to the anesthesiologist. Cutaneous manifestations, with particular sensitivity to ultraviolet light exhibited by skin fragility and bleeding, are the chief features of the other porphyrias. About 80% of patients with variegate porphyria are photosensitive. Some patients with hereditary coproporphyria also may have skin lesions. The porphyrias are very difficult to diagnose in the latent phase of the disorder. Direct assay of the intermediates themselves may be used in the acute state to measure the elevated levels of the heme intermediates. The inducible

porphyrias are seen as a neurologic syndrome with a variety of presentations.

Table 20-5. DRUGS KNOWN TO PRECIPITATE PORPHYRIA

The central, peripheral, and autonomic nervous systems may be involved in the porphyrias. A frequent manifestation is colicky abdominal pain, often with nausea and vomiting, which may suggest the diagnosis of acute abdomen, leading to exploratory laparotomy. Other symptoms are psychiatric disturbance, quadriplegia, hemiplegia, alterations of consciousness, and pain. Hyponatremia and hypokalemia may result from vomiting during the acute attack or may be related to hypothalamic disturbance. Death may result from paralysis of the respiratory muscles. The cause of these changes is unknown; they may be related to metabolites of the intermediates or result from deficiency of the heme pigment in the nerve cell itself.

A number of patients with concurrent human immunodeficiency virus and porphyria cutanea tarda have been recognized. The etiology of the association of these two disorders is unknown at this time.²⁷²

Because the porphyrias are unusual disorders, there is limited experience with the clinical use of many anesthetic drugs. *In vitro* studies suggest that certain anesthetics or anesthetic adjuvants may be contraindicated, but sufficient clinical experience is lacking (see below).²⁷³

Management of Patients with Porphyria

It is important to recognize porphyria in patients who are scheduled for surgery. It may become apparent through a careful family history and personal history related to anesthesia. A careful history in the patient with porphyria should concentrate on neurologic background. Laboratory work should include electrolyte and blood urea nitrogen levels. Physical examination includes inspection of cutaneous lesions over the body.

In the anesthetic management of patients with porphyria, the chief concern is to avoid the administration of drugs that can induce a crisis; the drugs that induce cytochrome enzyme production can trigger the syndrome. Chief among those are the barbiturates; therefore, all barbiturates are contraindicated in porphyria. Ethyl alcohol, nonbarbiturate sedatives, hydantoin anticonvulsants, and a variety of other drugs also can induce a crisis (see Table 20-5). Endogenous factors, such as fasting, infection, and estrogens, may also precipitate porphyria. Diagnosis can be especially difficult because attacks may occur at a variable time period after drug administration or they may not occur at all despite administration of inducing drugs.

Propofol appears to be a safe induction agent.²⁷⁴ Nitrous oxide, muscle relaxants, and opioids are unequivocally safe drugs. Experience with other inhalation agents and reversal agents has been favorable, but *in vitro* studies suggest that they might exacerbate a crisis.

Most experts have advised that regional techniques be avoided to prevent confusion should neurologic signs develop after operation. However, reports of uneventful epidural anesthesia in the parturient with acute intermittent porphyria may indicate that this technique can be safely performed in these patients.²⁷⁵ Blistered or fragile skin areas should be padded and given special attention. Glucose infusion should be started because starvation may induce an attack.

The acute attack should be treated with glucose infusion, and hyponatremia, hypokalemia, and hypomagnesemia should be treated. Pyridoxine and hematin also have been valuable in some cases. Supportive therapy for respiratory insufficiency and treatment of pain is also suggested.

GLYCOGEN STORAGE DISEASES

The metabolic pathways involving glucose degradation to lactate, glucose conversion to glycogen, and the breakdown of glycogen to glucose are important to the whole body biochemistry as well as to cellular physiology in general. The enzymatic steps involved in glucose metabolism have been studied intensively since the earliest days of modern biochemistry. The glycogen storage diseases are inherited and are characterized by dysfunction of one of the many enzymes involved in glucose metabolism. To date, several different glycogen storage disorders, each based on the deficiency of an enzyme involved in glucose metabolism, have been identified. Some of the glycogen storage diseases are incompatible with life past infancy, whereas others are not. Anesthetic experience with these diseases is limited, but several particular problems have been identified²⁷⁶:

Hypoglycemia. Hypoglycemia is a constant risk in these patients. It results from failure to metabolize stored glycogen to glucose.

Acidosis. This is related to fat and protein metabolism because glycogen stores are not metabolically available.

Cardiac and Hepatic Dysfunction. This is secondary to destruction and displacement of normal tissue by the accumulated glycogen.

Detailed descriptions of glucose metabolism are given elsewhere. Figure 20-6 outlines the glycogen–glucose–lactate pathway. There are, of course, multiple enzymatic steps to reach each of the end points.

Figure 20-6. The glycogen–glucose–lactate pathway.

Defects in Glucose Metabolism

Type I (Von Gierke's Disease; Glucose-6-phosphate Deficiency). Inheritance is autosomal recessive. The prognosis is moderately good, with many patients surviving into adulthood. Short stature and liver enlargement are characteristic. These patients tolerate fasting very poorly. Hypoglycemia, acidosis, and convulsions may be a problem. Prolonged bleeding has been described. Often, preoperative hyperalimentation is used to reduce liver glycogen stores. Portacaval shunt has been

performed with limited success in these patients.²⁷⁷

Type II (Pompe's Disease). Inheritance of this disease is considered to be autosomal recessive. This is a devastating disease with a very poor prognosis. There is a deficiency of lysosomal acid maltase with an accumulation of glycogen in the lysosomes, especially in the heart, liver, muscle, and central nervous system. Cardiac compromise resulting from outflow obstruction of hypertrophied muscle occurs, as does congestive heart failure secondary to myocardial disruption by glycogen stores. A case report has been described in which halothane was used without incident.²⁷⁸ In another case, halothane led to prompt hypotension and intractable cardiac failure.²⁷⁹ A late-onset form with a better prognosis has been described as well.

Type III (Forbes' Disease; Debranching Enzyme Deficiency). Inheritance of this disease is autosomal recessive.

Type IV (Andersen's Disease; Branching Enzyme Deficiency). This is a very rare disorder, characterized by a defect in the synthesis of normal glycogen. Cirrhosis of the liver and death are characteristic before a patient reaches age 2 years.

Type V (McArdle's Disease; Muscle Phosphorylase Deficiency). An autosomal recessive inheritance pattern and cramping with exercise are characteristic of this disorder. Skeletal muscle is not able to mobilize glycogen stores, the usual fuel in muscle, for sustained exercise. Myoglobinuria occurs with overexertion in these patients and may occur after succinylcholine administration as well. Muscle atrophy occurs in adulthood. Tourniquets should not be used in these patients, and frequent automated blood pressure readings should be done with caution. Severe rhabdomyolysis has been observed after bypass for cardiac surgery.²⁸⁰

Type VI (Hers' Disease; Reduced Hepatic Phosphorylase). A decreased ability to mobilize hepatic glycogen occurs in this disorder, with normal muscle and cardiac physiology.

Type VII (Muscle Phosphofructokinase Deficiency). This disorder is similar to McArdle's disease and is characterized by muscle cramping. The same enzymatic defect in erythrocytes leads to chronic hemolysis.

Type VIII (Deficient Hepatic Phosphorylase Kinase). This results from a deficiency in the regulatory enzyme controlling the phosphorylase enzyme. A case report has described fever and acidosis during succinylcholine, halothane, and ketamine anesthesia.²⁸¹ Liver transplantation has been used with success in the more severe forms of the glycogen storage diseases.

Defects of Fructose Metabolism

Fructose-6-phosphate is converted to fructose-1,6-diphosphate during glucose breakdown to lactate. Conversely, fructose-1,6-diphosphate is converted to fructose-6-phosphate by the enzyme fructose-1,6-diphosphatase during gluconeogenesis.

In fructose-1,6-diphosphatase deficiency, there is an inability to produce glycogen from lactate. Hypoglycemia may result. Acidosis has been reported because lactate is formed preferentially. In errors of fructose metabolism, like those of glucose metabolism, hypoglycemia and acidosis pose the greatest threats to the patient.²⁸²

The Mucopolysaccharidoses

The mucopolysaccharides are polysaccharides that yield mixtures of monosaccharides and derived products after hydrolysis. The mucopolysaccharides contain *N*-acetylated hexosamine in a characteristic repeating unit. For example, chondroitin sulfate A is a monosaccharide of *D*-glucuronic acid and *N*-acetyl *D*-galactosamine 4-sulfate. Monopolysaccharides are found in all cells.

The mucopolysaccharidoses are genetically determined diseases in which mucopolysaccharides are stored in tissues in abnormal quantities and excreted in large amounts in the urine. The disorders result from a deficiency of a specific lysosomal enzyme that is required to break down these compounds. As a result, mucopolysaccharides accumulate in tissues, producing specific clinical manifestations. There are seven basic forms of mucopolysaccharidoses and several subgroups. Most of the mucopolysaccharidoses are inherited as autosomal recessive traits. All the mucopolysaccharidoses are progressive, and patients characteristically are marked by coarse facial features (gargoylism); associated skeletal abnormalities such as lumbar lordosis, stiff joints, chest deformity, dwarfing, and hypoplasia of the odontoid process (Morquio's syndrome); corneal opacities; limitation of joint motion; and heart, liver, and spleen enlargement resulting from mucopolysaccharide accumulation. Mental deterioration also occurs frequently.

The Hunter and Hurler syndromes are the best known variants of the mucopolysaccharidoses. The Hunter syndrome is an X-linked recessive disease.²⁸³ Respiratory infection and heart disease, both valvular and ischemic, often lead to death when patients are young. Patients may commonly present for repair of inguinal hernia or ear, nose, and throat or orthopedic procedures. The thick, soft tissues and the copious, thick secretions make perioperative and intraoperative airway management a particular problem.²⁸³ In Leroy and Crocker's series, minor difficulties occurred with anesthesia in patients in more than one third of 60 operations.²⁸⁴ Postoperative respiratory obstruction was noted in several cases. Because of the underlying heart disease, these patients should have electrocardiograms and echocardiographic tests performed before surgery.

Mucopolysaccharidosis IV (Morquio's syndrome) is associated with perhaps the most significant skeletal deformities. In addition to cardiovascular disorders and respiratory insufficiency from marked chest wall deformity, acute, subacute, or chronic myelopathy is extremely common. This is secondary to severe hypoplasia or absence of the odontoid process of the second cervical vertebra. In anesthesia care, the head should be positioned carefully and precautions such as avoidance of succinylcholine should be taken with patients with spinal cord compromise.

Osteogenesis Imperfecta

Osteogenesis imperfecta is seen in approximately 1 of 50,000 births. Most cases are autosomal dominant; some are autosomal recessive. The pathophysiologic characteristics include decreased collagen synthesis, which leads to osteoporosis, joint laxity, and tendon weakness. The manifestations of osteogenesis imperfecta are small bowed limbs, large head, short neck, blue sclerae, otosclerosis, joint laxity, brittle teeth, and a tendency to fractures. An increased bleeding tendency is also seen resulting from abnormal platelet function, and aortic and mitral valve dysfunction resulting from dilation of the valve ring.

The patient should be handled carefully because minor trauma may lead to fractures. Airway management may also be difficult because of cervical spine involvement with this disorder. Patients have short necks, and mandibular fractures frequently occur. The patient's cardiovascular status should be evaluated, especially mitral and aortic valve function. Kyphoscoliosis may also occur, with pulmonary compromise. Care should be taken to pad the pressure areas, particularly for long procedures. One should be prepared to obtain platelet transfusions. The patient's temperature should be monitored because hyperthermia (possibly resulting from central nervous system dysfunction or excessive metabolism in bone) has been reported.²⁸⁵ Signs consistent with MH have been observed, but contracture tests for MH susceptibility have not confirmed a constant association between osteogenesis imperfecta and MH.³⁹

Prader-Willi Syndrome

The inheritance pattern of Prader-Willi syndrome is debated.^{286,287} Its clinical features include hypotonia, obesity, diabetes, hypogonadism, mental deficiency, and dental caries. The problems related to anesthesia are those that are secondary to the patient's hypoglycemia, obesity, and hypotonia. There are possible problems related to the neuromuscular blockade. The airway must be protected during surgery with an endotracheal tube, and the blood glucose level should be monitored during operation. Careful attention must also be paid to maintaining airway patency intraoperatively as well as postoperatively.

Riley-Day Syndrome (Familial Dysautonomia)

A deficiency of dopamine β -hydroxylase that leads to decreased norepinephrine at the nerve endings is thought to be the cause of Riley-Day syndrome.²⁸⁸ This syndrome is inherited in an autosomal recessive fashion. Patients with Riley-Day syndrome exhibit copious pulmonary secretions, dysphagia, denervation supersensitivity, no sensitivity to pain, no response to histamine, and impairment of temperature control. The impairment of temperature control leads to intermittent fevers.

There are numerous problems related to anesthesia. These include corneal abrasions, excess secretions, pneumonia, labile blood pressure secondary to baroreceptor insensitivity, a decreased vascular volume, possible decreased response to hypoxia and hypercarbia, increased potential for aspiration because of swallowing

Anesthetic management for patients begins with preoperative psychological preparation and, if necessary, preoperative medication. Specific pharmacologic actions should be kept in mind when these drugs are administered before operation, and they should be tailored to the needs of each patient. The anesthesiologist should assess the patient's mental and physical condition during the preoperative visit. Because it is part of and the beginning of the anesthetic, choice of preoperative medication is based on the same considerations as the choice of anesthesia, including the patient's medical problems, requirements of the surgery, and the anesthesiologist's skills. Satisfactory preoperative preparation and medication facilitate an uneventful perioperative course. Poor preparation may begin a series of problems and misadventures.

No consensus exists on the choice of preoperative medications. Their use has been dominated by tradition, which has been modified somewhat by the change in anesthetic agents and techniques over the years. Beecher stated that "empirical procedures firmly established in the habits of good doctors have a life, not to say, immortality of their own."¹ Similarly, "the emotional attachment of an anesthesiologist to his own regimen is often more obvious than his objective assessment of its effects."² Another reason for lack of consensus may be that several different drugs or combinations of drugs can accomplish the same goals. However, there is general agreement that most patients should enter the operating room after anxiety has been relieved and other specific goals have been met through preoperative preparation and medication. This should be accomplished without undue sedation, which can interfere with patient safety or, given the dramatic increase in the number of outpatient surgical procedures, prolong length of stay in the operating room.

PSYCHOLOGICAL PREPARATION

Psychological preparation of the patient involves the preoperative visit and interview with the patient and family members. The anesthesiologist should explain anticipated events and the proposed anesthetic management in an effort to reduce anxiety and allay apprehension. Patients may perceive the day of surgery as the biggest, most threatening day in their lives; they do not wish to be treated impersonally in the operating room. The anesthesiologist's first direct encounter with the patient may be in the immediate preoperative period. A growing number of outpatients, particularly those in ASA classes I and II, receive their preanesthetic evaluations just prior to surgery. Preoperative visits must be conducted efficiently, but they must also be informative and reassuring, answering all questions. Most of the anesthesiologist's time is spent with an unconscious or sedated patient; therefore, he or she must take time before the operation to earn the trust and confidence of that patient.

Most patients are anxious before surgery. Studies show that, depending on the intensity of inquiry, from 40 to 85% of patients are apprehensive before surgery.^{3,4} Preoperative anxiety states are at a high level, and patients expect apprehension to be relieved before they arrive in the operating room.⁵ A study by Egbert *et al* showed that an average of 57% of patients felt anxious before operation.⁴ The highest levels of anxiety were noted in patients scheduled for major genitourologic surgery (79%) and for cancer surgery (86%). They found neither age nor gender differences in levels of apprehension among the study population. In an analysis of 500 adult surgical patients, Norris and Baird found that female patients were more likely than males to experience preoperative anxiety.³ Furthermore, they noted an increased incidence of anxiety in female patients who weighed more than 70 kg and in patients previously or currently taking sedative drugs. They also documented a trend toward greater levels of anxiety in more ill patients. There was no difference in anxiety with respect to age, social status, nature of the operation, or previous hospital experience.

An informative and comforting preoperative visit may replace many milligrams of depressant medication. The study by Egbert and colleagues showed that more patients were adequately prepared for surgery after a preoperative interview than after 2 mg · kg⁻¹ of pentobarbital given intramuscularly 1 hour before surgery (Table 21-1).⁴ During ward rounds on the afternoon before surgery, the patients in their preoperative interview group were visited by the anesthesiologist, who discussed each patient's condition, the time of the operation, and the anesthetic. The patient was informed about perioperative events and asked about previous anesthetic experiences. The patients in this study who received pentobarbital for preoperative medication but had no interview appeared and felt drowsy but were not calm. Leigh *et al* investigated adult preoperative patients using objective tests of anxiety.⁶ They found that the anesthesiologist's 10-minute preoperative visit produced lower anxiety levels before operation than no visit at all. Furthermore, they found that the preoperative visit was more effective than a booklet given to the patients the day before surgery, which was specifically designed to reassure them about anesthesia. The booklet was not a substitute for a proper preoperative visit and interview. Likewise, Done and Lee found viewing a preoperative video to increase patients' recall of anesthesia-related information, but stressed the need to provide patient-specific details.⁷

| | Felt Drowsy | Felt Nervous | Adequate Preparation |
|--------------------------------------|-------------|--------------|----------------------|
| Control group | 18 | 58 | 35 |
| Pentobarbital group | 30 | 61 | 48 |
| Preoperative visit | 26 | 40 | 65 |
| Preoperative visit and pentobarbital | 38 | 38 | 71 |

Table 21-1. COMPARISON OF PREOPERATIVE VISIT AND PENTOBARBITAL (2 mg · kg⁻¹ im)(PERCENTAGE OF PATIENTS)

Psychological preparation cannot accomplish everything and will not relieve all anxiety. Besides psychological preparation, there are other goals of preoperative medication. Control of pain and satisfactory levels of amnesia or sedation cannot be achieved with consistent success at the preoperative visit alone. In addition, emergency situations may provide little or no time for a preoperative interview. More seriously ill or elderly patients, conversely, may not tolerate the physiologic effects of sedative medications. Always remember that the substitution of preoperative depressant drugs for a comforting and tactful preoperative visit may compromise patient safety.

PHARMACOLOGIC PREPARATION

The ideal drug or combination of drugs for preoperative pharmacologic preparation is as elusive as is the ideal anesthetic technique. Routine administration of the same drugs to all patients has fallen into disfavor as a selective approach has emerged. In selecting the appropriate drugs for preoperative medication, the patient's psychological condition and physical status must be considered. The patient's age is also important. Is the patient in the pediatric or the geriatric age group? The surgical procedure and its duration are important factors, as well. Is this an outpatient procedure? Is it elective surgery or emergency surgery? The anesthesiologist must know the patient's weight; prior response to depressant drugs, including unwanted side effects; and allergies. Finally, the anesthesiologist's experience and familiarity with certain preoperative medications more than others are determinants.

The goals to be achieved for each patient with preoperative medication are intimately involved in the selection process (Table 21-2). The desired goals may be multiple and should be tailored to the needs of each patient. Some of the goals, such as relief of anxiety and production of sedation, apply to almost every patient, whereas others are important only occasionally. Prophylaxis against allergic reactions applies in just a few instances. Prevention of autonomic reflexes mediated through the vagus nerve or an antiemetic effect may be better attempted immediately before the anticipated need rather than achieved at the time of preoperative medication. Most preoperative medication regimens do not produce sufficient obtundation to be clinically significant in reducing anesthetic requirement. But preoperative medication often prevents preoperative elevations of plasma concentrations of b-endorphins that normally accompany the stress response (Fig. 21-1).^{8,9}

Table 21-2. VARIOUS GOALS FOR PREOPERATIVE MEDICINE

Figure 21-1. Plasma b-endorphin (B-END) concentrations as measured in control (CON) patients or in presurgical patients receiving no premedication (UNP), intramuscular saline (PLB), oral diazepam 10 mg (DZP), intramuscular diphenhydramine 1 mg · kg⁻¹ (DPH), or intramuscular meperidine 1 mg · kg⁻¹ (MEP). Measurements were made 1 hour after treatment. Mean ± SEM. (Reprinted with permission from Walsh J, Puig MM, Lovitz MA *et al*: Premedication abolishes the increase in plasma b-endorphin observed in the immediate preoperative period. *Anesthesiology* 66:402, 1987.)

Some patients should not receive depressant drugs before surgery. Patients with little physiologic reserve, at the extremes of age, with a head injury, or with hypovolemia may be harmed more than helped by many of the medications normally used before operation. In contrast, the conditions of others demand that attempts be made pharmacologically to reduce anxiety, provide analgesia, or dry secretions in the airway to produce a safer perioperative course. For elective surgery, the anesthesiologist will, in most instances, want the patient to enter the operating room free of anxiety and sedated, yet easily arousable and cooperative. The patient should not be overly obtunded or display other unwanted side effects of the preoperative drugs. The patient who asks to be "asleep" before leaving the hospital room should be told that apprehension and sedation may be reduced but it would be unsafe to produce a comatose state. The time and route of administration of the preoperative medications are important. As a general rule, oral medications should be given to the patient 60–90 minutes before arrival in the operating room. It is acceptable to administer oral drugs with up to 150 ml of water.¹⁰ For full effect, intramuscular medications should be given at least 20 minutes and preferably 30–60 minutes before the patient's arrival in the operating room. Every attempt should be made to have the preoperative medications achieve their full effect before the patient's arrival in the operating room rather than after induction of anesthesia. The drug(s), doses, route of administration, and effects should be recorded on the anesthetic record. A list of common preoperative medications is presented in Table 21-3.

| Medication | Administration Route | Dose (mg) |
|----------------|----------------------|-------------------------------|
| Diazepam | Oral | 5–20 |
| Lorazepam | Oral, im | 1–4 |
| Midazolam | im | 3–7 |
| | iv | Titration of 1.0–2.5-mg doses |
| Secobarbital | Oral, im | 50–200 |
| Fentobarbital | Oral, im | 50–200 |
| Morphine | im | 5–15 |
| Meperidine | im | 50–150 |
| Cymetidine | Oral, im, iv | 150–300 |
| Ranitidine | Oral | 50–200 |
| Misoprostol | Oral, im, iv | 8–20 |
| Atropine | im, iv | 0.3–0.6 |
| Glycopyrrolate | im, iv | 0.1–0.3 |
| Scopolamine | im, iv | 0.3–0.6 |

im = intramuscular; iv = intravenous.

Table 21-3. COMMON PREOPERATIVE MEDICATIONS, DOSES, AND ADMINISTRATION ROUTES

The choice of premedicant drugs is not based on a large body of scientific data that is either definitive or persuasive. The subject is difficult to study. Often, the investigations involve only one dose of drug or one dose of a number of drugs given in combination. In some studies drugs are given parenterally, whereas in others they are administered orally or even rectally. Different investigations may study the effect of the drugs at different times after administration. The patients' responses and the investigators' observations of those responses are subjective and difficult to quantify. Also, the studies may involve heterogeneous groups of patients in whom the psychological preoperative preparation has not been standardized.

Sedative Hypnotics and Tranquilizers

Benzodiazepines

Benzodiazepines are among the most popular drugs used for preoperative medication (Table 21-4). They are used to produce anxiolysis, amnesia, and sedation. The anticonvulsant and muscle relaxant effects of the benzodiazepines are not usually important when preoperative medication is considered. Because the site of action of benzodiazepines is on specific receptors in the central nervous system, there is relatively little depression of ventilation or of the cardiovascular system with premedicant doses. Benzodiazepines have a wide therapeutic index and a low incidence of toxicity. Other than central nervous system depression, there are few side

effects of this group of drugs. Specifically, nausea and vomiting are not usually associated with administration of benzodiazepines for preoperative medication. These drugs are also used before operation to reduce the unpleasant dreams and delirium that may occur after ketamine administration.

| | Diazepam | Lorazepam | Midazolam |
|--|----------|-----------|-----------|
| Dose equivalent (mg) | 10 | 1-2 | 3-5 |
| Time to peak effect after oral dose (hr) | 1-1.5 | 2-4 | 0.5-1 |
| Elimination half-time (hr) | 20-40 | 10-20 | 1-4 |
| Clearance ($\text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) | 0.2-0.5 | 0.7-1.0 | 6.4-11.1 |
| Volume of distribution ($\text{l} \cdot \text{kg}^{-1}$) | 0.7-1.7 | 0.8-1.3 | 1.1-1.7 |

Adapted from Reeves JG, Faagen RJ, Vireick HR *et al*: Midazolam: Pharmacology and uses. *Anesthesiology* 62:310, 1985; and Stoelting EK: *Pharmacology and Physiology in Anesthetic Practice*. Philadelphia, JB Lippincott, 1987.

Table 21-4. COMPARISON OF PHARMACOLOGIC VARIABLES OF BENZODIAZEPINES

There are some hazards and unwanted side effects of the benzodiazepines. The central nervous system depression they cause is sometimes long and excessive, especially with use of lorazepam. There may be pain at the intramuscular or intravenous injection site with diazepam, as well as the possibility of phlebitis. These drugs are not analgesic agents. Benzodiazepines may not always produce a calming effect but may cause agitation, as evidenced by restlessness and delirium.

The proposed mechanisms of action of the benzodiazepines describe specific receptors and actions within the central nervous system (Fig. 21-2).¹¹ The sedative action is said to result from a facilitation or enhancement of inhibitory neurotransmission mediated by g-aminobutyric acid. The anxiolytic effect comes from the action of glycine-mediated inhibition of neuronal pathways in the brain stem and in the brain. The site of action of the benzodiazepines in producing amnesia is unknown.

Figure 21-2. Schematic diagram of possible mechanisms for pharmacologic effects of benzodiazepines (BNZs). GABA = g-aminobutyric acid. (Reprinted from Richter JJ: Current theories about the mechanisms of benzodiazepines and neuroleptic drugs. *Anesthesiology* 54:66, 1981.)

Diazepam. The calming, amnesic, and sedative effects of diazepam make it a very popular choice for premedication. It is the standard against which other benzodiazepines are usually compared. Because diazepam is insoluble in water and must be dissolved in organic solvents (propylene glycol, sodium benzoate), pain may occur on intramuscular or intravenous injection. Phlebitis is often a sequela of intravenous injection. Administration of diazepam orally with up to 150 ml of water is preferable to an intramuscular injection. More than 90% of an oral dose of diazepam is rapidly absorbed. Peak effect after oral administration occurs within 0.5–1 hour in adults and within 15–30 minutes in children (Fig. 21-3).¹² Diazepam does cross the placenta, with fetal concentrations equaling or exceeding maternal levels.¹³ Because the drug is highly protein-bound, patients with low serum albumin levels, such as those with cirrhosis of the liver or chronic renal failure, may exhibit an increased effect of the drug. Hepatic microsomal enzymes metabolize the drug via oxidative *N*-demethylation to metabolites possessing weaker pharmacologic activity. Desmethyldiazepam and oxazepam are the primary metabolites; a smaller amount of the drug is converted to temazepam. Prolonged sedation resulting from active metabolites is usually seen after chronic use of diazepam rather than after the use of a single dose in the preoperative setting. The elimination half-time of diazepam is 21–37 hours in healthy volunteers. It may be prolonged in patients with cirrhosis or in elderly patients. Because absorption is unpredictable after intramuscular injection and because of pain with parenteral administration, many prefer to administer diazepam orally (see Fig. 21-3).¹² It is not as reliable in preventing recall as lorazepam, but the anterograde amnesia effect may be enhanced by scopolamine.¹⁴ There is no evidence for the production of retrograde amnesia after diazepam administration.

Figure 21-3. Individual and mean (*horizontal bar*) times of peak plasma concentrations after oral or intramuscular (deltoid) administration of diazepam, 5 mg, to adult patients (20–78 years of age) categorized as young male (YM), young female (YF), elderly male (EM), and elderly female (EF) patients. (Reprinted with permission from Divoll M, Greenblatt DJ, Ochs HR *et al*: Absolute bioavailability of oral and intramuscular diazepam: Effects of age and sex. *Anesth Analg* 62:1, 1983.)

There is little effect of diazepam outside the central nervous system. Minimal depression of ventilation, circulation, or hepatic or renal function occurs. Soroker *et al* demonstrated little or no effect on ventilation after diazepam administration.¹⁵ Detectable PaCO_2 increases were demonstrable only after intravenous administration of $0.2 \text{ mg} \cdot \text{dc} \cdot \text{kg}^{-1}$ of diazepam in another study.¹⁶ The increase in carbon dioxide results from a decrease in tidal volume. In another investigation, after intravenous doses of $0.4 \text{ mg} \cdot \text{dc} \cdot \text{kg}^{-1}$, the slope of the carbon dioxide response curve decreased, but the curve was not shifted to the right.¹⁷ Despite the safety of relatively high intravenous doses of diazepam, respiratory arrest has been reported with as little as 2.5 mg .¹⁸ Furthermore, ventilatory depression may be compounded by other depressant drugs, especially opioids and alcohol. There is little cardiovascular depression seen after the doses of diazepam used for preoperative medication. Indeed, higher intravenous doses produce little circulatory depression.¹⁶ There is not much clinical effect on the neuromuscular junction after diazepam has been given for preoperative medication. There have been attempts to reduce myalgias and fasciculations produced by succinylcholine with diazepam. The effect on fasciculations has been variable, but myalgias were reduced in one study.¹⁹ Premedication with diazepam does not reliably prevent an increase in intraocular pressure after intubation of the trachea.²⁰ In animals, diazepam has reduced the seizure threshold for lidocaine, but this effect has not been proved in humans.²¹

Some controversy exists with regard to interaction of diazepam with other drugs. Cimetidine delays the hepatic clearance of diazepam.²² The proposed mechanism is the inhibition of microsomal enzymes of cimetidine. There is some question as to whether this is clinically significant when diazepam is used as a single dose before operation. Diazepam $0.2 \text{ mg} \cdot \text{dc} \cdot \text{kg}^{-1}$ has been shown to decrease the minimum alveolar concentration for halothane.²³ The magnitude in reduction of anesthetic

requirement from premedication doses may or may not be important to the anesthesiologist.

Lorazepam. Lorazepam resembles oxazepam structurally and is 5–10 times as potent as diazepam. Lorazepam can produce profound amnesia, relief of anxiety, and sedation (Fig. 21-4).²⁴ When lorazepam is compared with diazepam, their effects are very similar. Although it is insoluble in water and requires a solvent such as polyethylene glycol or propylene glycol, administration of lorazepam, unlike diazepam, is not associated with pain on injection or phlebitis. Prolonged sedation is more likely after lorazepam administration. Even though the elimination half-life of diazepam is longer than that of lorazepam (20–40 hours vs. 10–20 hours), the effect of diazepam may be shorter because it more rapidly dissociates from the benzodiazepine receptor.²⁵

Figure 21-4. Percentage of patients in each group failing to recall specific events of the operative day. Medications were administered intramuscularly. (Reprinted with permission from Fragen RJ, Caldwell N: Lorazepam premedication: Lack of recall and relief of anxiety. *Anesth Analg* 55:792, 1976.)

Lorazepam is reliably absorbed both orally and intramuscularly. Maximal effect occurs 30–40 minutes after intravenous injection.²⁶ Bradshaw *et al* demonstrated clinical effects 30–60 minutes after oral administration of lorazepam.²⁷ A study by Blitt *et al* demonstrated that lack of recall was not produced until 2 hours after intramuscular injection.²⁸ Peak plasma concentrations may not occur until 2–4 hours after oral administration. Therefore, lorazepam must be ordered well before surgery so that the drug has time to be effective before the patient arrives in the operating room. Lorazepam also may be given sublingually.²⁹ As stated previously, the elimination half-life is 10–20 hours. The usual dose is about 25–50 μ mg·dc·kg⁻¹. The dose for an adult should not exceed 4.0 mg.^{24,25,30} With recommended doses, anterograde amnesia may be produced for as long as 4–6 hours without excessive sedation. Higher doses lead to prolonged and excessive sedation without more amnesia. Because of its slow onset and length of action, lorazepam is not useful in instances in which rapid awakening is necessary, such as with outpatient anesthesia. There are no active metabolites of lorazepam; and because its metabolism is not dependent on microsomal enzymes, there is less influence on its effect from age or liver disease.³¹ As with diazepam, little cardiorespiratory depression occurs with lorazepam. However, there is the danger of unwanted respiratory depression in those with lung disease.³²

Midazolam. Midazolam has predominantly replaced diazepam in its use for preoperative medication and conscious sedation. The physicochemical properties of the drug allow for its water solubility and rapid metabolism. As with other benzodiazepines, midazolam produces anxiolysis, sedation, and amnesia. It is two to three times as potent as diazepam because of its increased affinity for the benzodiazepine receptor. The usual intramuscular dose is 0.05–0.1 mg · kg⁻¹ and titration of 1.0–2.5 mg at a time intravenously. There is no irritation or phlebitis with injection of midazolam. The incidence of side effects after administration is low, although depression of ventilation and sedation may be greater than expected, especially in elderly patients or when the drug is combined with other central nervous system depressants. There is more rapid onset of action and predictable absorption after intramuscular injection of midazolam than after diazepam. The time of onset after intramuscular injection is 5–10 minutes, with peak effect occurring after 30–60 minutes. The onset after intravenous administration of 5 mg would be expected to occur after 1–2 minutes. In addition to quicker onset, more rapid recovery occurs after midazolam administration compared with diazepam. This is probably the result of the lipid solubility of midazolam and its rapid distribution in the peripheral tissues and metabolic biotransformation. For these reasons, midazolam usually should be given within an hour of induction.³³ Midazolam is metabolized by hepatic microsomal enzymes to essentially inactive hydroxylated metabolites. H₂ receptor antagonists do not interfere with its metabolism.³⁴ The elimination half-life of midazolam is approximately 1–4 hours and may be extended in the elderly.³⁵ Tests show that mental function usually returns to normal within 4 hours of administration.³³ After administration of 5 mg, amnesia lasts from 20 to 32 minutes.³⁶ Intramuscular administration may produce longer periods of amnesia. The lack of recall may be augmented by concomitant administration of scopolamine. The properties of midazolam make it ideal for shorter procedures.

Other Benzodiazepines. Oxazepam, another benzodiazepine that has been used for preoperative medication, is one of the pharmacologically active metabolites of diazepam. It is absorbed slowly after oral administration and has an elimination half-life of 5–15 hours. Temazepam has been given in oral doses of 20–30 mg before surgery. It must be given well before surgery because peak plasma levels do not occur until approximately 2–2.5 hours after administration. Triazolam is a short-acting benzodiazepine. The adult oral dose of the drug is 0.25–0.5 mg. Peak plasma concentrations occur in about 1 hour and its elimination half-life is 1.7–5.2 hours. The drug may become long-acting in the elderly. Similarly, a study by Pinnock *et al* did not show triazolam to be of short duration when compared with diazepam for premedication for minor gynecologic surgery.³⁷ Alprazolam (1 mg) given to adults has been shown to produce a modest reduction in anxiety before surgery.³⁸

Barbiturates

Use of barbiturates for preoperative medication is a time-tested practice with a long record of safety. These drugs are used primarily for their sedative effects. While barbiturate administration for pharmacologic preparation before surgery has been replaced in many instances by the use of benzodiazepines, they may be useful in certain settings. There is little cardiorespiratory depression associated with the usual preoperative doses. The barbiturates may be given orally as well as parenterally, and the drugs are relatively inexpensive. Barbiturates, however, are unlikely to produce sedation in the presence of pain. In fact, disorientation and paradoxical excitation may result. Low doses of barbiturates have been said to lower the pain threshold and be antianalgesic. The agents lack specificity of action on the central nervous system and have a lower therapeutic index than the benzodiazepines. Barbiturates should not be used in patients with certain kinds of porphyria.

Secobarbital. Secobarbital usually is administered to adults in oral doses of 50–200 mg when used for preoperative medication. Onset usually occurs 60–90 minutes after administration, and sedative effects last 4 hours or longer. Indeed, even though secobarbital traditionally has been considered a “short-acting” barbiturate, it may impair performance for as long as 10–22 hours.³⁹

Pentobarbital. Pentobarbital may be administered orally or parenterally. The oral dose used for adults is usually 50–200 mg. Pentobarbital has a biotransformation half-life of about 50 hours. Therefore, its use is not often suitable for shorter procedures.

Butyrophenones

Intravenous or intramuscular doses of 2.5–7.5 mg of droperidol produce the appearance of sedation in patients before operation. Calmness and tranquility may be observed, but patients often state that they feel dysphoric and restless and even experience fear of death. Patients' dysphoric feelings have led to refusal of surgery. Because droperidol is a dopamine antagonist, extrapyramidal signs may appear after its administration.⁴⁰ This has been reported to occur in about 1% of patients. The butyrophenones also cause mild α -blocking effects. Another butyrophenone, haloperidol, is a long-acting antipsychotic drug that has been used infrequently for preoperative medication.

Currently, droperidol is usually administered for its antiemetic effect rather than its sedative properties (see [Antiemetics](#)). Low clinical doses (up to 2.5 mg) of droperidol have been used before operation or just before emergence from anesthesia to prevent nausea and vomiting in the recovery room.

As a dopaminergic receptor blocker, droperidol counters the inhibitory effect of dopamine on the carotid body and the ventilatory response to hypoxia. Consequently, it preserves the carotid body response to hypoxia. For these reasons, it is said that droperidol may be a good premedication for patients who are dependent on the hypoxic ventilatory drive (Fig. 21-5).⁴¹

Figure 21-5. Hypoxic sensitivity (change in ventilation for each 1% decrease in oxygen saturation) is increased after intravenous administration of droperidol, 2.5 mg. Solid symbols represent repeated experiments on the same subjects as those represented by the open symbols. (Reprinted from Ward DS: Stimulation of hypoxic ventilatory drive by droperidol. *Anesth Analg* 63:106, 1984.)

Other Sedative Drugs

Hydroxyzine. Hydroxyzine is a nonphenothiazine tranquilizer. It is often given for its proposed additive effects to opioids and does not cause an increase in side effects. Hydroxyzine has sedative action and anxiolytic properties. It has limited analgesic properties and does not produce amnesia. It is an antihistamine and an antiemetic.

Diphenhydramine. Diphenhydramine is a histamine receptor antagonist with sedative and anticholinergic activity. It is also an antiemetic. A dose of 50 mg will last 3–6 hours in an adult. Diphenhydramine has been used recently in combination with cimetidine, steroids, and other drugs for prophylaxis in patients with chronic atopy and for prophylaxis before chemonucleolysis and dye studies.⁴² Diphenhydramine blocks the histamine receptor to prevent effects of histamine peripherally.

Phenothiazines. Promethazine, promazine, and perphenazine are often used in combination with opioids. Phenothiazines have sedative, anticholinergic, and antiemetic properties. These effects, added to the analgesic effects of the opioids, have been used for preoperative medication.

Opioids

Morphine and meperidine were historically the most frequently used opioids for intramuscular preoperative medication. Recently, the use of intravenous fentanyl just before surgery has become popular. Opioids are used when analgesia is needed before operation. It has been stated in the strict sense that “unless there is pain, there is no need for narcotic in preanesthetic medication.”⁴³ For the patient experiencing pain before operation, the opioids can produce good analgesia and even euphoria. Opioids have been ordered for patients before operation to ameliorate the discomfort that may occur during regional anesthesia or the insertion of invasive monitoring catheters or large intravenous lines. The dose of opioid may need to be reduced in the debilitated or elderly patient. The elderly patient often exhibits a reduced sensitivity to pain. Furthermore, elderly patients can have an increased analgesic response to opioids. Opioids also have been used before operation in the opioid-dependent patient.

Preoperative administration of opioids in other settings has been controversial. They have been given before surgery prior to a nitrous oxide–opioid anesthetic. This is done in an attempt to have a basal state of anesthesia on board when the patient arrives in the operating room and to get a preview of the patient’s response to opioids. Opioids have been given to patients before operation to provide analgesia on their awakening in the recovery room. The other approach is to titrate the opioid intravenously during emergence or on the patient’s arrival in the recovery room. Preoperative administration of opioids can lower anesthetic requirements.⁴⁴ This may or may not be clinically significant for a specific patient receiving a particular anesthetic technique. Some anesthesiologists use opioids in combination with other drugs before operation to facilitate anesthetic induction by mask. This is popular especially in patients in whom an intravenous route for induction drugs cannot be used. It must be remembered that opioids decrease ventilation during spontaneous breathing and therefore decrease uptake of inhalation drugs. If necessary, the anesthesiologist may want to use assisted or controlled ventilation of the lungs to overcome the respiratory depressant effects of the opioids. Finally, opioids are not the best drugs to relieve apprehension, produce sedation, or prevent recall.

Administration of opioids has the potential for causing several side effects. They usually exhibit no direct myocardial effects except in the case of very high doses of meperidine. However, opioids do interfere with the compensatory constriction of smooth muscles of the peripheral vasculature. This may lead to orthostatic hypotension. Histamine release after injection of morphine may compound these circulatory effects. As with most preoperative medications, it is probably safest to have the patient remain at bed rest after opioid premedication. The analgesic properties and respiratory depressant effects of opioids go hand in hand. The decrease in the carbon dioxide drive at the medullary respiratory center may be prolonged. Furthermore, there is a decrease in the responsiveness to hypoxia at the carotid body after injection of only low doses of opioids.⁴⁵ The anesthesiologist may wish to consider supplemental oxygen for the patient receiving opioid premedication. In general, the opioid agonist-antagonists produce less respiratory depression, but they also produce less analgesia. Rather than euphoria, the opioids may produce dysphoria. When this side effect does occur, it is most commonly seen in a patient who does not have pain before operation and has received the opioid premedication. Nausea and vomiting may result from opioid administration. The effect of opioids on the vestibular apparatus leading to motion sickness or stimulation of the medullary chemoreceptor trigger zone is a postulated reason for nausea and vomiting. Choledochoduodenal sphincter (sphincter of Oddi) spasm has occasionally been noted subsequent to injection of opioids. The opioid produces smooth muscle constriction, which leads to right upper quadrant pain.⁴⁶ Pain relief may be achieved with naloxone or possibly glucagon. Occasionally, the pain from biliary tract spasm is difficult to differentiate from the pain of angina pectoris. The administration of nitroglycerin should relieve angina pectoris and pain resulting from biliary tract spasm; an opioid antagonist should relieve only pain resulting from biliary tract spasm. Some question the use of opioid premedication in patients with biliary tract disease. All opioids have the potential to induce choledochoduodenal sphincter spasm. Meperidine is less likely than morphine to produce this side effect. Opioids may produce pruritus. Morphine, possibly through histamine release, often produces itching, especially around the nose. Opioids also may cause flushing, dizziness, and miosis.

Other drugs are often combined with opioids for their additive effects or to overcome the disadvantages of opioid side effects. The sedative-hypnotics and scopolamine are often used with opioids to produce sedation, anxiolysis, and amnesia in addition to analgesia. In selected patients, the combination of morphine and a benzodiazepine or scopolamine may be useful for pharmacologic preoperative preparation.

Morphine

Morphine is well absorbed after intramuscular injection. The onset of effect should occur within 15–30 minutes. The peak effect occurs in 45–90 minutes and lasts as long as 4 hours. After intravenous administration, the peak effect usually occurs within 20 minutes. Morphine is not reliably absorbed after oral administration. As with the other opioids, depression of ventilation and orthostatic hypotension may occur after injection of morphine. The effect of morphine on the chemoreceptive trigger zone may produce nausea and vomiting. Nausea and vomiting may also occur owing to a vestibular component. This has been postulated because the supine patient is less likely to complain of nausea and vomiting. After morphine administration, motility of the gastrointestinal tract is decreased. Also, gastrointestinal secretions may be increased. Inclusion of morphine in the preoperative medication reduces the likelihood that undesirable increases in heart rate will accompany surgical stimulation in the presence of volatile anesthetics.

Meperidine

Meperidine is about one tenth as potent as morphine. It may be given orally or parenterally. A single dose of meperidine usually lasts 2–4 hours. The onset after intramuscular injection is unpredictable, and a great deal of variability in time to peak effect exists. Meperidine is primarily metabolized in the liver. An increase in heart rate may be seen after meperidine administration, as may orthostatic hypotension.

Fentanyl

Fentanyl is a synthetic opioid agonist structurally similar to meperidine. It is 75–125 times more potent than morphine in its analgesic characteristics. The lipid solubility of fentanyl is greater than that of morphine, which contributes to its rapid onset of action. Peak plasma concentrations occur within 6–7 minutes following intravenous administration and its elimination half-time is 3–6 hours. The drug’s short duration of action is attributed to redistribution to inactive tissues, such as the lungs, fat, and skeletal muscle. Metabolism occurs primarily by *N*-demethylation to norfentanyl, which is a less potent analgesic. A decreased clearance rate in the elderly may

prolong elimination.

In doses of 1–2 $\mu\text{mg} \cdot \text{kg}^{-1}$ intravenously, fentanyl may be used to provide preoperative analgesia. Oral transmucosal fentanyl preparations of fentanyl are available, delivering 5–20 $\mu\text{mg} \cdot \text{kg}^{-1}$ of the drug. This form has been examined as a premedicant in both adults and children to relieve anxiety and pain. Due to a high incidence of preoperative nausea and vomiting, oral transmucosal fentanyl (in doses greater than 15 $\mu\text{mg} \cdot \text{kg}^{-1}$) is not recommended in children younger than six years of age.⁴⁷ Fentanyl causes neither myocardial depression nor histamine release, but may be associated with ventilatory depression and profound bradycardia. Synergistic effects with benzodiazepines warrant close observation when this combination is given in the preoperative period.

Opioid Agonist-Antagonists

Opioid agonist-antagonists have been chosen for preoperative medication in an attempt to reduce the ventilatory side effects of pure opioid agonists. However, there is a ceiling on the analgesia that can be produced by agonist-antagonist drugs. They are similar to the pure opioids with regard to side effects. In addition, dysphoria may be even more likely to occur after their administration. Another issue to remember is that the agonist-antagonist drug can reduce the effectiveness of a pure opioid agonist needed to control postoperative pain. The most commonly used opioid agonist-antagonists are pentazocine, butorphanol, and nalbuphine.

Gastric Fluid pH and Volume

Many patients who come to the operating room are at risk for aspiration pneumonitis. The classic example is the patient with acute pain and a “full stomach” who must have emergency surgery. The pregnant patient, the obese patient, the diabetic, the patient with hiatus hernia or gastroesophageal reflux, all may be at risk for aspiration of gastric contents and subsequent chemical pneumonitis. Although it is not certain, it is believed that in adults aspiration of more than 25 ml of gastric fluid with a pH lower than 2.5 will cause pulmonary sequelae. This has not been, and probably never will be, proved in humans. However, using these guidelines, some have estimated that 40–80% of patients scheduled for elective surgery may be at risk.^{48,49} However, clinically significant pulmonary aspiration of gastric contents is very rare in healthy patients having elective surgical procedures, and few anesthesiologists advocate routine prophylaxis.^{50,51} An earlier suggestion that gastric fluid volume is greater and pH lower in outpatients compared with inpatients has not been confirmed.^{51,52}

The necessity of prolonged fasting (nothing by mouth after midnight) before induction of anesthesia for elective surgery has been challenged.⁵³ Some institutions allow ingestion of clear liquids until 3 or even 2 hours before surgery in selected patients. Indeed, gastric fluid volume immediately after induction of anesthesia is not increased by ingestion of 150 ml of water, coffee, or orange juice 2–3 hours earlier.⁵⁴ A similar study by Shevde and Trivedi described the administration of 240 ml of water, coffee, or pulp-free orange juice to healthy volunteers. All had gastric volumes of less than 25 ml with a slight decrease in pH within 2 hours of taking one of the three liquids.⁵⁵ There is concern about comfort, hypovolemia, and hypoglycemia in the pediatric age group perioperatively after prolonged fasting. An investigation by Splinter and associates concluded that drinking clear fluid up to 3 hours before scheduled surgery does not have a measurable effect on gastric volume and pH of healthy children aged 2–12 years.⁵⁶ Other studies in infants, children, and healthy adults scheduled for elective surgery have found similar results.⁵⁷ Therefore, fears that ingestion of oral fluid on the morning of surgery will invariably result in a predictable increase in gastric fluid volume are unfounded. It must be appreciated, however, that these data are from healthy patients not “at risk” for aspiration and apply only to ingestion of clear liquids. The American Society of Anesthesiologists has defined and summarized preoperative fasting practices through guidelines adapted in 1998 (see [Table 21-5](#)).⁵¹

| Ingested Material | Minimum Fasting Period (applied to all ages) |
|--------------------------------------|--|
| Clear liquid† | 2 hours |
| Breast milk | 4 hours |
| Infant formula | 6 hours |
| Nonhuman milk | 6 hours |
| Light meal (toast and clear liquids) | 6 hours |

* Applies only to healthy patients who are undergoing elective procedures and are not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying.

† Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

Adapted from Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures. A Report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. *Anesthesiology* 90:896, 1999.

Table 21-5. SUMMARY OF FASTING RECOMMENDATIONS TO REDUCE THE RISK OF PULMONARY ASPIRATION*

Many different kinds of drugs have been used to alter gastric fluid volume and increase the pH of gastric fluid. Anticholinergics, H₂ receptor antagonists, antacids, and gastrokinetic agents have all been used to reduce the possibility of aspiration pneumonitis.

Anticholinergics

Neither atropine nor glycopyrrolate has been shown to be very effective in increasing gastric fluid pH or reducing gastric fluid volume. A study by Stoelting demonstrated that when given intramuscularly 1–1.5 hours before operation, neither atropine (0.4 mg) nor glycopyrrolate (0.2 mg) was successful in altering the gastric fluid pH or volume.⁴⁸ A similar study reported that glycopyrrolate (4–5 $\mu\text{mg} \cdot \text{kg}^{-1}$) given before operation did not reduce the percentage of patients at risk for aspiration pneumonitis.⁴⁹ That is, in a significant number of patients the gastric fluid pH remained below 2.5 and the gastric fluid volume was greater than 0.4 ml · kg⁻¹. Giving higher doses of glycopyrrolate (0.3 mg) is not more effective. Furthermore, intravenous doses of anticholinergics may cause relaxation of the gastroesophageal junction ([Fig. 21-6](#)). Theoretically, this may also occur after intramuscular doses. Therefore, the risk of aspiration pneumonitis may be increased, but this specific effect of intramuscular administration of anticholinergics for preoperative use has not been proved.

Figure 21-6. Barrier pressure (esophageal sphincter pressure minus gastric pressure) before and after intravenous administration of glycopyrrolate, 0.3 mg, to adult patients. Mean \pm SE. (Reprinted with permission from Brock-Utne JG, Welman RS, Moshal MG *et al*: The effect of glycopyrrolate (Robinul) on the lower esophageal sphincter. *Can Anaesth Soc J* 25:144, 1978.)

Histamine Receptor Antagonists

The H₂ receptor antagonists, cimetidine, ranitidine, famotidine, and nizatidine reduce gastric acid secretion. They block the ability of histamine to induce secretion of gastric fluid with a high hydrogen ion concentration. Therefore, the H₂ receptor antagonists increase gastric fluid pH. Their antagonism of the histamine receptor occurs in a selective and competitive manner. It is important to remember that these drugs cannot be expected reliably to affect gastric fluid volume or gastric emptying time. Compared with other premedicants, they have relatively few side effects. Because there are few side effects and because many elective patients are at risk for aspiration pneumonitis, some anesthesiologists have advocated the preoperative use of H₂ receptor antagonists. Multiple-dose regimens may be more effective in

increasing gastric pH than a single dose before operation on the day of surgery.⁵⁸ An H₂ antagonist also may be used for the allergic patient or in preparing a patient for exposure to a trigger of the allergic response, such as chymopapain or dye.

Cimetidine. Cimetidine usually is administered in 150–300 mg doses orally or parenterally. Administration of 300 mg of cimetidine orally 1–1.5 hours before surgery has been shown to increase the gastric fluid pH above 2.5 in 80% of patients.⁵⁹ There was no effect on gastric fluid volume. However, a study by Maliniak *et al* reported that cimetidine (300 mg) given intravenously 2 hours before operation increased gastric fluid pH and decreased gastric fluid volume.⁶⁰ Cimetidine can be given intravenously for those unable to take oral medications. It may be necessary to increase the dose for the very obese patient. Cimetidine can cross the placenta, but adverse fetal effects are unproved. In one multicenter investigation, 126 patients were studied who were to have elective cesarean section with general anesthesia.⁶¹ These patients received either 30 ml of an antacid 1–3 hours before operation or 300 mg of cimetidine orally at bedtime and again intramuscularly 1–3 hours before operation. There was an increase in gastric fluid pH and a reduction in gastric fluid volume in the cimetidine-treated group. Most important for this discussion, there were no differences in the neurobehavioral scores of the neonates between the two groups. The gastric effects of cimetidine last as long as 3 or 4 hours, and therefore this drug is suitable for operations of that duration.

Cimetidine has few side effects, but there are some of note. It inhibits the hepatic mixed-function oxidase enzyme system; therefore, it can prolong the half-life of many drugs, including diazepam, chlordiazepoxide, theophylline, propranolol, and lidocaine. The clinical significance of this after one or two preoperative doses of cimetidine is uncertain. There is also some question of hepatic blood flow reduction by cimetidine and a prolonged effect of the drug in patients with renal failure. Life-threatening cardiac dysrhythmias, hypotension, cardiac arrest, and central nervous system depression have been reported after cimetidine administration. These side effects may be especially likely to occur in critically ill patients after rapid intravenous administration. It has been postulated that airway resistance may increase in asthmatic patients because cimetidine could produce unopposed H₂ receptor–mediated bronchial constriction. As discussed previously, cimetidine does not affect gastric fluid already present.

Ranitidine. Ranitidine is more potent, specific, and longer acting than cimetidine. The usual oral dose is 50–200 mg. Ranitidine, 50–100 mg, given parenterally will decrease gastric fluid pH within 1 hour. It is as effective in reducing the number of patients at risk for gastric aspiration as cimetidine and produces fewer cardiovascular or central nervous system side effects. The effects of ranitidine last up to 9 hours. Thus, it may be superior to cimetidine at the conclusion of lengthy procedures in reducing the risk of aspiration pneumonitis during emergence from anesthesia and extubation of the trachea.

Other Histamine Receptor Antagonists. Famotidine is a third H₂ receptor blocker that has been given preoperatively to raise gastric fluid pH. Its pharmacokinetics are similar to those of cimetidine and ranitidine, with the exception of having a longer serum elimination half-life than the other two drugs.⁶² Famotidine in a dose of 40 mg orally 1.5–3 hours preoperatively has been shown to be effective in increasing gastric pH.⁶³ Nizatidine 150–300 mg orally 2 hours before surgery will similarly decrease preoperative gastric acidity.⁶⁴

Antacids

Antacids are used to neutralize the acid in gastric contents. A single dose of antacid given 15–30 minutes before induction of anesthesia is almost 100% effective in increasing gastric fluid pH above 2.5. The nonparticulate antacid, 0.3 M sodium citrate, is commonly given before operation when an increase in gastric fluid pH is desired. The nonparticulate antacids do not produce pulmonary damage themselves if aspiration of gastric fluid containing these antacids should occur. Colloid antacid suspension may be more effective than the nonparticulate antacids in increasing gastric fluid pH. However, aspiration of gastric fluid containing particulate antacids may cause significant and persistent pulmonary damage, despite the increase in gastric fluid pH.⁶⁵ The serious pulmonary sequelae have been manifested in the form of pulmonary edema and arterial hypoxemia.

Antacids work at the time given. There is no “lag time,” as with the H₂ receptor blockers. Antacids are effective on the fluid already present in the stomach. This makes them especially attractive in emergency situations for those patients who are able to take medications orally.

However, antacids do increase gastric fluid volume, unlike H₂ receptor blockers.⁵⁹ The risk of aspiration depends on both the pH and the volume of gastric content. The increase in gastric fluid volume from antacid administration may become readily apparent after repeated doses, such as during labor, during which opioid administration may also contribute to delayed gastric emptying. Withholding antacids because of concern about increasing gastric volume is not warranted, considering animal evidence documenting increased mortality after aspiration of low volumes of acidic gastric fluid (0.3 ml · kg⁻¹, pH 1) compared with aspiration of large volumes of buffered gastric fluid (1–2 ml · kg⁻¹, pH 1.8).⁶⁶ Antacids may slow gastric emptying, and complete mixing with all gastric contents may be questionable in the immobile patient. The effect of antacids on food particles within the stomach is unknown.

Omeprazole

Omeprazole suppresses gastric acid secretion in a dose-dependent manner by binding to the proton pump of the parietal cell. For an adult patient intravenous doses of 40 mg 30 minutes before induction have been used. Oral doses of 40–80 mg must be given 2–4 hours before surgery to be effective. Effect on gastric pH may last as long as 24 hours. Much like the other H₂ receptor antagonists, investigators have found increases in gastric pH and inconsistent effects on gastric volume with administration of omeprazole.^{67,68,69}

Gastrokinetic Agents

Gastrokinetic agents are useful because of their effectiveness in reducing gastric fluid volume. Metoclopramide is an example of a gastrokinetic agent that may be administered before operation.

Metoclopramide. Metoclopramide is a dopamine antagonist that stimulates upper gastrointestinal motility, increases gastroesophageal sphincter tone, and relaxes the pylorus and duodenum. It also has antiemetic properties. Metoclopramide speeds gastric emptying but has no known effect on acid secretion and gastric fluid pH. It may be administered orally or parenterally. A parenteral dose of 5–20 mg is usually given 15–30 minutes before induction. When the drug is administered intravenously over 3–5 minutes, it usually prevents the abdominal cramping that can occur from more rapid administration. An oral dose of 10 mg achieves onset within 30–60 minutes. The elimination half-life of metoclopramide is approximately 2–4 hours.

The clinical usefulness of the gastrokinetic agents is found in those patients who are likely to have large gastric fluid volumes, such as parturients, patients scheduled for emergency surgery who have just eaten, obese patients, patients with trauma, outpatients, and those with gastroparesis secondary to diabetes mellitus.

However, the administration of metoclopramide does not guarantee gastric emptying. Significant gastric fluid volume may still be present despite its administration. The effect of metoclopramide on the upper gastrointestinal tract may be offset by concomitant atropine administration or prior injection of opioids. It will not further reduce gastric volume in patients undergoing elective surgery with already small gastric volumes. It may not be effective after administration of sodium citrate.^{70,71,72} In contrast, metoclopramide may be especially effective in reducing the risk of aspiration pneumonitis when combined with an H₂ receptor antagonist (for example, ranitidine) before elective surgery.⁷³

As mentioned previously, the drugs used to alter gastric fluid pH and volume are relatively free of side effects. The risk–benefit ratio for these drugs in reducing the risk of pulmonary sequelae from aspiration is often very favorable. Indeed, the drugs do decrease the number of patients at risk. However, none of the drugs or combinations of drugs is absolutely reliable in preventing the risk of aspiration pneumonitis in all patients all of the time. Therefore, their use does not eliminate the need for careful anesthetic techniques to protect the airway during induction, maintenance, and emergence from anesthesia.

Antiemetics

There are several groups of patients in whom the antiemetic effects of drugs may be helpful in reducing nausea and vomiting. These are patients scheduled for ophthalmologic surgery, patients with a prior history of nausea and vomiting or motion sickness, patients scheduled for laparoscopic surgery or gynecologic procedures, and patients who are obese. A risk score for predicting postoperative nausea and vomiting after inhalation anesthesia identified four risk factors: female gender, prior history of motion sickness or postoperative nausea, nonsmoking, and the use of postoperative opioids. The investigators suggested prophylactic antiemetic therapy when two or more of the risk factors were present when using volatile anesthetics.⁷⁴ Many anesthesiologists prefer not to administer antiemetics as part of a preoperative regimen, but believe that antiemetics should be administered intravenously just before they are needed at the conclusion of surgery.

Droperidol

Droperidol has been administered, usually intravenously, in low clinical doses to prevent postoperative nausea and vomiting. An investigation by Korttila *et al* showed that 1.25 mg of droperidol given intravenously 5 minutes before the conclusion of surgery reduced the incidence of nausea and vomiting after operation.⁷⁵ They found the antiemetic effect of droperidol to be better than that of either metoclopramide or domperidone. Another study by Santos and Datta demonstrated the effectiveness of droperidol as an antiemetic for patients having cesarean section with spinal anesthesia (Fig. 21-7).⁷⁶ However, low doses of droperidol may not always be effective in preventing nausea and vomiting. Higher doses at the end of surgery may lead to excessive sedation in the recovery room.

Figure 21-7. Incidence of nausea and vomiting after elective cesarean section after intravenous administration of droperidol, 2.5 mg (Group 1), or saline (Group 2). (Reprinted from Santos A, Datta S: Prophylactic use of droperidol for control of nausea and vomiting during spinal anesthesia for cesarean section. *Anesth Analg* 63:85, 1984.)

Metoclopramide

As mentioned in the section on gastrokinetic agents, metoclopramide does have antiemetic properties. The effect after preoperative administration is controversial and inconsistent, as demonstrated and discussed in the study by Cohen *et al*.⁷⁷ This may partially result from the brief duration of action of metoclopramide.

Ondansetron

Ondansetron is a serotonin subtype-3 receptor antagonist. Administered in doses of 4–8 mg intravenously to adults before induction, ondansetron has been shown to be highly effective in preventing postoperative nausea and vomiting.⁷⁸ Its use preoperatively is not warranted in most patient populations, but should be reserved for highly selective situations.

Other Antiemetics

Some of the phenothiazines, especially prochlorperazine, have antiemetic action. Hydroxyzine and diphenidol are two other drugs with antiemetic value. Although it has antiemetic properties, domperidone has not been proved effective in reducing postoperative nausea and vomiting.⁷⁵

Anticholinergics

Previously, anticholinergic drugs were widely used when inhalation anesthetics produced copious respiratory tract secretions and intraoperative bradycardia was a frequent danger. The advent of newer inhalation agents has almost completely dispelled the routine use of anticholinergic drugs for preoperative medication. Their routine use has been questioned by several authors, who believe that the same care in selection of anticholinergics should be exhibited as in the choice of other drugs. Specific indications for an anticholinergic before surgery are (1) antisialagogue effect and (2) sedation and amnesia (Table 21-6). Uses that are less firmly established and not universally agreed on include the preoperative prescription of anticholinergics for their vagolytic action or in an attempt to decrease gastric acid secretion.

| | Atropine | Glycopyrrolate | Scopolamine |
|----------------------|----------|----------------|-------------|
| Increased heart rate | +++ | ++ | + |
| Antisialagogue | + | ++ | +++ |
| Sedation | + | 0 | +++ |

0 = no effect; + = small effect; ++ = moderate effect; +++ = large effect.

Adapted from Stoelting RK: *Pharmacology and Physiology in Anesthetic Practice*. Philadelphia, JB Lippincott, 1991.

Table 21-6. COMPARISON OF SOME OF THE EFFECTS OF ANTICHOLINERGIC DRUGS

Antisialagogue Effect

Anticholinergics have been prescribed in a selective fashion when drying of the upper airway is desirable. For example, when endotracheal intubation is contemplated, an anesthesiologist may want to reduce secretions. In the study by Falick and Smiler, conditions were more often rated as satisfactory after endotracheal intubation when an anticholinergic drug had been administered.²⁹ The antisialagogue effect may be important for intraoral operations and instrumentations of the airway such as bronchoscopic examination. Administration of anticholinergics may be desirable before the use of topical anesthesia for the airway to prevent a dilutional effect of secretions and to allow contact of the local anesthetic with the mucosa.

Scopolamine is a more potent drying agent than atropine. It is less likely to increase heart rate and more likely to produce sedation and amnesia. Glycopyrrolate is a more potent and longer-acting antisialagogue than atropine, with less likelihood of increasing heart rate. Because glycopyrrolate is a quaternary amine, it does not easily cross the blood–brain barrier and does not produce sedation. Anticholinergics are not the only drugs that can dry secretions. As demonstrated by the study of Forrest *et al*, several other drugs and placebo (presumably a reflection of apprehension) can cause a patient to have a dry mouth before operation⁸⁰ (Table 21-7).

| Medication | Dry Mouth | Shared Speech | Dizzy | Nauseated | Relaxed |
|---------------------------|-----------|---------------|-------|-----------|---------|
| Pentobarbital (50–150 mg) | 29 | 27 | 18 | 7 | 2 |
| Secobarbital (50–150 mg) | 41 | 32 | 8 | 9 | 4 |
| Diazepam (5–15 mg) | 35 | 28 | 18 | 3 | 12 |
| Hydroxyzine (50–150 mg) | 48 | 31 | 6 | 2 | 9 |
| Morphine (5–10 mg) | 81 | 33 | 15 | 7 | 20 |
| Meperidine (50–100 mg) | 65 | 45 | 20 | 12 | 25 |
| Placebo | 34 | 21 | 7 | 12 | 4 |

Modified from Forrest WH, Brown CR, Brown BW *et al*: Subjective responses to six common preoperative medications. *Anesthesiology* 62:201, 1977.

Table 21-7. INCIDENCE OF SIDE-EFFECTS 1 HOUR AFTER PREOPERATIVE MEDICATION (PERCENTAGE OF PATIENTS)

Sedation and Amnesia

When sedation and amnesia are desired before operation, scopolamine is frequently the anticholinergic chosen, especially in combination with morphine. Scopolamine and atropine both cross the blood–brain barrier. Scopolamine is a much more potent sedative and amnestic drug than atropine. In a study of patient acceptance of preoperative medication, the combination of morphine and scopolamine was superior to that of morphine and atropine.⁸¹ Scopolamine does not produce amnesia in all patients. It may not be as effective as lorazepam or diazepam in preventing recall. Scopolamine has an additive amnestic effect when combined with benzodiazepines. The study by Frumin *et al* showed that the combination of diazepam and scopolamine produced amnesia more often than did diazepam alone.¹⁴

Vagolytic Action

Vagolytic action of the anticholinergic drugs is produced through the blockade of effects of acetylcholine on the sinoatrial node. Atropine given intravenously is more potent than glycopyrrolate and scopolamine in increasing heart rate. The vagolytic action of the anticholinergic drugs is useful in the prevention of reflex bradycardia during surgery. Bradycardia may result from traction on extraocular muscles or abdominal viscera, from carotid sinus stimulation, or after the administration of repeated doses of intravenous succinylcholine. The prevention of reflex bradycardia with intramuscular doses of the anticholinergics is unreliable, given the drug dosages and timing usually involved with preoperative medication administered on the unit. Many anesthesiologists prefer to give atropine or glycopyrrolate intravenously just before surgery and the anticipated bradycardic stimulus. Atropine and glycopyrrolate given intravenously immediately before surgery have been equally effective in preventing bradycardia resulting from repeated doses of succinylcholine.⁸²

Elevation of Gastric Fluid pH Level

High doses of anticholinergics often are needed to alter gastric fluid pH. Even then, when given in the preoperative setting, anticholinergics cannot be relied on consistently to decrease gastric hydrogen ion secretion.^{49,50} This function has largely been replaced by the use of H₂ receptor antagonists (see [Gastric Fluid pH and Volume](#)).

Side Effects in Anticholinergic Drugs

Scopolamine and atropine may cause central nervous system toxicity, the so-called “central anticholinergic syndrome.” This is most likely to occur after the administration of scopolamine, but can be seen after high doses of atropine. The symptoms of central nervous system toxicity resulting from anticholinergic drugs include delirium, restlessness, confusion, and obtundation. Elderly patients and patients with pain appear to be particularly susceptible. The central nervous system toxic effect of anticholinergics has been noted to be potentiated by inhalation anesthetics. Some clinicians have successfully treated the syndrome after it occurred with 1–2 mg of physostigmine intravenously.

The anticholinergics relax the lower esophageal sphincter. In theory, after parenteral administration of an anticholinergic drug, the risk of pulmonary aspiration of gastric contents is increased. This has yet to be proved as an important clinical issue.

Mydriasis and cycloplegia from anticholinergic drugs could be unwanted in patients with glaucoma because of resulting increased intraocular pressure. This seems unlikely with the doses used for preoperative medication. Atropine and glycopyrrolate may be less likely to increase intraocular pressure than scopolamine. In patients with glaucoma, most anesthesiologists feel safe in continuing medications for glaucoma up until the time of surgery and using atropine or glycopyrrolate when necessary (see [Chapter 34](#)).

Because anticholinergic drugs block vagal activity, relaxation of bronchial smooth muscle occurs and respiratory dead space increases. The magnitude of the increase in dead space depends on prior bronchomotor tone, but increases as large as 25–33% have been reported. Anticholinergic drugs cause secretions to dry and thicken. In theory, a dose of anticholinergic drug given before operation could lead to inspissation of secretions and an increase in airway resistance. This may develop into more than a theoretical issue when patients with diseases such as cystic fibrosis are being considered.

Sweat glands of the body are innervated by the sympathetic nervous system and use cholinergic transmission. Therefore, administration of anticholinergic agents interferes with the sweating mechanism, which may cause body temperature to increase. This side effect of anticholinergic medication must be considered carefully in a child with a fever.

Atropine is more likely than glycopyrrolate or scopolamine to cause an increase in heart rate. Unwanted increases in heart rate are much more likely after intravenous administration than after intramuscular administration. In fact, heart rate may transiently decrease after intramuscular administration as a result of a peripheral agonist effect of the anticholinergic agent.

α_2 -Adrenergic Agonists

α_2 -Adrenergic agonists have been used as premedicants.^{83,84} Clonidine in doses of 2.5–5 μ g · kg⁻¹ has been administered preoperatively to produce sedation, reduce maximum allowable concentration, and prevent hypertension and tachycardia from endotracheal intubation and surgical stimulation. It has even been used as part of anesthetic technique to produce induced hypotension.⁸⁵ Dexmedetomidine is another α_2 -adrenergic agonist studied for preoperative use to attenuate intraoperative sympathoadrenal responses.⁸⁶ After the administration of clonidine preoperatively, one is more likely to see episodes of hypotension and bradycardia during anesthesia when there are periods of little surgical stimulation. Furthermore, some anesthesiologists ask if preoperative α_2 -adrenergic agonists are a substitute for a properly conducted anesthetic if appropriate attention is given to depth of anesthesia.

Other Drugs Given with Preoperative Medications

Although they are not preoperative medications in the strict sense, other drugs are often given at the time of preoperative medication. Examples of such drugs are insulin, steroids, antibiotics, and methadone for patients who are addicted to opioids. They may be prescribed by either the anesthesiologist or the surgeon to be given on the ward or in the operating room immediately prior to surgery. Regardless of these factors, their actions may affect the anesthetic, and the anesthesiologist must be knowledgeable about their administration and actions.

Antibiotics

Antibiotics are often administered immediately before operation for contaminated, potentially contaminated, or dirty surgical wounds. Prophylactic antibiotics may be warranted for “clean” surgical procedures when infection would be catastrophic. Other instances for the use of prophylactic antibiotics include in the immunosuppressed patient, in the aged, or in patients taking steroids. Antibiotics given immediately before surgery are also used for the prevention of endocarditis. Patients with valvular heart disease, prosthetic valves, mitral valve prolapse, or other cardiac abnormalities may be endangered by bacteremia produced during surgery.⁸⁷ Antibiotic administration comes under the anesthesiologist’s purview because of the desire to have such agents given immediately before exposure to pathogens, which is just before the beginning of surgery.

It has been estimated that 60–70% of surgical patients receive antibiotics just before surgery or intraoperatively. Cephalosporins are the most popular. However, no drug or combination of drugs may be relied on to protect against all potential pathogens in all patients for all types of surgery. As with any other medication, the anesthesiologist must know the side effects and complications of the antibiotics to be administered. Some are associated with allergic reactions, hypotension, and bronchospasm (e.g., penicillin and vancomycin). Allergic reactions from cephalosporin administration have been estimated to occur in about 5% of patients. Cross-reactivity of the cephalosporins in patients with a known penicillin allergy has been estimated at anywhere from 5 to 20%. The aminoglycosides, vancomycin, and the polymyxins have been implicated in nephrotoxicity. In addition, ototoxicity has resulted from aminoglycoside and vancomycin administration. Pseudomembranous colitis is a known complication of clindamycin administration. Finally, the aminoglycosides are known to extend the neuromuscular blocking effects of muscle relaxants.

Steroids

Steroid administration may be necessary immediately before surgery in the patient treated for hypoadrenocorticism or in the patient with suppression of the pituitary-adrenal axis owing to present or previous administration of corticosteroids. It is impossible to identify the specific duration of therapy or dose of steroids that produces pituitary and adrenal suppression. Marked variability among patients exists. Certainly, more suppression may be expected the higher the dose and the longer the duration of therapy. A conservative estimate is to consider treatment in any patient who has received corticosteroid therapy for at least 1 month in the past 6–12 months.

Because of disease states of the pituitary-adrenal axis or its suppression from steroid therapy, patients may not be able to respond to the stress of surgery. The dose and duration of supplemental steroid administration depend on an estimate of the stress of the surgical procedure in the perioperative period. One regimen is to administer 25 mg of cortisol preoperatively and then give an intravenous infusion of 100 mg of cortisol over the next 12–24 hours for adult patients.⁸⁸ Another method is to administer 100 mg of hydrocortisone intravenously before, during, and after surgery. This dose is meant to equal the estimated maximum amount of steroid that stress could produce in patients perioperatively. When considering whether to administer steroids or a higher dose of steroids, the anesthesiologist should keep in mind that the risk–benefit ratio is usually very small.

Insulin

Anesthesia and surgery may interrupt the regular meal schedule and insulin administration of diabetics (see [Chapter 18](#) and [Chapter 41](#)). Perioperative stress may increase serum glucose concentrations. A plan for perioperative insulin and glucose management must be agreed on among the anesthesiologist, the surgeon, and the endocrinologist involved in the diabetic patient's care. There are several methods of doing this, none of which has proved superior to the others. One method is to administer one fourth to one half of the usual daily dose of intermediate-acting insulin preoperatively in the morning of surgery and begin an infusion of glucose-containing fluid. A second way is to administer no insulin or no glucose preoperatively and to measure serum glucose levels frequently during anesthesia. Regular insulin or glucose is then administered intraoperatively and postoperatively as needed. A third method is to begin an infusion of insulin and glucose immediately preoperatively and to check serum glucose levels frequently.

Opioid Dependency

Withdrawal produced by drug cessation is a preoperative issue in the patient who is taking methadone or is dependent on other opioids. There should be an attempt to maintain opioid use at the usual level by continuing methadone or substituting other appropriate agents for methadone. The anesthesiologist should be cautioned about using agonist-antagonist drugs in these patients in the preoperative period for fear of producing withdrawal.

DIFFERENCES IN PREOPERATIVE MEDICATION BETWEEN PEDIATRIC AND ADULT PATIENTS

Differences between children and adults with regard to preoperative medication include aspects of psychological preparation, the emphasis on oral medications when pharmacologic preparation is desired, and more frequent use of anticholinergics for their vagolytic activity. What remains the same is the need to assess the needs of each child individually and to tailor the psychological preparation and preoperative medication accordingly (see [Chapter 44](#)).

Psychological Factors in Pediatric Patients

Hospital admission and major surgery can produce long-lasting psychological effects in some children. The hospital stay is stressful and full of apprehension over the short term for almost all children. Psychological stress and anxiety are less likely to occur with minor procedures and brief hospitalizations. Repeated hospitalizations have not necessarily been shown to increase the number of pediatric patients manifesting long-lasting psychological trauma.^{89,90} The demeanor and communicative efforts of the anesthesiologist can make a difference to the child who is getting ready for a trip to the operating room, anesthesia, and surgery.

Age is probably the most important aspect when psychological preparation of the pediatric patient is considered.⁹¹ A baby younger than 6 months of age is not emotionally upset when separated from his or her mother. Others in the health care team can substitute very easily. Preoperative preparation in this age group is often directed toward other goals, for example, obtundation of vagal reflex responses. However, preschool children are upset when separated from their mothers and fear the operating room. This is an age when hospitalization may be the most upsetting.^{89,90,91,92,93} It is difficult to explain the forthcoming events to children in this age group. It is easier to communicate with patients from age 5 years to adolescence. The anesthesiologist can explain and offer reassurance about such issues as separation from parents and the home, operating room events, and any of the patient's perceived fears of surgery and anesthesia. Adolescent patients may already be anxious and apprehensive. They may also be worried about loss of consciousness, have a fear of death, or be apprehensive about what they will do or say after preoperative sedation or during anesthesia. The more fearful child may be difficult to identify. This is usually the child who is quiet during the preoperative interview and appears nonchalant or even detached. If these patients can be identified before operation, they are often candidates for heavy pharmacologic preparation.

Other important psychological aspects in preoperative preparation include the anxiety level, attitude, and behavior of the parents, the socioeconomic status of the family, the magnitude of the planned surgery, and the hospital environment.

Psychological Preparation

For the above reasons, a good preoperative visit and proper psychological preparation may be even more important in children than adults.^{94,95,96} This is an art that is acquired by the anesthesiologist. The preoperative visit is a time of reassurance and explanation. It is an opportunity to gain the child's trust. Most anesthesiologists will want to involve the parents when possible. The child can then see the parents' acceptance of the anesthesiologist. Some hospitals have found brochures, motion pictures, and slide shows to be helpful in preparing pediatric patients for the operating room.⁹⁷ The child may want to bring a personal belonging, such as a stuffed animal or blanket, to the operating room for security. Some children wish to take an active role by doing such things as holding the face mask during inhalation induction of anesthesia. It may be helpful in a case with supportive parents to have them accompany the child to the operating room suite after an examination of events that may occur during induction. It is common in many hospitals for a parent to go into the operating room and stay until induction is complete.

Differences in Pharmacologic Preparation

The discussion of pharmacologic preparation for the pediatric patient presumes proper psychological preparation, a satisfactory operating room environment, and preparation for an efficient and timely induction of anesthesia (see [Chapter 44](#)).

Sedative-Hypnotics

As in adults, the sedative-hypnotic medications are used to reduce apprehension and produce sedation and amnesia. They are also used to facilitate smooth induction of anesthesia when an inhalation method is to be used. The use of preoperative medication is controversial in pediatric patients and may not be completely successful in 20% of instances. It has not been proved to reduce unwanted psychological outcome after surgery in anesthesia. It has been shown that the uneventful induction of anesthesia is less likely to produce long-lasting psychological problems in children.^{89,92} After 6 months to 1 year of age, the child scheduled for a surgical procedure may benefit from a sedative hypnotic drug before surgery. There is some emphasis on avoiding intramuscular injections in children. The oral route is often used for preoperative medication in the older child, whereas in preschool children drugs may also be given rectally. Many different sedative-hypnotic drugs via different routes (oral, intranasal, and rectal) have been prescribed for children before operation. Midazolam can be given intramuscularly ($0.2 \text{ mg} \cdot \text{kg}^{-1}$). However, the most effective and acceptable route for midazolam is the oral route, achieved by mixing $0.5\text{--}0.75 \text{ mg} \cdot \text{kg}^{-1}$ with flavored syrup, apple juice, or cola because of its bitter taste.⁹⁸ It is effective in producing sedation and compliance, but not usually sleep, in about 15 minutes and lasts for 30–60 minutes. Oral ketamine $5\text{--}10 \text{ mg}$ has been prescribed 20–30 minutes before induction. Although often allowing smooth separation from parents, oral secretions and preoperative or postoperative delirium can be problems. Both ketamine ($3\text{--}8 \text{ mg} \cdot \text{kg}^{-1}$) and midazolam ($0.2 \text{ mg} \cdot \text{kg}^{-1}$) can be given using a nasal atomizer, with the caveat that nasal drug administration and bitter aftertaste are disadvantageous. Ketamine ($5 \text{ mg} \cdot \text{kg}^{-1}$) and midazolam ($0.3\text{--}1.0 \text{ mg} \cdot \text{kg}^{-1}$) have also been given rectally before induction of anesthesia. A further option in the pharmacologic preparation of children is the rectal administration of methohexital ([Fig. 21-8](#)). Methohexital ($20\text{--}30 \text{ mg} \cdot \text{kg}^{-1}$) may be given immediately before operation, while the child is still in the parent's arms. The intramuscular route is also possible.

Figure 21-8. Frequency distribution of sleep induction times after rectal instillation of methohexital. Patients averaged 3.3 years in age and 15 kg in body weight. (Reprinted from Liu LMP, Goudsouzian NG, Liu PL: Rectal methohexital premedication in children, a dose-comparison study. *Anesthesiology* 53:343, 1980.)

Opioids

There is the occasional need for opioid premedication in children. Methadone has the advantage of oral administration, usually prescribed in the 0.1–0.2 mg · kg⁻¹ dose range. Intramuscular morphine and meperidine are used, often in combination with other premedications. Intramuscular morphine is often seen as part of the pharmacologic preparation for the child with congenital heart disease. In many hospitals, opioids have been combined with sedative-hypnotic and anticholinergic drugs to make a “cocktail” that may be given orally for preoperative medication. Transmucosal administration of fentanyl (5–20 μg · kg⁻¹) appears to be effective in producing sedation preoperatively. However, transmucosal fentanyl may increase gastric fluid volume and also increase the incidence of rigidity, respiratory depression, pruritus, nausea, and vomiting.^{47,99,100,101} Fentanyl (2 μg · kg⁻¹) and sufentanil (3.0 μg · kg⁻¹) given by the intranasal route have been shown to calm pediatric patients preoperatively. Again, postoperative nausea and vomiting, in addition to respiratory complications, have resulted in lack of enthusiasm for this technique.

Anticholinergics

Easily induced vagal reflexes make anticholinergics especially important in children. Bradycardia may result from airway manipulation, surgical manipulation, or anesthetic drugs such as halothane or succinylcholine. Also, the child's cardiac output is more dependent on heart rate than is the adult's. If no contraindication exists, most pediatric patients receive atropine intravenously immediately after induction of anesthesia and placement of an intravenous catheter. If the intramuscular route has been used for atropine, it will often be administered immediately after the patient becomes unconscious during induction of anesthesia. Glycopyrrrolate also has been used in children in this setting. Scopolamine has a place in premedication of the pediatric patient to produce sedation, amnesia, and drying of the airways. One must be aware of the hazards of administering an anticholinergic to a child with a fever or when inspissation of secretions is not wanted. Finally, it has been noted that patients with Down syndrome appear to be sensitive to atropine. This is especially evident with the effect on heart rate and mydriasis.

An anesthesia system consists of the various components that communicate with each other during the administration of inhalation anesthesia.¹ System components include the anesthesia machine, the vaporizers, the anesthetic circuit, the ventilator, and the scavenging system. A thorough understanding of these parts is essential to the safe practice of anesthesia. Malpractice claims associated with gas delivery equipment are infrequent but severe, and continued to occur throughout the 1990s.² This chapter discusses the normal operation, function, and integration of major system components. More importantly, it illustrates some problems and hazards associated with each and describes appropriate preoperative checks.

ANESTHESIA MACHINES

Anesthesia machines have evolved from simple, pneumatic devices to sophisticated, computer-based, fully integrated anesthesia systems (Fig. 22-1 and Fig. 22-2). A few years ago, a rudimentary background in pneumatics sufficed; but today, an understanding of pneumatics, electronics, and even computer science is useful. Even though it is more difficult for the anesthesiologist to achieve a thorough understanding of modern anesthesia machines, it is essential to the safe practice of anesthesia. The anesthesiologist must be aware of design differences between manufacturers so that appropriate preoperative checks can be performed.

Anesthesia Machine Standards

Anesthesia machine standards provide guidelines to manufacturers regarding minimum performance, design characteristics, and safety requirements for anesthesia machines. During the past two decades, the progression of anesthesia machine standards has been as follows:

1979: American National Standards Institute (ANSI) Z79.8-1979³

1988: American Society for Testing and Materials (ASTM) F1161-88⁴

1994: ASTM 1161-94⁵

1998: ASTM F1850-98a⁶

To comply with the new 1998 ASTM F1850-98a standard, newly manufactured workstations must have monitors that measure the following parameters: continuous breathing system pressure, exhaled tidal volume, ventilatory carbon dioxide concentration, anesthetic vapor concentration, inspired oxygen concentration, oxygen supply pressure, arterial hemoglobin oxygen saturation, arterial blood pressure, and continuous electrocardiogram. The anesthesia workstation must have a prioritized alarm system that groups the alarms into three categories: high, medium, and low priority. These monitors and alarms may be automatically enabled and made to function by turning on the anesthesia workstation, or the monitors and alarms can be manually enabled and made functional by following a pre-use checklist.⁶

Generic Anesthesia Machine

A diagram of a generic two-gas anesthesia machine is shown in [Figure 22-3](#). Both oxygen and nitrous oxide have two supply sources—a *pipeline supply source* and a *cylinder supply source*. The pipeline supply source is the primary gas source for the anesthesia machine. The hospital piping system provides gases to the machine at approximately 50 pounds per square inch gauge (psig), which is the normal working pressure of most machines. The cylinder supply source serves as a backup if the pipeline fails. The oxygen cylinder source is regulated from 2200 to approximately 45 psig, and the nitrous oxide cylinder source is regulated from 745 to approximately 45 psig.^{7,8,9,10,11,12,13,14,14,15,16,17,18,19,20,21,22 and 23}

Figure 22-3. Diagram of a generic two-gas anesthesia machine. (Modified with permission from Check-Out, A Guide for Preoperative Inspection of an Anesthesia Machine. American Society of Anesthesiologists, Park Ridge, Illinois, 1987.)

A safety device traditionally referred to as the *fail-safe valve* is located downstream from the nitrous oxide supply source. It serves as an interface between the oxygen and nitrous oxide supply sources. This valve shuts off or proportionally decreases the supply of nitrous oxide (and other gases) if the oxygen supply pressure decreases. Contemporary machines have an alarm device to monitor the oxygen supply pressure. An alarm is actuated at a predetermined oxygen pressure, such as 30 psig.^{7,8,18,23}

Most Ohmeda machines have a *second-stage oxygen regulator* located downstream from the oxygen supply source. It is adjusted to a precise pressure level, such as 14 psig.^{8,11,12,13,14,15,16 and 17} This regulator supplies a constant pressure to the oxygen flow control valve regardless of fluctuating oxygen pipeline pressures. For example, the flow from the oxygen flow control valve will be constant if the oxygen supply pressure is greater than 14 psig.

The *flow control valves* are an important anatomic landmark because they divide the anesthesia machine into two parts. The *high-pressure circuit* is the part of the machine that is upstream from the flow control valves, and the *low-pressure circuit* is the part of the machine that is downstream from the flow control valves. The operator regulates flow entering the low-pressure circuit by adjusting the flow control valves. The oxygen and nitrous oxide flow control valves are linked mechanically or pneumatically by a *proportioning system* to help prevent delivery of a hypoxic mixture. The flow travels through a *common manifold* and may be directed to a *calibrated vaporizer*. Precise amounts of inhaled anesthetic can be added, depending on the vaporizer setting. The total fresh gas flow travels toward the *common gas outlet*.^{7,8}

Many Ohmeda machines have a *machine outlet check valve* between the vaporizers and the common gas outlet.^{8,9,10,11,12,13,14 and 15} Its purpose is to prevent backflow into the vaporizer, thereby minimizing the effects of downstream intermittent pressure fluctuations on inhaled anesthetic concentration (see Vaporizers: [Intermittent Back Pressure](#)). The presence or absence of a check valve profoundly influences which preoperative leak test is indicated (see [Checking Anesthesia Machines](#)). The *oxygen flush connection* joins the mixed-gas pipeline between the one-way check valve and the machine outlet. Thus, the oxygen flush, when activated, has a “straight shot” to the common gas outlet.^{7,8}

Pipeline Supply Source

The pipeline supply source is the primary gas source for the anesthesia machine. Most hospitals today have a central piping system to deliver medical gases such as oxygen, nitrous oxide, and air to the operating room. The central piping system must supply the anesthesia machine with the appropriate gas at the appropriate pressure for the machine to function properly. Unfortunately, this does not always occur.

In a survey of approximately 200 hospitals in 1976, 31% reported difficulties with pipeline systems.²⁴ The most common problem was inadequate oxygen pressure, followed by excessive pipeline pressures. The most devastating reported hazard, however, was accidental crossing of oxygen and nitrous oxide pipelines, which caused several deaths. This problem caused 23 deaths in a newly constructed wing of a general hospital in Sudbury, Ontario, during a 5-month period.^{24,25}

The operator must take two actions if a pipeline crossover is suspected. First, the backup oxygen cylinder should be turned on. Then, the pipeline supply must be disconnected. This second step is mandatory because the machine will preferentially use the inappropriate 50-psig pipeline supply source instead of the lower pressure (45 psig) oxygen cylinder source.

Gas enters the anesthesia machine through the pipeline inlet connections ([Fig. 22-3](#); see arrows). The pipeline inlet fittings are gas-specific Diameter Index Safety System (DISS) threaded body fittings. The DISS provides threaded noninterchangeable connections for medical gas lines, which minimizes the risk of misconnection. A check valve is located downstream from the inlet. It prevents reverse flow of gases from the machine to the pipeline or the atmosphere.⁶

Cylinder Supply Source

Anesthesia machines have reserve E cylinders if a pipeline supply source is not available or if the pipeline fails. Color-coded cylinders are attached to the anesthesia machine through the hanger yoke assembly. The hanger yoke assembly orients and supports the cylinder, provides a gas-tight seal, and ensures a unidirectional flow of gases into the machine.⁷ Each hanger yoke is equipped with the Pin Index Safety System (PISS). The PISS is a safeguard introduced to eliminate cylinder interchanging and the possibility of accidentally placing the incorrect gas on a yoke designed to accommodate another gas. Two pins on the yoke are arranged so that

they project into the cylinder valve. Each gas or combination of gases has a specific pin arrangement.²⁶

Gas travels from the high-pressure cylinder source to the anesthesia machine when the cylinder is turned on (Fig. 22-3). A check valve is located downstream from each cylinder if a double-yoke assembly is used. The check valve has several functions. First, it minimizes gas transfer from a cylinder at high pressure to one with lower pressure. Second, it allows an empty cylinder to be exchanged for a full one while gas flow continues from the other cylinder into the machine with minimal loss of gas. Third, it minimizes leakage from an open cylinder to the atmosphere if one cylinder is absent.^{7,8} A cylinder supply pressure gauge is located downstream from the check valves. The gauge will indicate the pressure in the cylinder having the higher pressure when two reserve cylinders of the same gas are opened at the same time.²⁰

Each cylinder supply source has a pressure-reducing valve known as the cylinder pressure regulator. It reduces the high and variable storage pressure present in a cylinder to a lower, more constant pressure suitable for use in the anesthesia machine. The oxygen cylinder pressure regulator reduces the oxygen cylinder pressure from a high of 2200 psig to approximately 45 psig. The nitrous oxide cylinder pressure regulator receives pressure of up to 745 psig and reduces it to approximately 45 psig.^{7,8}

The cylinders should be turned off except during the preoperative machine checking period or when a pipeline source is unavailable. If left on, the reserve cylinder supply can be silently depleted whenever the pressure inside the machine decreases to a value lower than the regulated cylinder pressure. Oxygen pressure within the machine can decrease below 45 psig with oxygen flushing or with ventilator use, particularly at high peak flow rates. The pipeline supply pressures of all gases can be less than 45 psig if problems exist in the central piping system. If the cylinders are left on, they will eventually become depleted. Then, no reserve supply will be available if there is a pipeline failure.^{8,27}

Oxygen Supply Pressure Failure Safety Devices

Oxygen and nitrous oxide supply sources existed as independent entities in older models of anesthesia machines, and they were not pneumatically or mechanically interfaced. Therefore, abrupt or insidious oxygen pressure failure had the potential to lead to the delivery of a hypoxic mixture. The 1998 ASTM F1850-98a standard states that, "The anesthesia gas supply device shall be designed so that whenever oxygen supply pressure is reduced to below the manufacturer specified minimum, the delivered oxygen concentration shall not decrease below 19% at the common gas outlet."⁶ Contemporary anesthesia machines have a number of safety devices that act together in a cascade manner to minimize the risk of hypoxia as oxygen pressure decreases. Several of these devices are described below.

Pneumatic and Electronic Alarm Devices

Many older anesthesia machines have a pneumatic alarm device that sounds a warning when the oxygen supply pressure decreases to a predetermined threshold value, such as 30 psig. The 1998 ASTM F1850-98a standard mandates that a medium priority alarm shall be activated within 5 seconds when the oxygen pressure decreases below a manufacturer-specific pressure threshold.⁶ Electronic alarm devices are now used to meet this guideline.

Fail-Safe Valves

A fail-safe valve is present in the gas line supplying each of the flowmeters except oxygen. Controlled by oxygen supply pressure, the valve shuts off or proportionally decreases the supply pressure of all other gases (nitrous oxide, air, carbon dioxide, helium, nitrogen) as the oxygen supply pressure decreases. Unfortunately, the misnomer "fail-safe" has led to the misconception that the device prevents administration of a hypoxic mixture. This is not the case. Machines that are not equipped with a flow proportioning system (see [Proportioning Systems](#)) can deliver a hypoxic mixture under normal working conditions. The oxygen flow control valve can be closed intentionally or accidentally. Normal oxygen pressure will keep other gas lines open so that a hypoxic mixture can result.^{7,8}

Ohmeda machines are equipped with a fail-safe valve known as the pressure-sensor shut off valve (Fig. 22-4). The valve is threshold in nature, and it is either open or closed. Oxygen supply pressure opens the valve, and the valve return spring closes the valve. Figure 22-4 shows a nitrous oxide pressure-sensor shutoff valve with a threshold pressure of 20 psig.^{12,13,15,16} and ¹⁷ In Figure 22-4A, an oxygen supply pressure greater than 20 psig is exerted upon the mobile diaphragm. This pressure moves the piston and pin upward and the valve opens. Nitrous oxide flows freely to the nitrous oxide flow control valve. In Figure 22-4B, the oxygen supply pressure is less than 20 psig, and the force of the valve return spring completely closes the valve.⁸ Nitrous oxide flow stops at the closed fail-safe valve, and it does not advance to the nitrous oxide flow control valve.

Figure 22-4. Pressure-sensor shutoff valve. The valve is open in A because the oxygen supply pressure is greater than the threshold value of 20 psig. The valve is closed in B because of inadequate oxygen pressure. (Redrawn with permission from Bowie E, Huffman LM: *The Anesthesia Machine: Essentials for Understanding*. Madison, WI, Ohmeda, a division of BOC Health Care Inc., 1985.)

North American Dräger uses a fail-safe valve known as the Oxygen Failure Protection Device (OFPD) that interfaces the oxygen pressure with that of other gases, such as nitrous oxide, air, carbon dioxide, helium, and nitrogen.^{18,19,20,21,22} and ²³ It differs from Ohmeda's oxygen pressure-sensor shutoff valve because the OFPD is based on a proportioning principle rather than a threshold principle. The pressure of all gases controlled by the OFPD will decrease proportionally with the oxygen pressure. The OFPD consists of a seat-nozzle assembly connected to a spring-loaded piston, as shown in Figure 22-5. The oxygen supply pressure in the left panel is 50 psig. This pressure pushes the piston upward, forcing the nozzle away from the valve seat. Nitrous oxide (or other gases) advances toward the flow control valve at 50 psig. The oxygen pressure in the right panel is 0 psig. The spring is expanded and forces the nozzle against the seat, preventing flow through the device. Finally, the center panel shows an intermediate oxygen pressure of 25 psig. The force of the spring partially closes the valve. The nitrous oxide pressure delivered to the flow control valve is 25 psig. There is a continuum of intermediate configurations between the extremes (0–50 psig) of oxygen supply pressure. These intermediate valve configurations are responsible for the proportional nature of the OFPD.¹⁸

Figure 22-5. Oxygen Failure Protection Device (OFPD), which responds proportionally to changes in oxygen supply pressure. (Redrawn with permission from Narkomed 2A Anesthesia System. Technical Service Manual, 6th ed. Telford, PA, North American Dräger, June 1985.)

Second-Stage Oxygen Pressure Regulator

Most contemporary Ohmeda machines have a second-stage oxygen pressure regulator set at a specific value ranging from 12 to 19 psig.^{12,13,14,15,16} and ¹⁷ Oxygen flowmeter output is constant when the oxygen supply pressure exceeds the set value. Ohmeda pressure-sensor shutoff valves are set at a higher threshold value (20–30 psig). This ensures that oxygen is the last gas flow to decrease if oxygen pressure fails.

Flowmeter Assembly

The flowmeter assembly (Fig. 22-6) precisely controls and measures gas flow to the common gas outlet. The flow control valve regulates the amount of flow that enters a tapered, transparent flow tube known as a Thorpe tube. A mobile indicator float inside the flow tube indicates the amount of flow passing through the flow control valve. The quantity of flow is indicated on a scale associated with the flow tube.^{7,8}

Figure 22-6. Oxygen flowmeter assembly. The oxygen flowmeter assembly is composed of the flow control valve assembly plus the flowmeter subassembly. (Reproduced with permission from Bowie E, Huffman LM: *The Anesthesia Machine: Essentials for Understanding*. Madison, WI, Ohmeda, a division of BOC Health Care Inc, 1985.)

Physical Principles of Flowmeters

Opening the flow control valve allows gas to travel through the space between the float and the flow tube. This space is known as the annular space (Fig. 22-7). The indicator float hovers freely in an equilibrium position where the upward force resulting from gas flow equals the downward force on the float resulting from gravity at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flowmeters are commonly referred to as *constant pressure flowmeters* because the pressure decrease across the float remains constant for all positions in the tube.^{7,26,28}

Figure 22-7. The annular space. The clearance between the head of the float and the flow tube is known as the annular space. It can be considered an equivalent to a circular channel of the same cross-sectional area. (Redrawn with permission from Macintosh R, Mushin WW, Epstein HG: *Physics for the Anaesthetist*, 3rd ed. Oxford, Blackwell Scientific Publications, 1963.)

Flow tubes are tapered, with the smallest diameter at the bottom of the tube and the largest diameter at the top. The term *variable orifice* designates this type of unit because the annular space between the float and the inner wall of the flow tube varies with the position of the float. Flow through the constriction created by the float can be laminar or turbulent, depending on the flow rate (Fig. 22-8). The characteristics of a gas that influence its flow rate through a given constriction are viscosity (laminar flow) and density (turbulent flow). Because the annular space is tubular at low flow rates, laminar flow is present and viscosity determines the gas flow rate. The annular space simulates an orifice at high flow rates, and turbulent gas flow then depends predominantly on the density of the gas.^{7,28}

Figure 22-8. Flow tube constriction. The lower pair of illustrations represents the lower portion of a flow tube. The clearance between the head of the float and flow tube is narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining gas flow rate through this tubular constriction. The upper pair of illustrations represents the upper portion of a flow tube. The equivalent channel is orificial because its length is less than its width. Density is dominant in determining gas flow rate through this orificial constriction. (Redrawn with permission from Macintosh R, Mushin WW, Epstein HG: *Physics for the Anaesthetist*, 3rd ed. Oxford, Blackwell Scientific Publications, 1963.)

Components of Flowmeter Assembly

Flow Control Valve Assembly. The flow control valve (see Fig. 22-6) assembly is composed of a flow control knob, a needle valve, a valve seat, and a pair of valve stops.⁷ The assembly can receive its pneumatic input either directly from the pipeline source (50 psig) or from a second-stage pressure regulator. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Extreme clockwise rotation results in damage to the needle valve and valve seat. Therefore,

flow control valves are equipped with valve “stops” to prevent this occurrence.⁸

SAFETY FEATURES Contemporary flow control valve assemblies have numerous safety features. The oxygen flow control knob is physically distinguishable from other gas knobs. It is distinctively fluted, projects beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases. All knobs are color-coded for the appropriate gas, and the chemical formula or name of the gas is permanently marked on each. Flow control knobs are recessed or protected with a shield or barrier to minimize inadvertent change from a preset position. If a single gas has two flow tubes, the tubes are arranged in series and are controlled by a single flow control valve.⁶

Flowmeter Subassembly. The flowmeter subassembly (see Fig. 22-6) consists of the flow tube, the indicator float with float stops, and the indicator scale.⁷

FLOW TUBES Contemporary flow tubes are made of glass. Most have a single taper in which the inner diameter of the flow tube increases uniformly from bottom to top. Manufacturers provide double flow tubes for oxygen and nitrous oxide to provide better visual discrimination at low flow rates. A fine flow tube indicates flow from approximately 200 ml.min⁻¹ to 1 l.min⁻¹, and a coarse flow tube indicates flow from approximately 1 l.min⁻¹ to 10–12 l.min⁻¹. The two tubes are connected in series and supplied by a single flow control valve. The total gas flow is that shown on the higher flowmeter.

INDICATOR FLOATS AND FLOAT STOPS Contemporary anesthesia machines use several different types of bobbins or floats, including plumb-bob floats,^{11,12,13,16,17} rotating skirted floats,^{14,15} and ball floats.^{18,19,20,21} and ²² Flow is read at the top of plumb-bob and skirted floats and at the center of the ball on the ball-type floats.⁷ Flow tubes are equipped with float stops at the top and bottom of the tube. The upper stop prevents the float from ascending to the top of the tube and plugging the outlet. It also ensures that the float will be visible at maximum flows instead of being hidden in the manifold. The bottom float stop provides a central foundation for the indicator when the flow control valve is turned off.^{7,8}

SCALE The flowmeter scale can be marked directly on the flow tube or located to the right of the tube.⁶ Gradations corresponding to equal increments in flow rate are closer together at the top of the scale because the annular space increases more rapidly than does the internal diameter from bottom to top of the tube. Rib guides are used in some flow tubes with ball-type indicators to minimize this compression effect. They are tapered glass ridges that run the length of the tube. There are usually three rib guides that are equally spaced around the inner circumference of the tube. In the presence of rib guides, the annular space from the bottom to the top of the tube increases almost proportionally with the internal diameter. This results in a nearly linear scale.⁷ Rib guides are employed on North American Dräger flow tubes.^{18,19,20,22}

SAFETY FEATURES The flowmeter subassembly for each gas on the Ohmeda Modulus I, Modulus II, Modulus II Plus, and CD is housed in an independent, color-coded, pin-specific module. The flow tubes are adjacent to a gas-specific, color-coded backing. The flow scale and the chemical formula or name of the gas are permanently etched on the backing to the right of the flow tube.^{11,12,13,16,17} Flowmeter scales are individually hand-calibrated using the specific float to provide a high degree of accuracy. The tube, float, and scale make an inseparable unit. The entire set must be replaced if any component is damaged.^{11,12,13,16,17}

North American Dräger does not use a modular system for the flowmeter subassembly. The flow scale, the chemical symbol, and the gas-specific color codes are etched directly onto the flow tube.^{18,19,20,21} and ²²The scale in use is obvious when two flow tubes for the same gas are used.

Problems with Flowmeters

Leaks. Flowmeter leaks are a substantial hazard because the flowmeters are located downstream from all machine safety devices except the oxygen analyzer.¹ Leaks can occur at the O-rings between the glass flow tube and the metal manifold and in the glass flow tubes, the most fragile pneumatic component of the anesthesia machine. Gross damage to glass flow tubes is usually apparent, but subtle cracks and chips may be overlooked, resulting in errors of delivered flows.²⁹

Eger *et al* in 1963³⁰ demonstrated that, in the presence of a flowmeter leak, a hypoxic mixture is less likely to occur if the oxygen flowmeter is located downstream from all other flowmeters.²⁸ Figure 22-9 is a contemporary version of the figure in Eger's original publication. The unused air flow tube has a large leak. Nitrous oxide and oxygen flow rates are set at a ratio of 3:1. A potentially dangerous arrangement is shown in Figure 22-9A and Figure 29-9B because the nitrous oxide flowmeter is located in the downstream position. A hypoxic mixture can result because a substantial portion of oxygen flow passes through the leak, and all nitrous oxide is directed to the common gas outlet. A safer configuration is shown in Figure 22-9C and Figure 22-9D. The oxygen flowmeter is located in the downstream position. A portion of the nitrous oxide flow escapes through the leak, and the remainder goes toward the common gas outlet. A hypoxic mixture is less likely because all the oxygen flow is advanced by the nitrous oxide.³⁰ North American Dräger flowmeters are arranged as in Figure 22-9C, and Ohmeda flowmeters are arranged as in Figure 22-9D.

Figure 22-9. Flowmeter sequence—a potential cause of hypoxia. In the event of a flowmeter leak, a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (A and B). The safest configuration exists when oxygen is located in the downstream position (C and D). (Modified with permission from Eger EI II, Hylton RR, Irwin RH *et al*: Anesthetic flowmeter sequence—a cause for hypoxia. *Anesthesiology* 24:396, 1963.)

A leak in the oxygen flow tube can produce a hypoxic mixture even when oxygen is located in the downstream position (Fig. 22-10).^{1,29} Oxygen escapes through the leak and nitrous oxide flows toward the common outlet, particularly at high ratios of nitrous oxide to oxygen flow.

Figure 22-10. Oxygen flow tube leak. An oxygen flow tube leak can produce a hypoxic mixture regardless of flow tube arrangement. (Reproduced with permission from Andrews JJ: Inhaled anesthetic delivery systems. In Miller RD (ed): *Anesthesia*, 5th ed, p 174. Philadelphia, Churchill Livingstone, 1999.)

Inaccuracy. Flow error can occur even when flowmeters are assembled properly with appropriate components. Dirt or static electricity can cause a float to stick, and the actual flow may be higher or lower than that indicated. Sticking is more common in the low flow range because the annular space is smaller. A damaged float can

cause inaccurate readings because the precise relationship between the float and the flow tube is altered. Back pressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flow-meters are not aligned properly in the vertical position, readings can be inaccurate because tilting distorts the annular space.^{7,29,31}

Ambiguous Scale. Before the standardization of flowmeter scales and the widespread use of oxygen analyzers, at least two deaths resulted from confusion created by ambiguous scales.^{29,31,32} The operator read the float position beside an adjacent but erroneous scale in both cases. Today, this error is less likely to occur because contemporary flowmeter scales are marked either directly onto or to the right of the appropriate flow tube.⁶ Confusion is minimized when the scale is etched directly onto the tube.

Proportioning Systems

Manufacturers have equipped newer machines with proportioning systems in an attempt to prevent delivery of a hypoxic mixture. Nitrous oxide and oxygen are interfaced either mechanically or pneumatically so that the minimum oxygen concentration at the common outlet is 25%.

Ohmeda Link-25 Proportion Limiting Control System

Contemporary Ohmeda machines use the Link-25 System. The heart of the system is the mechanical integration of the nitrous oxide and oxygen flow control valves. It allows independent adjustment of either valve, yet automatically intercedes to maintain a minimum 25% oxygen concentration with a maximum nitrous oxide–oxygen flow ratio of 3:1. The Link-25 automatically increases oxygen flow to prevent delivery of a hypoxic mixture.^{11,12,13,14,15,16} and ¹⁷

Figure 22-11 shows the Ohmeda Modulus II Link-25 System. The nitrous oxide and oxygen flow control valves are identical. A 14-tooth sprocket is attached to the nitrous oxide flow control valve, and a 28-tooth sprocket is attached to the oxygen flow control valve. A chain physically links the sprockets. When the nitrous oxide flow control valve is turned through two revolutions, or 28 teeth, the oxygen flow control valve will revolve once because of the 2:1 gear ratio. The final 3:1 flow ratio results because the nitrous oxide flow control valve is supplied by approximately 26 psig, whereas the oxygen flow control valve is supplied by 14 psig. Thus, the combination of the mechanical and pneumatic aspects of the system yields the final oxygen concentration.^{12,13}

Figure 22-11. Ohmeda Link-25 Proportion Limiting Control System.

North American Dräger Oxygen Ratio Monitor Controller

North American Dräger's proportioning system, the Oxygen Ratio Monitor Controller (ORMC), is used on the North American Dräger Narkomed 2A, 2B, 3, and 4.^{18,19,20,21,22} and ²³ It is a pneumatic oxygen–nitrous oxide interlock system designed to maintain a fresh gas oxygen concentration of at least $25 \pm 3\%$. The device controls the fresh gas oxygen concentration to levels substantially higher than 25% at oxygen flow rates less than $1 \text{ l}\cdot\text{min}^{-1}$. The ORMC limits nitrous oxide flow to prevent delivery of a hypoxic mixture.^{18,19,20,21} and ²² This is unlike the Ohmeda Link-25, which actively increases oxygen flow.

A schematic of the ORMC is shown in Figure 22-12. It is composed of an oxygen chamber, a nitrous oxide chamber, and a nitrous oxide slave control valve; all are interconnected by a mobile horizontal shaft. The pneumatic input into the device is from the oxygen and the nitrous oxide flowmeters. These flowmeters are unique because they have specific resistors located downstream from the flow control valves. These resistors create back pressures directed to the oxygen and nitrous oxide chambers. The value of the oxygen flow tube resistor is three to four times that of the nitrous oxide flow tube resistor, and the relative value of these resistors determines the value of the controlled fresh gas oxygen concentration. The back pressure in the oxygen and nitrous oxide chambers pushes against rubber diaphragms attached to the mobile horizontal shaft. Movement of the shaft regulates the nitrous oxide slave control valve, which feeds the nitrous oxide flow control valve.^{1,19,23}

Figure 22-12. North American Dräger Oxygen Ratio Monitor Controller. (Redrawn with permission from Schreiber P: Safety Guidelines for Anesthesia Systems. Telford, PA, North American Dräger, 1984.)

If the oxygen pressure is proportionally higher than the nitrous oxide pressure, the nitrous oxide slave control valve opens more widely, allowing more nitrous oxide to flow. As the nitrous oxide flow is increased manually, the nitrous oxide pressure forces the shaft toward the oxygen chamber. The valve opening becomes more restrictive and limits the nitrous oxide flow to the flowmeter.

Figure 22-12 illustrates the action of a single ORMC under different sets of circumstances. The back pressure exerted on the oxygen diaphragm, in the upper configuration, is greater than that exerted on the nitrous oxide diaphragm. This causes the horizontal shaft to move to the left, opening the nitrous oxide slave control valve. Nitrous oxide is then able to proceed to its flow control valve and out through the flowmeter. In the bottom configuration, the nitrous oxide slave control valve is closed because of inadequate oxygen back pressure.^{1,18,23}

Limitations

Proportioning systems are not foolproof. Machines equipped with proportioning systems still can deliver a hypoxic mixture under the following conditions.

Wrong Supply Gas. Both the Link-25 and the ORMC will be fooled if a gas other than oxygen is present in the oxygen pipeline. In the Link-25 System, the nitrous oxide and oxygen flow control valves will continue to be mechanically linked, and a hypoxic mixture will proceed to the common outlet. The oxygen rubber diaphragm of the ORMC will recognize adequate “oxygen” pressure, and flow of both the wrong gas plus nitrous oxide will result. The oxygen analyzer is the only machine monitor

that will detect this condition in both systems.

Defective Pneumatics or Mechanics. Normal operation of the Ohmeda Link-25 and the North American Dräger ORMC is contingent upon pneumatic and mechanical integrity.³³ Pneumatic integrity in the Ohmeda System depends on properly functioning second-stage regulators. A nitrous oxide-oxygen ratio other than 3:1 will result if the regulators are not precise. The chain connecting the two sprockets must be intact. A 97% nitrous oxide concentration can occur if the chain is cut or broken.³⁴ In the North American Dräger System, a functional Oxygen Failure Protection Device (OFPD) is necessary to supply appropriate pressure to the ORMC. The mechanical aspects of the ORMC, such as the rubber diaphragms, the flow tube resistors, and the nitrous oxide slave control valve, must likewise be intact.

Leaks Downstream. The ORMC and the Link-25 function at the level of the flow control valves. A leak downstream from these devices, such as a broken oxygen flow tube (see Fig. 22-10), can cause delivery of a hypoxic mixture. Oxygen escapes through the leak, and the predominant gas delivered at the common outlet is nitrous oxide. The oxygen analyzer is the only machine safety device that can detect the problem.¹ North American Dräger recommends a preoperative positive pressure leak test to detect such a leak.^{18,19,20,21} and ²² Ohmeda recommends a preoperative negative pressure leak test because of the check valve located at the common outlet^{9,10,11,12,13,15} (see [Checking Anesthesia Machines](#)).

Inert Gas Administration. Administration of a third inert gas, such as helium, nitrogen, or carbon dioxide, can cause a hypoxic mixture because contemporary proportioning systems link only nitrous oxide and oxygen.^{11,12,13,14,15,16,17,18,19,20,21,22,35} Use of an oxygen analyzer is mandatory if the operator uses a third inert gas.

Oxygen Flush Valve

The oxygen flush valve allows direct communication between the oxygen high-pressure circuit and the low-pressure circuit (see Fig. 22-3). Flow from the oxygen flush valve enters the low-pressure circuit downstream from the vaporizers and downstream from the Ohmeda machine outlet check valve. The spring-loaded oxygen flush valve stays closed until the operator opens it by depressing the oxygen flush button. Actuation of the valve delivers 35–75 l.min⁻¹ to the breathing circuit.⁸

The oxygen flush valve can provide effective jet ventilation if the anesthesia machine is equipped with a one-way check valve positioned between the vaporizer and the oxygen flush valve. Because the Ohmeda Modulus II has such a valve, the entire oxygen flow of 45–75 l.min⁻¹ is delivered to the common gas outlet at a high pressure of 50 psig. On the other hand, the Ohmeda Modulus II Plus, which does not have the check valve, provides only 7 psig at the common gas outlet because some oxygen flow travels retrograde through an internal relief valve located upstream from the oxygen flush valve. The North American Dräger Narkomed 2A, which also does not have the check valve, provides an intermediate pressure of 18 psig to the common gas outlet because some oxygen flow travels retrograde through a pop-off valve located in the vaporizers.³⁶

The oxygen flush valve is associated with several hazards. A defective or damaged valve can stick in the fully open position, causing barotrauma.³⁷ A valve sticking in a partially open position can result in patient awareness because the oxygen flow from the incompetent valve dilutes the inhaled anesthetic.³⁸ Improper use of normally functioning oxygen flush valves also can result in problems. Overzealous intraoperative oxygen flushing can dilute inhaled anesthetics. Oxygen flushing during the inspiratory phase of positive pressure ventilation can cause barotrauma. Excess volume cannot be vented from the breathing circuit because the ventilator relief valve is closed and the Adjustable Pressure Limiting (APL) valve is either out-of-circuit or closed.³⁹ If a machine is equipped with a freestanding vaporizer downstream from the common gas outlet, oxygen flushing can deliver large quantities of inhaled anesthetic to the patient. Finally, inappropriate preoperative use of the oxygen flush to evaluate the low-pressure circuit for leaks can be misleading, particularly on Ohmeda machines with a check valve at the common outlet.⁴⁰ Back pressure from the breathing circuit closes the check valve airtight, and major low-pressure circuit leaks can go undetected (see [Checking Anesthesia Machines](#)).

VAPORIZERS

Through the years, vaporizers have evolved from rudimentary ether inhalers to copper kettles to the present temperature-compensated, variable bypass vaporizers. With the introduction of the new inhaled anesthetic, desflurane, even more sophisticated vaporizers have been introduced. Before the discussion of variable bypass vaporizers, the Datex-Ohmeda Tec 6 desflurane vaporizer, and the Datex-Ohmeda Aladin cassette vaporizer, certain physical principles are reviewed briefly to facilitate understanding of the operating principles, construction, and design of contemporary vaporizers.

Physics

Vapor Pressure

Contemporary inhaled volatile anesthetics exist in the liquid state below 20°C. When a volatile liquid is in a closed container, molecules escape from the liquid phase to the vapor phase until the number of molecules in the vapor phase is constant. These molecules bombard the wall of the container and create a pressure known as the *saturated vapor pressure*. As the temperature increases, more molecules enter the vapor phase, and the vapor pressure increases (Fig. 22-13). Vapor pressure is independent of atmospheric pressure and is contingent only on the temperature and physical characteristics of the liquid. The boiling point of a liquid is that temperature at which the vapor pressure equals atmospheric pressure.^{41,42} and ⁴³ At 760 mm Hg, the boiling points for desflurane, isoflurane, halothane, enflurane, and sevoflurane are approximately 22.8, 48.5, 50.2, 56.5, and 58.5°C, respectively. Unlike other contemporary inhaled anesthetics, desflurane boils at temperatures commonly encountered in clinical settings such as pediatric and burn operating rooms. This unique physical characteristic mandates a special vaporizer design to deliver desflurane.

Figure 22-13. Vapor pressure versus temperature curves for desflurane, isoflurane, halothane, enflurane, and sevoflurane. The vapor pressure curve for desflurane is both steeper and shifted to higher vapor pressures when compared with the curves for other contemporary inhaled anesthetics. (From inhaled anesthetic package insert equations; from Susay SR, Smith MA, Lockwood GG: The saturated vapor pressure of desflurane at various temperatures. *Anesth Analg* 83:864, 1996.)

Latent Heat of Vaporization

Energy must be expended to convert a molecule from the liquid to gaseous state because the molecules of a liquid tend to cohere. The *latent heat of vaporization* is defined as the number of calories required to change 1 g of liquid into vapor without a temperature change. The energy for vaporization must come from the liquid itself or from an outside source. The temperature of the liquid decreases during vaporization in the absence of an outside energy source. Energy loss can lead to significant decreases in temperature of the remaining liquid. This temperature drop will greatly decrease vaporization.^{41,43,44}

Specific Heat

The *specific heat* of a substance is the number of calories required to increase the temperature of 1 g of a substance by 1°C.^{41,43,45} The substance can be solid, liquid, or gas. The concept of specific heat is important to the design, operation, and construction of vaporizers because it is applicable in two ways. First, the specific heat value for an inhaled anesthetic is important because it indicates how much heat must be supplied to the liquid to maintain a constant temperature when heat is lost during vaporization. Second, manufacturers select vaporizer metals that have a high specific heat to minimize temperature changes associated with vaporization.

Thermal Conductivity

Thermal conductivity is a measure of the speed with which heat flows through a substance. The higher the thermal conductivity, the better the substance conducts heat.⁴¹ Vaporizers are constructed of metals that have relatively high thermal conductivity, which helps maintain a uniform temperature.

Variable Bypass Vaporizers

The Ohmeda Tec 4, the Ohmeda Tec 5, and the North American Dräger Vapor 19.1 are classified as variable bypass, flow-over, temperature-compensated, agent-specific, out-of-circuit vaporizers.⁴¹ *Variable bypass* refers to the method for regulating output concentration. As gas flow enters the vaporizer's inlet, the setting of the concentration control dial determines the ratio of flow that goes through the bypass chamber and through the vaporizing chamber. The gas channeled to the vaporizing chamber flows over the liquid anesthetic and becomes saturated with vapor. Thus, *flow-over* refers to the method of vaporization. The Tec 4, the Tec 5, and the Vapor 19.1 are classified as *temperature-compensated* because they are equipped with an automatic temperature-compensating device that helps maintain a constant vaporizer output over a wide range of temperatures. These vaporizers are *agent-specific* and *out-of-circuit* because they are designed to accommodate a single agent and to be located outside the breathing circuit. Variable bypass vaporizers are used to deliver halothane, enflurane, isoflurane, and sevoflurane, but not desflurane.

Basic Operating Principles

A diagram of a generic, variable bypass vaporizer is shown in [Figure 22-14](#). Vaporizer components include the concentration control dial, the bypass chamber, the vaporizing chamber, the filler port, and the filler cap. Using the filler port, the operator fills the vaporizing chamber with liquid anesthetic. The maximum safe level is predetermined by the position of the filler port, which is positioned to minimize the chance of overfilling. If a vaporizer is overfilled or tilted, liquid anesthetic can spill into the bypass chamber, causing an overdose. The concentration control dial is a variable restrictor, and it can be located either in the bypass chamber or the outlet of the vaporizing chamber. The function of the concentration control dial is to regulate the relative flow rates through the bypass and vaporizing chambers.

Figure 22-14. Generic variable bypass vaporizer.

Flow from the flowmeters enters the inlet of the vaporizer. More than 80% of the flow passes straight through the bypass chamber to the vaporizer outlet, and this accounts for the name “bypass chamber.” Less than 20% of the flow from the flowmeters is diverted through the vaporizing chamber. Depending on the temperature and vapor pressure of the particular inhaled anesthetic, the flow through the vaporizing chamber entrains a specific flow of inhaled anesthetic. All three flows—flow through the bypass chamber, flow through the vaporizing chamber, and flow of entrained anesthetic—exit the vaporizer at the outlet. The final concentration of inhaled anesthetic is the ratio of the flow of the inhaled anesthetic to the total gas flow.^{41,46}

The vapor pressure of an inhaled anesthetic depends on the ambient temperature ([Fig. 22-13](#)). For example, at 20°C the vapor pressure of isoflurane is 238 mm Hg, whereas at 35°C the vapor pressure almost doubles (450 mm Hg). Variable bypass vaporizers have an internal mechanism to compensate for different ambient temperatures. The temperature-compensating valve of the Ohmeda Tec 4 is shown in [Figure 22-15](#).⁴⁷ At high temperatures, such as those commonly used in pediatric or burn operating rooms, the vapor pressure inside the vaporizing chamber is high. To compensate for this increased vapor pressure, the bimetallic strip of the temperature-compensating valve leans to the right. This allows more flow to pass through the bypass chamber and less flow to pass through the vaporizing chamber. The net effect is a constant vaporizer output. In a cold operating room environment, the vapor pressure inside the vaporizing chamber decreases. To compensate for this decrease in vapor pressure, the bimetallic strip swings to the left, causing more flow to pass through the vaporizing chamber and less to pass through the bypass chamber. The net effect is a constant vaporizer output.

Figure 22-15. Simplified schematic of the Ohmeda Tec 4 vaporizer.

Factors That Influence Vaporizer Output

The output of an ideal vaporizer with a fixed dial setting would be constant regardless of varied flow rates, temperatures, back pressures, and carrier gases. Designing such a vaporizer is difficult because as ambient conditions change, the physical properties of gases and of vaporizers themselves can change.⁴⁶ Contemporary vaporizers approach ideal but still have some limitations. Several factors can influence vaporizer output.

Flow Rate. With a fixed dial setting, vaporizer output varies with the rate of gas flowing through the vaporizer. This variation is particularly notable at extremes of flow rates. The output of all variable bypass vaporizers is less than the dial setting at low flow rates (less than 250 ml.min⁻¹). This results from the relatively high density of volatile inhaled anesthetics. Insufficient turbulence is generated at low flow rates in the vaporizing chamber to upwardly advance the vapor molecules. At extremely high flow rates, such as 15 l.min⁻¹, the output of most variable bypass vaporizers is less than the dial setting. This discrepancy is attributed to incomplete mixing and saturation in the vaporizing chamber. Also, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases. These changes can result in decreased output concentration.⁴⁶

Temperature. Because of improvements in design, the output of contemporary temperature-compensated vaporizers is almost linear over a wide range of temperatures. Automatic temperature-compensating mechanisms in bypass chambers maintain a constant vaporizer output with varying temperatures.^{8,47,48} A bimetallic strip ([Fig. 22-15](#)) or an expansion element ([Fig. 22-16](#)) directs a greater proportion of gas flow through the bypass chamber as temperature increases.⁴⁶ Wicks are placed in direct contact with the metal wall of the vaporizer to help replace heat used for vaporization. Vaporizers are constructed with metals having relatively high specific heat and high thermal conductivity to minimize heat loss.

Figure 22-16. Simplified schematic of the North American Dräger Vapor 19.1 vaporizer.

Intermittent Back Pressure. Intermittent back pressure associated with positive pressure ventilation or with oxygen flushing can cause higher vaporizer output concentration than the dialed setting. This phenomenon, known as the *pumping effect*,^{41,46,49,50} and ⁵¹ is more pronounced at low flow rates, low dial settings, and low levels of liquid anesthetic in the vaporizing chamber. Additionally, the pumping effect is increased by rapid respiratory rates, high peak inspired pressures, and rapid drops in pressure during expiration.^{47,48,49,50} and ⁵¹ The Ohmeda Tec 4 and North American Dräger Vapor 19.1 are relatively immune from the pumping effect.^{47,48} One proposed mechanism for the pumping effect is dependent on retrograde pressure transmission from the patient circuit to the vaporizer during the inspiratory phase of positive pressure ventilation. Gas molecules are compressed in both the bypass and vaporizing chambers. When the back pressure is suddenly released during the expiratory phase of positive pressure ventilation, vapor exits the vaporizing chamber via the vaporizing chamber outlet and retrograde through the vaporizing chamber inlet. This occurs because the output resistance of the bypass chamber is lower than that of the vaporizing chamber, particularly at low dial settings. The enhanced output concentration results from the increment of vapor that travels in the retrograde direction to the bypass chamber.^{46,49,50} and ⁵¹

To decrease the pumping effect, the vaporizing chambers of the Tec 4 and the Vapor 19.1 are smaller than those of older variable bypass vaporizers such as the Fluotec Mark II (750 ml).^{47,48,50} Therefore, no substantial volumes of vapor can be discharged from the vaporizing chamber into the bypass chamber during the expiratory phase. The North American Dräger Vapor 19.1 (Fig. 22-16) has a patented, long spiral tube that serves as the inlet to the vaporizing chamber.^{48,50} When the pressure in the vaporizing chamber is released, some of the vapor enters this tube but does not enter the bypass chamber because of tube length.⁵⁰ The Tec 4 (Fig. 22-15) has an extensive baffle system in the vaporizing chamber, and a one-way check valve has been inserted at the common gas outlet to minimize the pumping effect. This check valve attenuates but does not eliminate the pressure increase because gas still flows from the flowmeters to the vaporizer during the inspiratory phase of positive pressure ventilation.^{41,52}

Carrier Gas Composition. Vaporizer output is influenced by the composition of the carrier gas that flows through the vaporizer.^{47,48,53,54,55,56,57,58,59} and ⁶⁰ When the carrier gas is quickly switched from 100% oxygen to 100% nitrous oxide, there is a rapid transient decrease in vaporizer output followed by a slow increase to a new steady-state value (Fig. 22-17b).^{58,59} The transient decrease in vaporizer output is attributed to nitrous oxide's being more soluble than oxygen in halogenated liquid.⁵⁸ Therefore, the quantity of gas leaving the vaporizing chamber is transiently diminished until the anesthetic liquid is totally saturated with nitrous oxide.

Figure 22-17. Halothane output of a North American Dräger Vapor 19.1 vaporizer with different carrier gases. The initial output concentration is approximately 4% halothane when oxygen is the carrier gas at flows of 6 l·min⁻¹ (a). When the carrier gas is quickly switched to 100% nitrous oxide (b), the halothane concentration decreases to 3% within 8–10 sec. Then, a new steady-state concentration of approximately 3.5% is attained within 1 min. (Modified with permission from Gould DB, Lampert BA, MacKrell TN: Effect of nitrous oxide solubility on vaporizer aberrance. *Anesth Analg* 61:939, 1982.)

The explanation for the new steady-state output value is less well understood.⁶⁰ With contemporary vaporizers such as the North American Dräger Vapor 19.1 and the Ohmeda Tec 4, the steady-state output value is less when nitrous oxide rather than oxygen is the carrier gas (Fig. 22-17b).^{47,48} Conversely, the output of some older vaporizers is enhanced when nitrous oxide is the carrier gas instead of oxygen.^{53,55} The steady-state plateau is achieved more rapidly with increased flow rates, regardless of the ultimate output value.⁵⁹ Factors that contribute to the characteristic steady-state response resulting when various carrier gases are used include the viscosity and density of the carrier gas, the relative solubilities of the carrier gas in the liquid anesthetic, the flow splitting characteristics of the specific vaporizer, and the dial setting.^{55,58,59} and ⁶⁰

Safety Features

The North American Dräger 19.1, the Ohmeda Tec 4, and the Ohmeda Tec 5 have many safety features that have minimized or eliminated many hazards once associated with variable bypass vaporizers. Agent-specific, keyed filling devices help prevent filling a vaporizer with the wrong agent. Overfilling of these vaporizers is minimized because the filler port is located at the maximum safe liquid level. Today's vaporizers are firmly secured to the vaporizer manifold, and there is little need to move them. Thus, problems associated with tipping are minimized. Contemporary interlock systems prevent administration of more than one inhaled anesthetic.^{47,48,61}

Hazards

Despite many safety features, some hazards are still associated with contemporary variable bypass vaporizers.

Misfilling. Vaporizers not equipped with keyed fillers have occasionally been misfilled with the wrong anesthetic liquid.⁶² A potential for misfilling exists even on contemporary vaporizers equipped with keyed fillers.^{63,64} and ⁶⁵

Contamination. Contamination of anesthetic vaporizer contents has occurred by filling an isoflurane vaporizer with a contaminated bottle of isoflurane. A potentially serious incident was avoided because the operator did not use the contaminated vaporizer after detecting an abnormal acrid odor.⁶⁶

Tipping. Tipping can occur when vaporizers are incorrectly “switched out” or moved. However, tipping is unlikely when a vaporizer is attached to a manifold in the upright position. Excessive tipping can cause the liquid agent to enter the bypass chamber and can cause a high output concentration.⁶⁷ The Tec 4 is slightly more immune to tipping than is the Vapor 19.1 because of its extensive baffle system. However, if either vaporizer is tipped, it should not be used until it has been flushed for 20–30 minutes at high flow rates with the vaporizer set at a low concentration.⁴¹

Overfilling. Improper filling procedures combined with failure of the vaporizer sight glass can cause overfilling and overdose. Liquid anesthetic enters the bypass

chamber, and up to ten times the intended vapor concentration can be delivered.⁶⁸

Simultaneous Inhaled Anesthetic Administration. Two inhaled anesthetics can be administered simultaneously when the center Tec 4 vaporizer is removed from Ohmeda machines equipped with the older style Selectatec[®] vaporizer manifold. The left or right vaporizer should be moved to the central position if the central vaporizer is removed as indicated by the manifold label. The interlock system will then function properly because the two remaining vaporizers are adjacent.^{12,13 and 14}

Leaks. Leaks occur often with vaporizers, and vaporizer leaks can cause patient awareness during anesthesia.^{41,69,70 and 71} A loose filler cap is the most common source of vaporizer leaks. With some key-filled Penlon and Dräger vaporizers, a loose filler screw clamp allows escape of saturated anesthetic vapor.⁷¹ Leaks can occur at the O-ring junction between the vaporizer and its manifold. A vaporizer must be in the “on” position to detect a leak within it. Vaporizer leaks in the North American Dräger System can be detected with a conventional positive pressure leak test because of the absence of check valves. Ohmeda recommends a negative pressure leak testing device (suction bulb) to detect vaporizer leaks in the Modulus I, Modulus II, and the Excel because of the check valve at the machine outlet^{11,12,13,15} (see [Checking Anesthesia Machines](#)).

The Datex-Ohmeda Tec 6 Vaporizer for Desflurane

Controlled vaporization of desflurane requires an electrically heated, pressurized vaporizer because of desflurane's unique physical properties.^{72,73} The vapor pressure of desflurane is three to four times that of contemporary inhaled anesthetics, and it boils at 22.8°C,⁷² which is near room temperature ([Fig. 22-13](#)). Desflurane has minimum alveolar anesthetic concentration (MAC) values of 6–7%.⁷² Desflurane is valuable because it has a low blood gas solubility coefficient of 0.45 at 37°C, and recovery from anesthesia is more rapid than with most other potent inhaled anesthetics.⁷⁴

Unsuitability of Contemporary Variable Bypass Vaporizers for Controlled Vaporization of Desflurane

Desflurane's high volatility and moderate potency preclude its use with contemporary variable bypass vaporizers such as Ohmeda Tec 4, Tec 5, or the North American Dräger Vapor 19.1 for two reasons⁷²:

1. The vapor pressure of desflurane is near one atmosphere. The vapor pressures of sevoflurane, enflurane, isoflurane, halothane, and desflurane at 20°C are 160, 172, 240, 244, and 669 mm Hg,⁷⁴ respectively ([Fig. 22-13](#)). Normal flow through a traditional vaporizer would vaporize many more volumes of desflurane. For example, at 1 atm and 20°C, 100 ml.min⁻¹ passing through the vaporizing chamber entrains 735 ml.min⁻¹ desflurane versus 27, 29, 46, and 47 ml.min⁻¹ of sevoflurane, enflurane, isoflurane, and halothane, respectively.⁷² Under these same conditions, the amount of bypass flow necessary to achieve sufficient distribution of anesthetic vapor to produce 1% desflurane output would be approximately 73 l.min⁻¹, compared to 5 l.min⁻¹ or less for the other three anesthetics. Above 22.8°C at 1 atm, desflurane will boil. The amount of vapor produced would be limited only by the heat energy available from the vaporizer owing to its specific heat.⁷²
2. Contemporary vaporizers lack an external heat source. Although desflurane has a heat of vaporization approximately equal to that of sevoflurane, enflurane, isoflurane, and halothane, its MAC is 4–9 times higher than that of the other four inhaled anesthetics. Thus, the absolute amount of desflurane vaporized over a given time period is considerably higher than with other anesthetics. Supplying desflurane in higher concentrations would cause excessive cooling of the vaporizer. In the absence of an external heat source, temperature compensation using traditional mechanical devices would be almost impossible over a broad clinical range of temperatures because of desflurane's steep vapor pressure versus temperature curve ([Fig. 22-13](#)).⁷²

Operating Principles of the Tec 6

To achieve controlled vaporization of desflurane, Ohmeda has introduced the Tec 6 vaporizer, which is electrically heated and pressurized.⁷⁵ The physical appearance and operation of the Tec 6 are similar to contemporary vaporizers, but some aspects of the internal design and operating principles are radically different. A simplified schematic of the Tec 6 is shown in [Figure 22-18](#). The vaporizer has two independent gas circuits arranged in parallel. The fresh gas circuit is shown in gray, and the vapor circuit is shown in white. The fresh gas from the flowmeters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is electrically heated and thermostatically controlled to 39°C, a temperature well above desflurane's boiling point. The heated sump assembly serves as a reservoir of desflurane vapor. At 39°C, the vapor pressure in the sump is approximately 1300 mm Hg absolute,⁷⁶ or approximately 2 atm absolute ([Fig. 22-13](#)). Just downstream from the sump is the shutoff valve. After the vaporizer warms up, the shutoff valve fully opens when the concentration control valve is turned to the on position. A pressure-regulating valve downstream from the shutoff valve down-regulates the pressure to approximately 1.1 atm absolute (74 mm Hg gauge) at a fresh gas flow rate of 10 l.min⁻¹. The operator controls desflurane output by adjusting the concentration control valve (R2), which is a variable restrictor.⁷²

The vapor flow through R2 joins the fresh gas flow through R1 at a point downstream from the restrictors. Until this point, the two circuits are physically divorced. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When a constant fresh gas flow rate encounters the fixed restrictor R1, a specific back pressure proportional to the fresh gas flow rate pushes against the diaphragm of the control differential pressure transducer. The differential pressure transducer conveys the pressure difference between the fresh gas circuit and the vapor circuit to the control electronics system. The control electronics system regulates the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, and the working pressure is constant at a fixed fresh gas flow rate. If the operator increases the fresh gas flow rate, more back pressure is exerted upon the diaphragm of the control pressure transducer, and the working pressure of the vaporizer increases.⁷²

[Table 22-1](#) shows the approximate correlation between fresh gas flow rate and working pressure for a typical vaporizer. At a fresh gas flow rate of 1 l.min⁻¹, the working pressure is 10 millibars (mbar), or 7.4 mm Hg gauge. At a fresh gas flow rate of 10 l.min⁻¹, the working pressure is 100 mbar, or 74 mm Hg gauge. Therefore, there is a linear relationship between fresh gas flow rate and working pressure. When the fresh gas flow rate is increased tenfold, the working pressure increases tenfold.⁷²

| Fresh Gas Flow Rate (l·min ⁻¹) | Working Pressure at R1 and R2 (Gauge) (Gas Inlet Pressure) | | |
|--|--|----------|-------|
| | mbar | cm water | mm Hg |
| 1 | 10 | 10.2 | 7.4 |
| 5 | 50 | 51.0 | 37.0 |
| 10 | 100 | 102.0 | 74.0 |

Reprinted with permission from Andrews J, Johnston RV Jr: The new Tec 6 desflurane vaporizer. *Anesth Analg* 76:1338, 1993.

Table 22-1. FRESH GAS FLOW RATE VERSUS WORKING PRESSURE

Listed below are two specific examples to demonstrate the operating principles of the Tec 6.⁷²

Example A: Constant fresh gas flow rate of 1 l.min⁻¹, with an increase in the dial setting.

With a fresh gas flow rate of 1 l.min⁻¹, the working pressure of the vaporizer is 7.4 mm Hg. That is, the pressure supplying R1 and R2 is 7.4 mm Hg. As the operator increases the dial setting, the opening at R2 becomes larger, allowing more vapor to pass through R2. Specific vapor flow values at different dial settings are shown in [Table 22-2](#).

| Fresh Gas Flow Rate (l·min ⁻¹) | Working Pressure at R1 and R2 (Gauge) (Gas Inlet Pressure) | | |
|--|--|----------|-------|
| | mbar | cm water | mm Hg |
| 1 | 10 | 10.2 | 7.4 |
| 5 | 50 | 51.0 | 37.0 |
| 10 | 100 | 102.0 | 74.0 |

Table 22-2. DIAL SETTING VERSUS FLOW THROUGH RESTRICTOR R2

Example B: Constant dial setting with an increase in fresh gas flow from 1 to 10 l·min⁻¹.

At a fresh gas flow rate of 1 l·min⁻¹, the working pressure is 7.4 mm Hg, and at a dial setting of 6% the vapor flow rate through R2 is 64 ml·min⁻¹ (Table 22-1 and Table 22-2). With a tenfold increase in the fresh gas flow rate, there is a concomitant tenfold increase in the working pressure to 74 mm Hg. The ratio of resistances of R2 to R1 is constant at a fixed dial setting of 6%. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases tenfold to 640 ml·min⁻¹. Vaporizer output is constant because both the fresh gas flow and the vapor flow increase proportionally.

Factors that Influence Vaporizer Output

Varied altitude and carrier gas composition influence Tec 6 output. Each is discussed below:

Varied Altitudes. Unlike contemporary variable bypass vaporizers, the Tec 6 vaporizer requires manual adjustments of the concentration control dial at altitudes other than sea level to maintain a constant partial pressure of anesthetic. The Tec 6 itself works at absolute pressures; therefore, altitude makes no difference to the vaporizer's performance *per se*. It will accurately deliver the dialed volume percent (vol%) of desflurane. However, when this gas is brought to ambient atmosphere at high altitudes, the vol% will represent an absolute decrease in the partial pressure of the anesthetic. This is not the case with contemporary variable bypass vaporizers, which deliver a constant partial pressure of anesthetic. To compensate for the reduction of partial pressure of vapor at altitude, the Tec 6 rotary valve must be advanced to maintain the required anesthetic partial pressure. The required dial setting may be calculated using the following formula:⁷⁵

$$\begin{aligned} \text{Required dial setting} \\ &= \text{Normal dial setting (vol\%)} \\ &\quad \times (760 \text{ mm Hg}) / (\text{ambient pressure (mm Hg)}) \end{aligned}$$

For example, at an altitude of 2000 m (6564 feet), where the ambient pressure is 608 mm Hg, the operator must advance the concentration control dial from 10 to 12.5% to maintain the required anesthetic partial pressure.⁷⁵ In hyperbaric settings, the operator must decrease the dial setting to prevent delivery of an overdose.

Carrier Gas Composition. Vaporizer output approximates the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated using 100% oxygen.⁷⁵ At low flow rates when a carrier gas other than 100% oxygen is used, however, a clear trend toward reduction in vaporizer output emerges. This reduction parallels the proportional decrease in viscosity of the carrier gas. Nitrous oxide has a lower viscosity than oxygen, so the back pressure generated by resistor R1 (see Fig. 22-18) is lower when nitrous oxide is the carrier gas, and the working pressure is reduced. At low flow rates using nitrous oxide as the carrier gas, vaporizer output is approximately 20% less than the dial setting. This suggests that, at clinically useful fresh gas flow rates, the gas flow across resistor R1 is laminar, and the working pressure is proportional to both the fresh gas flow rate and the viscosity of the carrier gas.⁷⁷

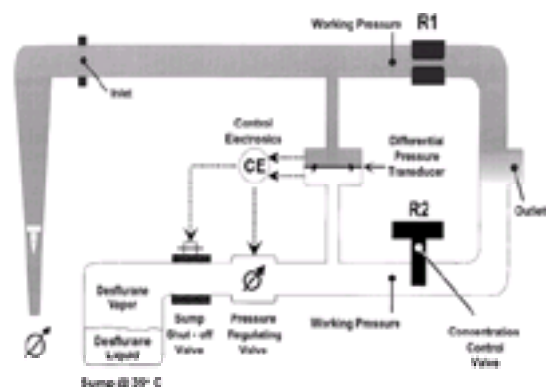

Figure 22-18. Simplified schematic of the Tec 6 desflurane vaporizer. (Modified with permission from Andrews JJ: Operating Principles of the Ohmeda Tec 6 Desflurane Vaporizer: A Collection of Twelve Color Illustrations. Washington, D.C., Library of Congress, 1996.)

Safety Features

Because desflurane's vapor pressure is near 1 atm, misfilling contemporary vaporizers with desflurane can theoretically cause desflurane overdose and hypoxemia.⁷⁸ Ohmeda has introduced a unique, anesthetic-specific filling system to minimize occurrence of this potential hazard. The agent-specific filler cap of the desflurane bottle prevents its use with traditional vaporizers. The filling system also minimizes spillage of liquid or vapor anesthetic by maintaining a "closed system" during the filling process. Each desflurane bottle has a spring-loaded filler cap with an O-ring on the tip. The spring seals the bottle until it is engaged in the filler port of the vaporizer. Thus, this anesthetic-specific filling system interlocks the vaporizer and the dispensing bottle, preventing loss of anesthetic to the atmosphere.⁷⁵ One case report described misfilling a Tec 6 desflurane vaporizer with sevoflurane, an error made possible by the similarities between the keyed fillers on the bottles of desflurane and sevoflurane. The desflurane vaporizer detected this error and promptly shut off.⁸⁵

Major vaporizer faults cause the shutoff valve located just downstream from the desflurane sump (Fig. 22-18) to close, producing a no-output situation. The valve is closed and a "no output" alarm is activated immediately if any of the following conditions occur: (a) the anesthetic level decreases to below 20 ml; (b) the vaporizer is tilted; (c) a power failure occurs; or (d) there is a disparity between the pressure in the vapor circuit versus the pressure in the fresh gas circuit exceeding a specified tolerance.⁷⁵

Summary

The Tec 6 vaporizer is an electrically heated, thermostatically controlled, constant-temperature, pressurized, electromechanically coupled dual circuit, gas-vapor blender. The pressure in the vapor circuit is electronically regulated to equal the pressure in the fresh gas circuit. At a constant fresh gas flow rate, the operator regulates vapor flow using a conventional concentration control dial. When the fresh gas flow rate increases, the working pressure increases proportionally. At a specific dial setting at different fresh gas flow rates, vaporizer output is constant because the amount of flow through each circuit is proportional.⁷²

The Datex-Ohmeda Aladin Cassette Vaporizer

The vaporizer system used in the Datex-Ohmeda Anesthesia Delivery Unit (ADU) is unique, and the electronically controlled vaporizer is designed to deliver five different inhaled anesthetics including halothane, isoflurane, enflurane, sevoflurane, and desflurane. The vaporizer consists of a permanent internal control unit housed within the ADU and an interchangeable Aladin agent cassette which contains anesthetic liquid. The Aladin agent cassettes are color-coded for each anesthetic agent, and they are also magnetically coded so that the Datex Ohmeda ADU can identify which anesthetic cassette has been inserted. The cassettes are filled using

agent-specific fillers.^{41,79}

The anatomy of the ADU vaporizer (see Fig. 22-19) is very similar to that of the Dräger vapor 19.1 and the Ohmeda Tec 4 vaporizer, and it is made up of the bypass chamber and vaporizing chamber. A fixed restrictor is located in the bypass chamber, and flow measurement units are located in the bypass chamber and in the outlet of the vaporizing chamber. The heart of the ADU vaporizer is the electronically controlled flow control valve located in the vaporizing chamber outlet. This valve is controlled by a central processing unit (CPU). The CPU receives input from multiple sources including the concentration control dial, a pressure sensor located inside the vaporizing chamber, a temperature sensor located inside the vaporizing chamber, a flow measurement unit located in the bypass chamber, and a flow measurement unit located in the outlet of the vaporizing chamber. The CPU also receives input from the flow meters regarding the composition of the carrier gas. Using data from these multiple sources, the CPU is able to precisely regulate the flow control valve to attain the desired vapor concentration. Appropriate electronic control of the flow control valve is essential to the proper function of this vaporizer.^{41,79}

Figure 22-19. Simplified schematic of the Datex-Ohmeda Aladin Cassette Vaporizer. The black arrows represent flow from the flowmeters, and the white circles represent anesthetic vapor. The heart of the vaporizer is the electronically controlled flow control valve located in the outlet of the vaporizing chamber. CPU = central processing unit; F_{BC} = flow measurement unit that measures flow through the bypass chamber; F_{VC} = flow measurement unit that measures flow through the vaporizing chamber; P = pressure sensor; T = temperature sensor. (Modified with permission from Andrews JJ: Operating Principles of the Datex-Ohmeda Aladin Cassette Vaporizer: A Collection of Twelve Color Illustrations. Washington, D.C., Library of Congress, 2000.)

A fixed restrictor is located in the bypass chamber, and it causes the vaporizer inlet flow to split into two portions (see Fig. 22-19). One portion passes through the bypass chamber, and the other portion enters the inlet of the vaporizing chamber and passes through a one-way check valve. The one-way check valve protects against back flow of agent into the bypass chamber.⁴¹ A precise amount of carrier gas flow and vapor flow passes through the flow control valve, which is regulated by the CPU. This flow then joins the bypass flow to the outlet of the vaporizer.^{41,79}

Vaporization of desflurane presents a unique challenge, particularly when the room temperature is greater than the boiling point of desflurane (22.8°C). At higher temperatures, the pressure inside the sump increases, and the sump becomes pressurized. When the sump pressure exceeds the pressure in the bypass chamber, the one-way check valve located in the vaporizing chamber inlet closes shut, preventing carrier gas from entering the vaporizing chamber. Then, the carrier gas passes straight through the bypass chamber. Under these conditions, the electronically controlled flow control valve simply meters in the appropriate flow of pure desflurane vapor.

When large quantities of anesthetic liquid are vaporized during high fresh gas flow rates and/or high dial settings, the vaporizer cools because of the latent heat of vaporization. To offset this cooling effect, the ADU is equipped with a fan which warms the vaporizer back up toward room temperature. The fan is activated during two common clinical scenarios: (1) desflurane induction and maintenance, and (2) sevoflurane induction.

ANESTHETIC CIRCUITS

Gas exits the anesthesia machine at the common gas outlet and then enters an anesthetic circuit. The function of an anesthetic circuit is not only to deliver oxygen and anesthetic gases to the patient, but also to eliminate carbon dioxide. Carbon dioxide can be removed either by washout with adequate fresh gas inflow or by soda lime absorption. This discussion is limited to semiclosed rebreathing circuits and the circle system.

Mapleson Systems

In 1954 Mapleson described and analyzed five different semiclosed anesthetic systems; these are now classically referred to as the Mapleson systems, designated A to E.⁸⁰ Willis *et al* added the F system to the original five.⁸¹ The Mapleson systems are shown in Figure 22-20. System components can include a face mask, a spring-loaded pop-off valve, reservoir tubing, fresh gas inflow tubing, and a reservoir bag. Three distinct functional groups emerge—the A, the BC, and DEF groups. The Mapleson A, also known as the Magill circuit, has a spring-loaded pop-off valve located near the face mask, and the fresh gas flow enters the opposite end of the circuit near the reservoir bag. In the B and C systems, the spring-loaded pop-off valve is located near the face mask, but the fresh gas inlet tubing is located near the patient. The reservoir tubing and breathing bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson DEF group, or T-piece group, the fresh gas enters near the patient, and excess gas is popped off at the opposite end of the circuit.

Figure 22-20. Gas disposition at end expiration during spontaneous (*left*) and controlled (*right*) ventilation in circuits A–F. FGF = fresh gas flow. (Modified with permission from Sykes MK: Rebreathing circuits: A review. Br J Anaesth 40:666, 1968.)

Even though the component arrangement and components are simple, functional analysis of the Mapleson systems can be complex.^{82,83} The amount of carbon dioxide rebreathing associated with each system is multifactorial, and variables that dictate the ultimate carbon dioxide concentration include the following: (1) the fresh gas inflow rate, (2) the minute ventilation, (3) the mode of ventilation (spontaneous or controlled), (4) the tidal volume, (5) the respiratory rate, (6) the I:E ratio, (7) the duration of the expiratory pause, (8) the peak inspiratory flow rate, (9) the volume of the reservoir tube, (10) the volume of the breathing bag, (11) ventilation by mask, (12) ventilation through an endotracheal tube, and (13) the CO₂ sampling site.

The performance of the Mapleson systems is best understood by studying the expiratory phase of the respiratory cycle (Fig. 22-20).⁸⁴ During spontaneous ventilation, the Mapleson A has the best efficiency of the six systems, requiring a fresh gas inflow rate of just 1 times the minute ventilation to prevent rebreathing of carbon dioxide. But it has the worst efficiency during controlled ventilation, requiring a minute ventilation as much as 20 l.min⁻¹ to prevent rebreathing. Systems DEF are slightly more efficient than systems BC. To prevent rebreathing CO₂, the DEF systems require a fresh gas inflow rate of approximately 2.5 times the minute ventilation, whereas the fresh gas inflow rates required for BC systems are somewhat higher.⁸³

To summarize the relative efficiency of different Mapleson systems with respect to prevention of rebreathing: during spontaneous ventilation, $A > DFE > CB$; during controlled ventilation, $DFE > BC > A$.^{83,85} The Mapleson A, B, and C systems are rarely used today, but the DEF systems are commonly employed. In the United States, the most popular representative from the DEF group is the Bain circuit.

Bain Circuit

The Bain circuit is a modification of the Mapleson D system. It is a coaxial circuit in which the fresh gas flows through a narrow inner tube within the outer corrugated tubing.⁸⁶ The central tube originates near the reservoir bag, but the fresh gas actually enters the circuit at the patient end (Fig. 22-21). Exhaled gases enter the corrugated tubing and are vented through the expiratory valve near the reservoir bag. The Bain circuit may be used for both spontaneous and controlled ventilation. The fresh gas inflow rate necessary to prevent rebreathing is 2.5 times the minute ventilation.

Figure 22-21. The Bain circuit. (Redrawn with permission from Bain JA, Spoerel WE: A streamlined anaesthetic system. *Can Anaesth Soc J* 19:426, 1972.)

There are many advantages to this circuit. It is lightweight, convenient, easily sterilized, and reusable. Scavenging of the gases from the expiratory valve is facilitated because the valve is located away from the patient. Exhaled gases in the outer reservoir tubing add warmth to inspired fresh gases. The hazards of the Bain circuit include unrecognized disconnection or kinking of the inner fresh gas hose. These problems can cause hypercarbia from inadequate gas flow or increased respiratory resistance. An obstructed bacterial filter positioned between the Bain circuit and the endotracheal tube can cause hypoxemia and mimic the signs and symptoms of severe bronchospasm.⁸⁷

The outer tube should be transparent to allow inspection of the inner tube. The integrity of the inner tube can be assessed as described by Pethick.⁸⁸ High-flow oxygen is fed into the circuit while the patient end is occluded until the reservoir bag is filled. The patient end is opened and oxygen is flushed into the circuit. If the inner tube is intact, the Venturi effect occurs at the patient end. This effect causes a decrease in pressure within the circuit, and the reservoir bag deflates. Conversely, a leak in the inner tube allows the fresh gas to escape into the expiratory limb, and the reservoir bag will remain inflated. This test is recommended as a part of the preanesthesia check if a Bain circuit is used.

Circle System

The circle system is the most popular breathing system in the United States. It is so named because its components are arranged in a circular manner. This system prevents rebreathing of carbon dioxide by soda lime absorption but allows partial rebreathing of other exhaled gases. The extent of rebreathing of the other exhaled gases depends on component arrangement and the fresh gas flow rate.

A circle system can be semiopen, semiclosed, or closed, depending on the amount of fresh gas inflow.⁸⁹ A *semiopen system* has no rebreathing and requires a very high flow of fresh gas. A *semiclosed system* is associated with rebreathing of gases and is the most commonly used system in the United States. A *closed system* is one in which the inflow gas exactly matches that being taken up, or consumed, by the patient. There is complete rebreathing of exhaled gases after absorption of carbon dioxide, and the overflow (pop-off) valve is closed.

The circle system (Fig. 22-22) consists of seven components, including the following: (1) a fresh gas inflow source; (2) inspiratory and expiratory unidirectional valves; (3) inspiratory and expiratory corrugated tubes; (4) a Y-piece connector; (5) an overflow or pop-off valve, referred to as the adjustable pressure-limiting (APL) valve; (6) a reservoir bag; and (7) a canister containing a carbon dioxide absorbent. The unidirectional valves are placed in the system to ensure unidirectional flow through the corrugated hoses. The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine.

Figure 22-22. Components of the circle system. B = reservoir bag; V = ventilator; APL = adjustable pressure limiting. (Reproduced with permission from Andrews JJ: Inhaled anesthetic delivery systems. In Miller RD (ed): *Anesthesia*, 5th ed, p 174. Philadelphia, Churchill Livingstone, 1999.)

Numerous variations of the circle arrangement are possible, depending on the relative positions of the unidirectional valves, the pop-off valve, the reservoir bag, the carbon dioxide absorber, and the site of fresh gas entry. However, to prevent rebreathing of carbon dioxide, three rules must be followed: (1) a unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit; (2) the fresh gas inflow cannot enter the circuit between the expiratory valve and the patient; and (3) the overflow (pop-off) valve cannot be located between the patient and the inspiratory valve. If these rules are followed, any arrangement of the other components will prevent rebreathing of carbon dioxide.⁹⁰

The most efficient circle system arrangement that allows the highest conservation of fresh gases is one with the unidirectional valves near the patient and the pop-off valve just downstream from the expiratory valve. This arrangement conserves dead space gas and preferentially eliminates alveolar gas. A more practical arrangement, used on all contemporary anesthesia machines (Fig. 22-22), is less efficient because it allows alveolar and dead space gas to mix before venting.^{90,91}

The advantages of the circle system include relative stability of inspired concentration, conservation of respiratory moisture and heat, and prevention of operating room pollution. Additionally, it can be used for closed-system anesthesia or with low oxygen flows. The major disadvantage of the circle system stems from its complex design. The circle system has approximately 10 connections, and the multiple connection sites set the stage for misconnections, disconnections, obstructions, and leaks. In a closed-claim analysis of adverse anesthetic outcomes arising from gas delivery equipment, a third (25/72) of malpractice claims resulted from breathing circuit misconnections or disconnections.² Malfunctioning valves can cause serious problems. Rebreathing can occur if the valves stick in the open position, and total occlusion of the circuit can occur if they are stuck closed. If the expiratory valve is stuck shut, breath stacking and tension pneumothorax can occur. Obstructed filters located in the expiratory limb of the circle breathing system have caused increased airway pressures, hemodynamic collapse, and bilateral tension pneumothorax. Causes of expiratory filter obstruction include defective filters, patient secretions, and albuterol nebulization.^{91,92,93} and ⁹⁴ The Datex-Ohmeda 7900 series Smart Ventilator uses flow transducers on both the inspiratory and expiratory limb of the circle system. Cracked flow transducer tubing can cause a leak in the circle system

that is difficult to detect.⁹⁵

CARBON DIOXIDE ABSORPTION

Different anesthesia systems eliminate carbon dioxide with varying degrees of efficiency. The closed and semiclosed circle system both require carbon dioxide absorption. Desirable features of carbon dioxide absorbents include lack of toxicity with common anesthetics, low resistance to air flow, low cost, ease of handling, and efficiency.

The Absorber Canister

On modern anesthesia machines, the absorber canister (see Fig. 22-22) is composed of two clear plastic canisters arranged in series. The canisters can be filled either with bulk absorbent or with absorbent supplied by the factory in prefilled plastic disposable cartridges called prepacks. Free granules from bulk absorbent can create a clinically significant leak if they lodge between the clear plastic canister and the O-ring gasket of the absorber. Leaks have also been caused by defective prepacks which were larger than factory specifications.⁹⁶ Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed prior to use.⁹⁷

Chemistry of Absorbents

Two formulations of carbon dioxide absorbents are commonly used today: These are soda lime and baralyme.

By weight, the approximate composition of "high moisture" soda lime is 80% calcium hydroxide, 15% water, 4% sodium hydroxide, and 1% potassium hydroxide (an activator). Small amounts of silica are added to produce calcium and sodium silicate. This addition produces a hard compound and reduces dust formation. The efficiency of the soda lime absorption varies inversely with hardness; therefore, little silicate is used in contemporary soda lime. Sodium hydroxide is the catalyst for the carbon dioxide absorptive properties of soda lime.^{98,99} Baralyme is a mixture of approximately 20% barium hydroxide and 80% calcium hydroxide. It may also contain some potassium hydroxide.

The size of the absorptive granules has been determined by trial and error, which represents a compromise between resistance to air flow and absorptive efficiency.¹⁰⁰ The smaller the granules, the more surface area is available for absorption. However, air flow resistance increases. The granular size of soda lime and baralyme in anesthesia practice is between 4 and 8 mesh, a size at which resistance to air flow is negligible. "Mesh" refers to the number of openings per linear inch in a sieve through which the granular particles can pass. A 4-mesh screen means that there are 4 quarter-inch openings per linear inch. An 8-mesh screen has 8 eighth-inch openings per linear inch.⁹⁸

The absorption of carbon dioxide by soda lime is a chemical process, not a physical process. Carbon dioxide combines with water to form carbonic acid. Carbonic acid reacts with the hydroxides to form sodium (or potassium) carbonate and water. Calcium hydroxide accepts the carbonate to form calcium carbonate and sodium (or potassium) hydroxide. The equations are as follows:

Some carbon dioxide may react directly with Ca(OH)_2 , but this reaction is much slower.

The reaction with baralyme differs from that of soda lime because more water is liberated by a direct reaction of barium hydroxide and carbon dioxide:

Then by direct reactions and by KOH and NaOH,

Absorptive Capacity

The maximum amount of carbon dioxide that can be absorbed is 26 l of CO_2 per 100 g of absorbent. However, channeling of gas through granules may substantially decrease this efficiency and allow only 10–20 l of carbon dioxide to actually be absorbed.¹⁰¹

Indicators

Ethyl violet, the pH indicator added to both soda lime and baralyme to help assess the functional integrity of the absorbent, is a substituted triphenylmethane dye with a critical pH of 10.3.⁹⁹ Ethyl violet changes from colorless to violet when the pH of the absorbent decreases as a result of carbon dioxide absorption. The pH of fresh absorbent exceeds the critical pH, so the dye exists in its colorless form (Fig. 22-23, left). As absorbent becomes exhausted, however, the pH decreases below 10.3, so ethyl violet changes to its violet form (Fig. 22-23, right) through alcohol dehydration. Ethyl violet is not always a reliable indicator of the functional status of absorbent. Fluorescent lights can deactivate the dye so that the absorbent appears white even though it is exhausted.¹⁰²

Figure 22-23. (A and B). Ethyl violet. (Reprinted with permission from Andrews JJ, Johnston RV Jr, Bee DE, Arens JF: Photodeactivation of ethyl violet: A potential hazard of sodasorb. *Anesthesiology* 72:59, 1990.)

Interactions of Inhaled Anesthetics with Absorbents

It is important and desirable to have carbon dioxide absorbents that are neither intrinsically toxic nor toxic when exposed to common anesthetics. Soda lime and baralyme generally fit this description, but inhaled anesthetics do interact with absorbents to some extent. Historically speaking, an uncommon anesthetic, trichloroethylene, reacts with soda lime to produce toxic compounds. In the presence of alkali and heat, trichloroethylene degrades into dichloroacetylene, which can cause cranial nerve lesions and encephalitis. Phosgene, a potent pulmonary irritant, is also produced, and phosgene can cause adult respiratory distress syndrome

(ARDS).¹⁰³

Sevoflurane has been shown to produce degradation products upon interaction with carbon dioxide absorbents.¹⁰⁴ The major degradation product produced is fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether, or *Compound A*. During sevoflurane anesthesia, factors apparently leading to an increase in the concentration of Compound A include: (1) low flow or closed-circuit anesthetic techniques; (2) the use of baralyme rather than soda lime; (3) higher concentrations of sevoflurane in the anesthetic circuit; (4) higher absorbent temperatures; and (5) fresh absorbent.^{104,105 and 106} Baralyme dehydration increases the concentration of Compound A, and soda lime dehydration decreases the concentration of Compound A.^{107,108} Apparently, the degradation products do not cause toxic effects in humans even during low-flow anesthesia,¹⁰⁵ but further studies are needed to verify this.^{109,110 and 111}

Desiccated soda lime and baralyme can degrade contemporary inhaled anesthetics to clinically significant concentrations of carbon monoxide (CO), which in turn can produce carboxyhemoglobin concentrations reaching 30% or more.¹¹² Higher levels of carbon monoxide are more likely after prolonged contact between absorbent and anesthetics, and after disuse of an absorber for at least two days, especially over a weekend. Thus, case reports describing carbon monoxide poisoning have been most common in patients anesthetized on Monday morning, presumably because continuous flow from the anesthesia machine dehydrated the absorbents over the weekend.^{113,114} A fresh gas flow rate of 5 l.min⁻¹ or more through absorbent (without a patient) is sufficient to cause critical drying of the absorbent, particularly if the breathing bag is left off the breathing circuit. Absence of the bag facilitates retrograde flow through the circle system (see [Fig. 22-22](#)).¹¹² Because the inspiratory valve leaflet produces some resistance to flow, the fresh gas flow takes the retrograde path of least resistance through the absorbent and out the 22-mm breathing bag terminal.

Several factors appear to increase the production of carbon monoxide and carboxyhemoglobin: (1) the inhaled anesthetic used (for a given MAC multiple, the magnitude of CO production from greatest to least is desflurane > g2 enflurane > isoflurane » g7 halothane = sevoflurane); (2) the absorbent dryness (completely dry absorbent produces more CO than hydrated absorbent); (3) the type of absorbent (at a given water content, baralyme produces more CO than does soda lime); (4) the temperature (an increased temperature increases CO production); (5) the anesthetic concentration (more CO is produced from higher anesthetic concentrations)¹¹⁵; (6) low fresh gas flow rates; and (7) reduced animal size.¹¹⁶

Interventions have been suggested to reduce the incidence of carbon monoxide exposure in humans undergoing general anesthesia.¹¹⁴ The interventions include: (1) educating anesthesia personnel regarding the etiology of CO production; (2) turning off the anesthesia machine at the conclusion of the last case of the day to eliminate fresh gas flow which dries the absorbent; (3) changing carbon dioxide absorbent if fresh gas was found flowing during the morning machine check; (4) rehydrating desiccated absorbent by adding water to the absorbent¹¹³; and (5) changing the chemical composition of soda lime. The elimination of sodium and potassium hydroxides from desiccated soda lime diminishes degradation of desflurane to carbon monoxide and sevoflurane to Compound A, but does not compromise carbon dioxide absorption.¹¹⁷

ANESTHESIA VENTILATORS

The anesthesia ventilator can substitute for the breathing bag of the circle system, the Bain circuit, and other breathing systems. Ten years ago, anesthesia ventilators were mere adjuncts to the anesthesia machine. Today, they have attained a prominent central role in newer anesthesia systems. This discussion focuses on the classification, operating principles, and hazards of anesthesia ventilators.

Classification

Ventilators can be classified according to their power source, drive mechanism, cycling mechanism, and bellows type.^{118,119} The following section reviews ventilator classification and terminology before the discussion of individual anesthesia machine ventilators.

Power Source

The power source required to operate a mechanical ventilator is provided by compressed gas, electricity, or both. Older pneumatic ventilators required only a pneumatic power source to function properly. Contemporary North American Dräger and Ohmeda electronic ventilators require both an electronic and a pneumatic power source.^{16,18,19,20,21,22,120,121}

Drive Mechanism

Most anesthesia machine ventilators are classified as double-circuit, pneumatically driven ventilators. In a double-circuit system, a driving force (compressed gas) compresses a bag or bellows, which in turn delivers gas to the patient. The driving gas in the Ohmeda 7000, 7810, and 7900 is 100% oxygen.^{16,120,121} In the North American Dräger AV-E, a Venturi device mixes oxygen and air.^{18,19,20,21,22}

Cycling Mechanism

Most anesthesia machine ventilators are time-cycled and provide ventilator support in the control mode. Inspiration is initiated by a timing device. Older pneumatic ventilators use a fluidic timing device. Contemporary electronic ventilators use a solid-state timing device and are thus classified as time-cycled and electronically controlled.

Bellows Classification

The direction of bellows movement during the expiratory phase determines the bellows classification. *Ascending (standing) bellows* ascend during the expiratory phase ([Fig. 22-24, right](#)), whereas *descending (hanging) bellows* descend during the expiratory phase. Older pneumatic ventilators use weighted descending bellows, while most contemporary electronic ventilators have ascending bellows. Of the two configurations, the ascending bellows is safer. An ascending bellows will not fill if a total disconnection occurs. The bellows of a descending bellows ventilator, however, will continue its up-and-down movement during a disconnection. The driving gas pushes the bellows upward during the inspiratory phase. During the expiratory phase, room air is entrained into the breathing system at the site of the disconnection because gravity acts on the weighted bellows. The disconnection pressure monitor and the volume monitor may be fooled even if a disconnection is complete¹ (see [Breathing Circuit Problems](#)).

Figure 22-24. Inspiratory and expiratory phase gas flows of a generic ascending bellows anesthesia ventilator. (Reprinted with permission from Andrews JJ: Understanding your anesthesia machine and ventilator. In 1989 Review Course Lectures, p 59. Cleveland, International Anesthesia Research Society, 1989.)

Operating Principles of Ascending Bellows Ventilators

Contemporary examples of ascending bellows, double-circuit, electronic ventilators include the North American Dräger AV-E and the Ohmeda 7000, 7800, and 7900 series. A generic ascending bellows ventilator is shown in [Figure 22-24](#). It may be viewed as a breathing bag (bellows) located within a clear plastic box. The bellows

physically separates the driving gas circuit from the patient gas circuit. The driving gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During the inspiratory phase (Fig. 22-24, left) the driving gas enters the bellows chamber, causing the pressure within it to increase. This increase in pressure is responsible for two events. First, the ventilator relief valve closes, preventing anesthetic gas from escaping into the scavenging system. Second, the bellows is compressed, and the anesthetic gas within the bellows is delivered to the patient's lungs. This compression action is analogous to the hand of the anesthesiologist squeezing the breathing bag.³⁹

During the expiratory phase (Fig. 22-24, right), the driving gas exits the bellows chamber. The pressure within the bellows chamber and the pilot line declines to zero, causing the mushroom portion of the ventilator relief valve to open. Exhaled patient gas fills the bellows before any scavenging. This occurs because a weighted ball similar to those used in ball-type positive end expiratory pressure (PEEP) valves is incorporated into the base of the ventilator relief valve. The ball produces 2–3 cm water of back pressure; therefore scavenging occurs only after the bellows fills completely and the pressure inside the bellows exceeds this pressure threshold. This design causes all ascending bellows ventilators to produce 2–3 cm water pressure of PEEP within the breathing circuit. Scavenging occurs only during the expiratory phase, as the ventilator relief valve is open only during expiration.³⁹

Gas flow from the anesthesia machine into the breathing circuit is continuous and independent of ventilator activity. During the inspiratory phase of mechanical ventilation, the ventilator relief valve is closed, and the breathing system's APL valve (pop-off valve) is either closed or out of circuit. Therefore, the patient receives volume from the bellows and flowmeters during the inspiratory phase. Factors that influence the correlation between set tidal volume and exhaled tidal volume include the flowmeter settings, the inspiratory time, the compliance of the breathing circuit, external leakage, and the location of the tidal volume sensor.^{16,17,120,121} Usually, the volume gained from the flowmeters during inspiration is counteracted by the volume lost to the breathing circuit compliance. The set tidal volume generally approximates the exhaled tidal volume. However, oxygen flushing during the inspiratory phase can result in barotrauma because excess volume cannot be vented.³⁹

Problems and Hazards

Numerous hazards are associated with anesthesia ventilators. These include problems with the breathing circuit, the bellows assembly, and the control assembly.

Breathing Circuit Problems

Breathing circuit disconnection is a leading cause of critical incidents in anesthesia.^{2,122} The most common disconnection site is at the Y-piece. Disconnections can be complete or partial (leaks). A common source of leaks with older absorbers is failure to close the APL valve (pop-off valve) upon initiation of mechanical ventilation. The bag/ventilator switch on contemporary absorbers helps minimize this problem. Pre-existing undetected leaks can occur in compressed, corrugated, disposable anesthetic circuits. To detect such a leak preoperatively, the circuit must be fully expanded before the circuit is checked for leaks.¹²³ As mentioned above, disconnections and leaks manifest more readily with the ascending bellows because the bellows will not fill.¹

Several disconnection monitors exist. The most important monitor is a vigilant anesthesia care provider monitoring breath sounds, chest wall excursion, and mechanical monitors.

Pneumatic and electronic pressure monitors are helpful in diagnosing disconnections. Factors that influence monitor effectiveness include the disconnection site, the pressure sensor location, the threshold pressure alarm limit, the inspiratory flow rate, and the resistance of the disconnected breathing circuit.^{124,125} Various anesthesia machines and ventilators have different locations for the pressure sensor and different values for the threshold pressure alarm limit (Table 22-3). The threshold pressure alarm limit may be preset at the factory or adjustable. An audible or visual alarm is actuated if the peak inspiratory pressure of the breathing circuit does not exceed the threshold pressure alarm limit. When an adjustable threshold pressure alarm limit is available, such as on the North American Dräger Narkomed 2A, 2B, 3, and 4, the operator should set the pressure alarm limit to within 5 cm water of the peak inspiratory pressure.^{15,16,17,18} and ¹⁹ Figure 22-25 illustrates how a partial disconnection (leak) may be unrecognized by the low-pressure monitor if the threshold pressure alarm limit is set too low or if the factory preset value is relatively low.

| Machine/Ventilator | Location of Pressure Sensor | Threshold Pressure Alarm Limit (cm water) |
|----------------------------------|-------------------------------------|---|
| OHMEDA MODULUS II | | |
| GMS Absorber Ohmeda 7000 Vent | Patient side of expiratory valve | 5 |
| OHMEDA MODULUS II PLUS | | |
| GMS Absorber Ohmeda 7510 | Patient side of inspiratory valve | 31–9 PEEP compensated |
| NAD NARKOMED 2A | | |
| NAD AV-E | CO ₂ absorber or Y-piece | 8, 12, 25 |
| NAD NARKOMED 2B,3 | | |
| NAD AV-E | CO ₂ absorber or Y-piece | 5–30 (12 default) |

Data from Ohmeda^{15,16,17,18} and North American Dräger.^{19–21}

Table 22-3. DISCONNECTION PRESSURE MONITORS

Figure 22-25. Threshold pressure alarm limit. (Top) The threshold pressure alarm limit (dotted line) has been set appropriately. An alarm is actuated when a partial disconnection occurs (arrow) because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. (Bottom) A partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has been set too low. (Redrawn with permission from Baromed Breathing Pressure Monitor. Operator's Instruction Manual. Telford, PA, North American Dräger, 1986.)

Respiratory volume monitors are useful in detecting disconnections. Volume monitors sense exhaled tidal volume, minute volume, or both. The user should bracket the high and low threshold volumes slightly above and below the exhaled volumes. For example, if the exhaled minute volume of a patient is 10 l.min⁻¹, reasonable alarm limits would be 8–12 l.min⁻¹. Some Datex-Ohmeda ventilators are equipped with volume monitor sensors that use infrared light/turbine technology. The volume sensor is located in the expiratory limb of the breathing circuit. Exposure of the sensor clip to a direct beam of overhead surgical lighting can cause erroneous volume readings because the surgical beam interferes with the infrared technology.¹²⁶

Carbon dioxide monitors are probably the best devices for revealing patient disconnections. Carbon dioxide concentration is measured near the Y-piece either directly or by aspiration of a gas sample to the instrument. A drastic change in the differences between the inspiratory and end-tidal carbon dioxide concentration or the absence of carbon dioxide indicates a disconnection, a nonventilated patient, or other problems.¹

Misconnections of the breathing system are not uncommon, despite efforts by standards committees to eliminate this problem by assigning different diameters to various hoses and terminals. Anesthesia machines, breathing systems, ventilators, and scavenging systems incorporate a multitude of hose terminals. Hoses have been connected to inappropriate terminals and even to various solid cylindrical shaped protrusions of the anesthesia machine.¹

Occlusion (obstruction) of the breathing circuit may occur. Tracheal tubes can become kinked. Hoses throughout the breathing circuit are subject to occlusion by external mechanical forces that can impinge on flow. Blockage of a bacterial filter in the expiratory limb of the circle system has caused a bilateral tension pneumothorax.⁹³ Incorrect insertion of flow direction-sensitive components can result in a no-flow state.¹ Examples of these components include some PEEP valves and cascade humidifiers. Depending on the location of the occlusion and the pressure sensor, a high-pressure alarm may alert the anesthesiologist to the problem.

Excess inflow to the breathing circuit from the anesthesia machine during the inspiratory phase can cause barotrauma. The best example of this phenomenon is oxygen flushing. Excess volume cannot be vented from the system during inspiration because the ventilator relief valve is closed and the APL valve is either out of circuit or closed.³⁹ A high-pressure alarm, if present, may be activated when the pressure becomes excessive. In the North American Dräger System, both audible and visual alarms are actuated when the high-pressure threshold is exceeded.^{18,19,20,21,22} In the Modulus II Plus System, the Ohmeda 7810 ventilator automatically switches from the inspiratory to the expiratory phase when the adjustable peak pressure threshold is exceeded.¹⁶ This minimizes the possibility of barotrauma if the peak pressure threshold is set appropriately by the anesthesiologist.

Bellows Assembly Problems

Leaks can occur in the bellows assembly. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas is vented to the atmosphere. A hole in the bellows can lead to alveolar hyperinflation and possibly barotrauma in some ventilators because high-pressure driving gas can enter the patient circuit. The value on the oxygen analyzer may increase when the driving gas is 100% oxygen, or it may decrease if the driving gas is composed of an air-oxygen mixture.¹²⁷

The ventilator relief valve can cause problems. Hypoventilation occurs if the valve is incompetent because anesthetic gas is delivered to the scavenging system during the inspiratory phase instead of to the patient. Gas molecules preferentially exit into the scavenging system because it represents the path of least resistance, and the pressure within the scavenging system can be subatmospheric. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or from a damaged flapper valve.^{128,129} A ventilator relief valve stuck in the closed position can produce barotrauma. Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases.¹ Breathing circuit pressure escalates because excess anesthetic gas cannot be vented.

Control Assembly Problems

The control assembly can be the source of both electrical and mechanical problems. Electrical failure can be total or partial; the former is the more obvious. Some mechanical problems include leaks within the system, faulty regulators, and faulty valves. An occluded muffler on the North American Dräger AV-E can cause barotrauma. Obstruction of driving gas outflow closes the ventilator relief valve, and excess patient gas cannot be vented.¹³⁰

Narkomed 6000 Piston Ventilator

The Narkomed 6000 ventilator may be classified as an electrically powered, piston-driven, single-circuit, electronically controlled ventilator with fresh gas decoupling. Unlike traditional double-circuit operating room ventilators that use compressed gas to drive the bellows, the 6000 uses a piston. The piston cylinder unit (see Fig. 22-26) consists of an outer cylinder and an internal piston that is controlled by a precise motor gear unit. The piston is sealed by two membranes, and patient gas is contained inside the piston unit. With volume-controlled IPPV or SIMV, the piston stops during plateau time in the end position. When the maximum airway pressure is reached in the volume-controlled or pressure-controlled ventilation, inspiratory flow will be reduced so that the pressure is held at a constant level.¹³¹

Figure 22-26. The Narkomed 6000. The horizontal arrow indicates the piston cylinder unit. The vertical arrow indicates a rectangular manifold that houses the valves for fresh gas decoupling.

With traditional ascending bellows ventilators during the inspiratory phase, the patient receives flow from the bellows and flow from the anesthesia machine (which can include flow from the oxygen flush valve) because the ventilator relief valve is closed shut. As mentioned earlier, the combination of these two flows can cause barotrauma. The Narkomed 6000 avoids this potential hazard by using fresh gas decoupling technology. During the inspiratory phase, fresh gas flow from the anesthesia machine and flow from the oxygen flush valve are diverted to the circle system reservoir bag using a series of pneumatic valves. This safety feature minimizes the potential hazard of barotrauma since the patient receives flow only from inside the piston unit.

SCAVENGING SYSTEMS

Scavenging is the collection and subsequent removal of vented gases from the operating room.¹³² The amount of gas used to anesthetize a patient commonly far exceeds the patient's needs. Therefore, scavenging minimizes operating room pollution. In 1977, the National Institute for Occupational Safety and Health (NIOSH) prepared a document entitled "Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors."¹³³ Although it was maintained that a safe level of exposure could not be defined, the NIOSH recommendations are shown in Table 22-4.¹³³ In 1991 the American Society for Testing and Materials (ASTM) released the ASTM F1343-91 standard entitled "Standard Specification for Anesthetic Equipment—Scavenging Systems for Anesthetic Gases."¹³⁴ The document provided guidelines for devices that safely and effectively scavenge excess anesthetic gas to reduce contamination in anesthetizing areas. In 1999, the American Society of Anesthesiology (ASA) Task Force on Trace Anesthetic Gases developed a booklet entitled "Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit." This publication addresses analysis of the literature, the role of regulatory agencies, scavenging and monitoring equipment, and recommendations.¹³⁵

| Anesthetic Gas | Maximum TWA* Concentration (ppm) |
|--|----------------------------------|
| Halogenated agent alone | 2 |
| Nitrous oxide | 25 |
| Combination of halogenated agent plus nitrous oxide: | |
| Halogenated agent | 0.5 |
| Nitrous oxide | 25 |
| Dental facilities (nitrous oxide alone) | 50 |

*TWA = Time-weighted average. Time-weighted average sampling, also known as time-integrated sampling, is a sampling method that evaluates the average concentration of anesthetic gas over a prolonged period of time, such as 1 to 8 hours. Reprinted with permission from US Department of Health, Education, and Welfare: Criteria for a recommended standard: Occupational exposure to waste anesthetic gases and vapors. March ed. Washington DC, 1977.

Table 22-4. NIOSH RECOMMENDATIONS, 1977¹³³

The two major causes of waste gas contamination in the operating room are the anesthetic technique employed and equipment issues.^{135,136} Regarding the anesthetic technique, the following factors cause operating room contamination: failure to turn off gas flow control valves at the end of an anesthetic; poorly fitting masks; flushing the circuit; filling anesthetic vaporizers; use of uncuffed endotracheal tubes; and use of breathing circuits such as the Jackson-Rees, which is difficult to scavenge. Equipment failure or failure to understand the equipment can cause operating room contamination. Leaks can occur in the high-pressure hoses, the nitrous oxide tank mounting, the high-pressure and low-pressure circuits of the anesthesia machine, or in the circle system, particularly the carbon dioxide canister. The anesthesia care provider must be certain that the scavenging system is operational and adjusted properly to ensure adequate scavenging. If side-stream carbon dioxide or multigas analyzers are used, the analyzed gas (50–250 ml.min⁻¹) must be directed to the scavenging system or returned to the breathing system.^{135,136}

Components

Scavenging systems have five components (Fig. 22-27): (1) the gas collecting assembly, (2) the transfer means, (3) the scavenging interface, (4) the gas disposal assembly tubing, and (5) an active or passive gas disposal assembly.¹³⁴ An active system uses a central vacuum to eliminate waste gases. The pressure of the waste gas itself produces flow through a passive system.

Figure 22-27. Components of a scavenging system. APL = adjustable pressure limiting valve.

Gas Collecting Assembly

The gas collecting assembly captures excess anesthetic gas and delivers it to the transfer tubing.¹³⁴ Excess gas is vented from the anesthesia system either through the APL valve or through the ventilator relief valve. All excess gas passes through these valves, accumulates in the gas collecting assembly, and is directed to the transfer means.

Transfer Means

The transfer means carries excess gas from the gas collecting assembly to the scavenging interface. The tubing must be either 19 or 30 mm, as specified by the ASTM F1343-91 standard.¹³⁴ The tubing should be sufficiently rigid to prevent kinking, and as short as possible to minimize the chance of occlusion. Some manufacturers color-code the transfer tubing with yellow bands to distinguish it from 22-mm breathing system tubing. Many machines have separate transfer tubes for the APL valve and for the ventilator relief valve. The two tubes frequently merge into a single hose before they enter the scavenging interface. Occlusion of the transfer means can be particularly problematic since it is upstream from the pressure-buffering scavenging interface. If the transfer means is occluded, breathing circuit pressure will increase, and barotrauma can occur.

Scavenging Interface

The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressure.¹³² The interface should limit the pressures immediately downstream from the gas collecting assembly to between -0.5 and +10 cm water with normal working conditions.¹³⁴ Positive pressure relief is mandatory, irrespective of the type of disposal system used, to vent excess gas in case of occlusion downstream from the interface. If the disposal system is active, negative pressure relief is necessary to protect the breathing circuit or ventilator from excessive subatmospheric pressure. A reservoir is highly desirable with active systems, since it stores excess waste gas until the evacuation system can eliminate it. Interfaces can be open or closed, depending on the method used to provide positive and negative pressure relief.¹³²

Open Interfaces. An open interface contains no valves and is open to the atmosphere, allowing both positive and negative pressure relief. Open interfaces should be used only with active disposal systems that use a central vacuum system. Open interfaces require a reservoir because waste gases are intermittently discharged in surges, whereas flow to the active disposal system is continuous.¹³²

Many contemporary anesthesia machines are equipped with open interfaces like those in Figure 22-28A and Figure 22-28B.¹³⁷ An open canister provides reservoir capacity. The canister volume should be large enough to accommodate a variety of waste gas flow rates. Gas enters the system at the top of the canister and travels through a narrow inner tube to the canister base. Gases are stored in the reservoir between breaths. Positive and negative pressure relief is provided by holes in the top of the canister. The open interface shown in Figure 22-28A differs somewhat from the one shown in Figure 22-28B. The operator can regulate the vacuum by adjusting the vacuum control valve shown in Figure 22-28B.¹³⁷

Figure 22-28. (A and B). Two open scavenging interfaces. Each requires an active disposal system. APL = adjustable pressure limiting valve. (Modified with permission from Dorsch JA, Dorsch SE: Controlling trace gas levels. In Dorsch JA, Dorsch SE (eds): Understanding Anesthesia Equipment, 4th ed, p 355. Baltimore, Williams & Williams, 1999.)

The efficiency of an open interface depends on several factors. The vacuum flow rate per minute must equal or exceed the minute volume of excess gases to prevent spillage. The volume of the reservoir and the flow characteristics within the interface are important. Spillage will occur if the volume of a single exhaled breath exceeds the capacity of the reservoir. Leakage can occur long before the volume of waste gas delivered to the reservoir equals the reservoir volume if large-scale turbulence occurs within the interface.¹³⁸

Closed Interfaces. A closed interface communicates with the atmosphere through valves. All closed interfaces must have a positive pressure relief valve to vent excess system pressure if obstruction occurs downstream from the interface. A negative pressure relief valve is mandatory to protect the breathing system from subatmospheric pressure if an active disposal system is used.¹³² Two types of closed interfaces are commercially available. One has positive pressure relief only; the

other has both positive and negative pressure relief.

POSITIVE PRESSURE RELIEF ONLY This interface (Fig. 22-29, left) has a single positive pressure relief valve and is designed to be used only with passive disposal systems. Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the pressure of the waste gas itself since a vacuum is not used. The positive pressure relief valve opens at a preset value such as 5 cm water if an obstruction between the interface and the disposal system occurs.¹³⁹ A reservoir bag is not necessary.

Figure 22-29. Closed scavenging interfaces. (Left) Interface used with a passive disposal system. (Right) Interface with an active system. (Left: Modified with permission from Scavenger Interface for Air Conditioning. Instruction Manual. Telford, PA, North American Dräger, October 1984. Right: Modified with permission from Narkomed 2A Anesthesia System. Technical Service Manual. Telford, PA, North American Dräger, October 1985.)

POSITIVE AND NEGATIVE PRESSURE RELIEF This interface has a positive pressure relief valve, at least one negative pressure relief valve, and a reservoir bag. It is used with active disposal systems. Figure 22-29 (right) is a schematic of North American Dräger's closed interface for suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir stores transient excess gas until the vacuum system eliminates it. The operator should adjust the vacuum control valve so that the reservoir bag is properly inflated (A) and not overdistended (B) or completely deflated (C). Gas is vented to the atmosphere through the positive pressure relief valve if the system pressure exceeds +5 cm water. Room air is entrained through the negative pressure relief valve if the system pressure is more negative than -0.5 cm water. A backup negative pressure relief valve opens at -1.8 cm water if the primary negative pressure relief valve becomes occluded.¹⁸

The effectiveness of a closed system in preventing spillage depends on the inflow rate of excess gas, the vacuum flow rate, and the volume of the reservoir. Leakage of waste gases into the atmosphere occurs only when the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive pressure relief valve. In contrast, the effectiveness of an open system to prevent spillage depends not only on the volume of the reservoir but also on the flow characteristics within the interface.¹³⁸

Gas Disposal Assembly Tubing

The gas disposal assembly tubing (Fig. 22-27) conducts waste gas from the scavenging interface to the gas disposal assembly. It should be collapse-proof and should run overhead, if possible, to minimize the chance of occlusion.¹³⁴

Gas Disposal Assembly

The gas disposal assembly ultimately eliminates excess waste gas (Fig. 22-27). There are two types of disposal systems: active and passive.

The most common method of gas disposal is the active assembly, which uses a central vacuum. The vacuum is a mechanical flow-inducing device that removes the waste gases. An interface with a negative pressure relief valve is mandatory because the pressure within the system is negative. A reservoir is very desirable, and the larger the reservoir, the lower the suction flow rate needed.^{132,138}

A passive disposal system does not use a mechanical flow-inducing device. Instead, the pressure of the waste gas itself produces flow through the system. Positive pressure relief is mandatory, but negative pressure relief and a reservoir are unnecessary. Excess waste gas can be eliminated in a number of ways. Some include venting through the wall, ceiling, floor, or to the room exhaust grill of a nonrecirculating air conditioning system.^{132,138}

Hazards

Scavenging systems minimize operating room pollution, yet they add complexity to the anesthesia system. A scavenging system extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Obstruction of scavenging pathways can cause excessive positive pressure in the breathing circuit, and barotrauma can occur. Excessive vacuum applied to a scavenging system can cause negative pressures in the breathing system.

CHECKING ANESTHESIA MACHINES

A complete anesthesia apparatus checkout procedure should be performed each day before the first case. An abbreviated version should be performed before each subsequent case. Several checkout procedures exist, but the 1993 FDA Anesthesia Apparatus Checkout Recommendations (Appendix A) is the most popular.^{140,141,142,143,144} The FDA checkout procedures serve only as generic guidelines because the designs of different machines vary considerably. Also, many machines have been modified in the field. Therefore, specific checks must be performed on specific machines. The user must refer to the operator's manual for special procedures or precautions.

The three most important preoperative checks are (1) oxygen analyzer calibration, (2) the low-pressure circuit leak test, and (3) the circle system test.

Oxygen Analyzer Calibration

The oxygen analyzer is the most important machine monitor because it is the only machine safety device that evaluates the integrity of the low-pressure circuit. Other machine safety devices, such as the fail-safe valve, the oxygen supply failure alarm, and the proportioning system, are all upstream from the flow control valves (Fig. 22-3). The only machine monitor that detects problems downstream from the flow control valves is the oxygen analyzer. Calibration of this monitor is described in Appendix A: Anesthesia Apparatus Checkout Recommendations, 1993, #9.

Low-Pressure Circuit Leak Test

The low-pressure leak test checks the integrity of the anesthesia machine from the flow control valves to the common outlet. It evaluates the portion of the machine that is downstream from all safety devices except the oxygen analyzer. The components located within this area are *precisely* the ones most subject to breakage and leaks. Leaks in the low-pressure circuit can cause hypoxia or patient awareness.^{71,145} Flow tubes, the most delicate pneumatic component of the machine, can crack or break. A typical three-gas anesthesia machine has 16 O-rings in the low-pressure circuit. Leaks can occur at the interface between the glass flow tube and the manifold, and at the O-ring junction between the vaporizer and its manifold. Loose filler caps on vaporizers are a common source of leaks, and these leaks can cause patient awareness under anesthesia.^{71,146}

Several different methods have been used to check the low-pressure circuit for leaks. They include the oxygen flush test, the common gas outlet occlusion test, the traditional positive-pressure leak test, the North American Dräger positive-pressure leak test, the Ohmeda 8000 internal-positive pressure leak test, the Ohmeda negative-pressure leak test, the 1993 FDA universal negative-pressure leak test, and others. One reason for the large number of methods is that the internal design of various machines differs considerably. The most notable example is that most Ohmeda machines have a check valve near the common gas outlet whereas North

American Dräger machines do not. The presence or absence of the check valve profoundly influences which preoperative check is indicated.

Several mishaps have resulted from application of the wrong leak test to the wrong machine.^{31,69,147} Therefore, it is mandatory to perform the appropriate low-pressure leak test before every case. To do this, it is essential to understand the exact location and operating principles of the Ohmeda check valve. Most Ohmeda anesthesia machines have a machine outlet check valve located in the low-pressure circuit (see Table 22-5). The check valve is located downstream from the vaporizers and upstream from the oxygen flush valve (Fig. 22-3). It is open (Fig. 22-30, left) in the absence of back pressure. Gas flow from the manifold moves the rubber flapper valve off its seat and allows gas to proceed freely to the common outlet. The valve closes (Fig. 22-30, right) when back pressure is exerted on it.⁸ Back pressure sufficient to close the check valve may occur with the following conditions: oxygen flushing, peak breathing circuit pressures generated during positive-pressure ventilation, or use of a positive-pressure leak test.

| Anesthesia Machine | Machine Outlet Check Valve | Vaporizer Outlet Check Valve | Leak Test Recommended by Manufacturer | |
|-------------------------|----------------------------|------------------------------|---------------------------------------|----------------------------------|
| | | | Positive Pressure | Negative Pressure (Suction Bulb) |
| North American Dräger | | | | |
| Northland 20, 20.1, & 4 | No | No | I | |
| Ohmeda Ultra | Yes | Variable | | I |
| Ohmeda 5070 | Yes | Variable | | I |
| Ohmeda Modulo I | Yes | Variable | | I |
| Ohmeda Modulo II | Yes | No | | I |
| Ohmeda Sleaf series | Yes | No | | I |
| Ohmeda Modulo II Plus | No | No | | I |
| Ohmeda CD | No | No | | I |

Table 22-5. CHECK VALVES AND RECOMMENDED LEAK TEST

Figure 22-30. Machine outlet check valve. (Reproduced with permission from Bowie E, Huffman LM: *The Anesthesia Machine: Essentials for Understanding*. Madison, WI, Ohmeda, a division of BOC Health Care, Inc., 1985.)

Generally speaking, machines without check valves can be tested using a positive-pressure leak test, and machines with check valves must be tested using a negative-pressure leak test. When performing a positive-pressure leak test, the operator generates positive pressure in the low-pressure circuit using flow from the anesthesia machine or from a positive-pressure bulb to detect a leak. When performing a negative-pressure leak test, the operator creates negative pressure in the low-pressure circuit using a suction bulb to detect leaks. Two different low-pressure circuit leak tests are described below.

Oxygen Flush Positive-Pressure Leak Test

Historically, older anesthesia machines did not have check valves in the low-pressure circuit. Therefore, it was common practice to pressurize the breathing circuit and the low-pressure circuit with the oxygen flush valve to test for internal anesthesia machine leaks. Because many modern Ohmeda machines now have check valves in the low-pressure circuit; however, application of a positive-pressure leak test to these machines can be misleading or even dangerous (Fig. 22-31). Inappropriate use of the oxygen flush valve to evaluate the low-pressure circuit for leaks can lead to a false sense of security despite the presence of huge leaks.^{31,40,69,147} Positive pressure from the patient circuit closes the check valve, and the value on the airway pressure gauge does not decline. The system appears to be tight, but in actuality, only the circuitry downstream from the check valve is leak-free.²⁷ Thus, a vulnerable area exists from the check valve back to the flow control valves because this area is not tested by a positive-pressure leak test.

Figure 22-31. Inappropriate use of the oxygen flush valve to check the low-pressure circuit of an Ohmeda machine equipped with a check valve. The area within the rectangle is not checked by the inappropriate use of the oxygen flush valve. The components located within this area are precisely the ones most subject to breakage and leaks. Positive pressure within the patient circuit closes the check valve, and the value on the airway pressure gauge does not decline despite leaks in the low-pressure circuit.

1993 FDA Universal Negative-Pressure Leak Test

The 1993 FDA universal negative-pressure leak test¹⁴⁴ (Appendix A, Section #5) is named “universal” because it can be used to check all contemporary anesthesia machines, regardless of the presence or absence of check valves in the low-pressure circuit. It can be applied to Ohmeda machines, North American Dräger machines, and others. The 1993 FDA check is based upon the Ohmeda negative-pressure leak test (Fig. 22-32). It is performed using a negative-pressure leak testing device, which is a simple suction bulb. The machine master switch, the flow control valves, and vaporizers are turned off. The suction bulb is attached to the common fresh gas outlet and squeezed repeatedly until it is fully collapsed. This action creates a vacuum in the low-pressure circuitry. The machine is leak-free if the hand bulb remains collapsed for at least 10 seconds. A leak is present if the bulb reinflates during this period. The test is repeated with each vaporizer individually turned to the on position because internal vaporizer leaks can be detected only with the vaporizer turned on.

Figure 22-32. FDA negative-pressure leak test. (Left) A negative-pressure leak testing device is attached directly to the machine outlet. Squeezing the bulb creates a vacuum in the low-pressure circuit and opens the check valve. (Right) When a leak is present in the low-pressure circuit, room air is entrained through the leak and the suction bulb inflates. (Reprinted with permission from Andrews JJ: Understanding anesthesia machines. In 1988 Review Course Lectures, p 78. Cleveland, International Anesthesia Research Society, 1988.)

The FDA universal negative-pressure low-pressure circuit leak test has several advantages.¹⁴⁵ It will help eliminate the present confusion regarding exactly which specific check should be performed on specific machines. The universal test is quick and simple to perform. It has an obvious end point, and it isolates the problem. For example, if the bulb reinflates in less than 10 seconds, a leak is present somewhere in the low-pressure circuit. Therefore, it differentiates between breathing-circuit leaks and leaks in the low-pressure circuit. The universal negative-pressure leak test is the most sensitive of all contemporary leak tests because it is not volume-dependent; that is, it does not involve a compliant breathing bag or corrugated hoses. It can detect leaks as small as $30 \text{ ml}\cdot\text{min}^{-1}$. Finally, the operator does not need a detailed or in-depth knowledge of proprietary design differences. If the operator performs the universal test correctly, the leak will be detected.

Circle System Test

The circle system test (Appendix A, Sections #11–12) evaluates the integrity of the circle breathing system, which spans from the common gas outlet to the Y-piece (Fig. 22-22). It has two parts—the *leak test* and the *flow test*. To thoroughly check the circle system for leaks, valve integrity, and obstruction, both tests must be performed preoperatively. The *leak test* is performed by closing the pop-off valve, occluding the Y-piece, and pressurizing the circuit to 30 cm water pressure using the oxygen flush valve. The value on the pressure gauge will not decline if the circle system is leak-free, but this does not assure valve integrity. The value on the gauge will read 30 cm water if the unidirectional valves are stuck shut or if the valves are incompetent.

The *flow test* checks the integrity of the unidirectional valves, and it detects obstruction in the circle system. It can be performed by removing the Y-piece from the circle system and breathing through the two corrugated hoses individually. The valves should be present, and they should move appropriately. The operator should be able to inhale but not be able to exhale through the inspiratory limb. The operator should be able to exhale but not inhale through the expiratory limb. The flow test can also be performed by using the ventilator and a breathing bag attached to the Y piece as described in the 1993 FDA Anesthesia Apparatus Checkout Recommendations (Appendix A, Section #12).¹⁴⁴

SUMMARY

Rapid advances in the anesthesia industry make it increasingly difficult for the anesthesia care provider to keep up with anesthesia system technology. Nevertheless, a thorough understanding of the anesthesia machine, ventilator, circuit and monitors is mandatory for the safe practice of anesthesia. Anesthesia systems are equipped with dozens of safety features, yet none of them is foolproof. The anesthesia care provider still must check all components of the system preoperatively using appropriate checkout procedures.

APPENDIX A

Anesthesia Apparatus Checkout Recommendations, 1993

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are only valid for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: Capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer) and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline which users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (step #5).

Emergency Ventilation Equipment

- * 1. Verify Back-up Ventilation Equipment Is Available & Functioning

High-Pressure System

- * 2. Check Oxygen Cylinder Supply
 - a. Open O₂ cylinder and verify at least half full (about 1000 psi).
 - b. Close cylinder.
- * 3. Check Central Pipeline Supplies
 - a. Check that hoses are connected and pipeline gauges read about 50 psi.

Low-Pressure System

- * 4. Check Initial Status of Low-Pressure System
 - a. Close flow control valves and turn vaporizers off.
 - b. Check fill level and tighten vaporizers' filler caps.

Low-Pressure System

- * 5. Perform Leak Check of Machine Low-Pressure System
 - a. Verify that the machine master switch and flow control valves are OFF.
 - b. Attach "Suction Bulb" to common (fresh) gas outlet.
 - c. Squeeze bulb repeatedly until fully collapsed.
 - d. Verify bulb stays *fully* collapsed for at least 10 seconds.
 - e. Open one vaporizer at a time and repeat 'c' and 'd' as above.
 - f. Remove suction bulb, and reconnect fresh gas hose.
- * 6. Turn on Machine Master Switch and all other necessary electrical equipment.
- * 7. Test Flowmeters
 - a. Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flow tubes.
 - c. Attempt to create a hypoxic O₂/N₂O mixture and verify correct changes in flow and/or alarm

Scavenging System

- * 8. Adjust and Check Scavenging System
 - a. Ensure proper connections between the scavenging system and both APL (pop-off) valve and ventilator relief valve.
 - b. Adjust waste gas vacuum (if possible).
 - c. Fully open APL valve and occlude Y-piece.
 - d. With minimum O₂ flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero.
 - e. With the O₂ flush activated, allow the scavenger reservoir bag to distend fully, and then verify that absorber pressure gauge reads > 10 cm H₂O.

Breathing System

- * 9. Calibrate O₂ Monitor
 - a. Ensure monitor reads 21% in room air.
 - b. Verify low O₂ alarm is enabled and functioning.
 - c. Reinstall sensor in circuit and flush breathing system with O₂.
 - d. Verify that monitor now reads greater than 90%.
- 10. Check Initial Status of Breathing System
 - a. Set selector switch to "Bag" mode.
 - b. Check that breathing circuit is complete, undamaged and unobstructed.
 - c. Verify that CO₂ absorbent is adequate.
 - d. Install breathing circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case.
- 11. Perform Leak Check of the Breathing System
 - a. Set all gas flows to zero (or minimum).
 - b. Close APL (pop-off) valve and occlude Y-piece.
 - c. Pressurize breathing system to about 30 cm H₂O with O₂ flush.
 - d. Ensure that pressure remains fixed for at least 10 seconds.
 - e. Open APL (pop-off) valve and ensure that pressure decreases.

Manual and Automatic Ventilation Systems

- 12. Test Ventilation Systems and Unidirectional Valves
 - a. Place a second breathing bag on Y-piece.
 - b. Set appropriate ventilator parameters for next patient.
 - c. Switch to automatic ventilation (Ventilator) mode.
 - d. Turn ventilator ON and fill bellows and breathing bag with O₂ flush.
 - e. Set O₂ flow to minimum, other gas flows to zero.
 - f. Verify that during inspiration bellows delivers appropriate tidal volume and that during expiration bellows fills completely.
 - g. Set fresh gas flow to about 5 l.⁻¹.
 - h. Verify that the ventilator bellows and simulated lungs fill *and empty* appropriately without sustained pressure at end expiration.
 - i. *Check for proper action of unidirectional valves.*
 - j. Exercise breathing circuit accessories to ensure proper function.
 - k. Turn ventilator OFF and switch to manual ventilation (Bag/APL) mode.
 - l. Ventilate manually and assure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
 - m. Remove second breathing bag from Y-piece.

Monitors

- 13. Check, Calibrate and/or Set Alarm Limits of all Monitors
 - Capnometer
 - Oxygen Analyzer
 - Pressure monitor with High and Low Airway Pressure Alarms
 - Pulse Oximeter
 - Respiratory Volume Monitor (Spirometer)

Final Position

- 14. Check Final Status of Machine
 - a. Vaporizers off.
 - b. APL valve open.
 - c. Selector switch to "Bag."
 - d. All flowmeters to zero (or minimum).
 - e. Patient suction level adequate.
 - f. Breathing system ready to use.

PERSPECTIVES ON AIRWAY MANAGEMENT

Perhaps the most important job of the anesthesiologist is the management of the patient's airway. Though many medical disciplines deal with airway management on an emergency basis, few others are responsible for the routine, deliberate, and usually elective ablation of the patient's intrinsic controls of respiration. Published morbidity and mortality data demonstrate that airway difficulties and mismanagement are responsible for a significant proportion of adverse anesthetic outcomes in clinical practice. Keenan and Boyan reported that failure to provide adequate ventilation was responsible for 12 of 27 cardiac arrests during the operative period.¹ The single largest source of unfavorable outcome in the American Society of Anesthesiologists (ASA) closed-claims study was for adverse respiratory episodes, which accounted for 34% of 1541 liability claims.² Three mechanisms of injury accounted for 75% of these undesirable events: inadequate ventilation (38%), esophageal intubation (18%), and difficult tracheal intubation (17%). Death and brain damage occurred in nearly 85% of the cases studied. In their analysis of 300 liability claims for less frequent, but important categories of ventilation-related undesirable outcomes, Cheney *et al* identified recurrent themes of management error or patterns of injury: airway trauma, pneumothorax, airway obstruction, aspiration, and bronchospasm.³ Given these statistics, it is clear that management of the airway is paramount to safe perioperative care and the following steps become necessary to favorably affect outcome: (1) a thorough airway history and physical examination; (2) a management plan for use of a supraglottic means of ventilation (*e.g.*, face mask, Laryngeal Mask Airway [LMA]); (3) a management plan for intubation and extubation techniques; (4) an alternative plan of action should emergencies arise.

Review of Airway Anatomy

The term "airway," refers to the upper airway—consisting of the nasal and oral cavities, pharynx, larynx, trachea, and principal bronchi. The airway in humans is primarily a conducting pathway. Because the oroesophageal and nasotracheal passages cross each other, anatomic and functional complexities have evolved for protection of the subglottic airway against aspiration of food that passes through the pharynx. Anatomically complex, the airway undergoes growth and development and significant changes in its size, shape, and relation to cervical spine between infancy and childhood.⁴ Similar to other systems in the body, it is not immune from the influence of genetic, nutritional, and hormonal factors. [Table 23-1](#) illustrates the anatomic differences in the larynx between the infant and adult.

| |
|--|
| Proportionately smaller infant/child larynx |
| Narrowest portion: Cricoid cartilage in infant/child; vocal folds in adult |
| Relative vertical location: C3, C4, C5 in infant/child; C4, C5, C6 in adult |
| Epiglottis: Longer, narrower, and stiffer in infant/child |
| Aryepiglottic folds closer to midline in infant/child |
| Vocal folds: Anterior angle with respect to perpendicular axis of larynx in infant/child |
| Pliable laryngeal cartilage in infant/child |
| Mucosa more vulnerable to trauma in infant/child |

Table 23-1. ANATOMIC DIFFERENCES BETWEEN THE PEDIATRIC AND ADULT AIRWAYS

The laryngeal skeleton consists of nine cartilages (three paired and three unpaired); together, these house the vocal folds, which extend in an anterior–posterior plane from the thyroid cartilage to the arytenoid cartilages. The shield-shaped thyroid cartilage acts as the anterior "protective housing" of the vocal mechanism ([Fig. 23-1](#)). Movements of the laryngeal structures are controlled by two groups of muscles: the extrinsic muscles, which move the larynx as a whole, and the intrinsic muscles, which move the various cartilages in relation to one another. The larynx is innervated bilaterally by two branches of each vagus nerve: the superior laryngeal nerve and the recurrent laryngeal nerve. Because the recurrent laryngeal nerves supply all of the intrinsic muscles of the larynx (with the exception of cricothyroid), trauma to these nerves can result in vocal cord dysfunction. As a result of unilateral nerve injury, airway function is usually unimpaired, but the protective role of larynx in preventing aspiration may be compromised.

Figure 23-1. The major landmarks of the airway mechanism. Note that the cricoid cartilage is less than 1 cm in height in its anterior aspect, but may be 2 cm in height posteriorly (*small arrow*).

The cricothyroid membrane, provides coverage to the cricothyroid space. The membrane, which is typically 9 mm in height and 3 cm in width, is composed of a yellow elastic tissue that lies directly subcutaneous to the skin and a thin facial layer. It is located in the anterior neck between the thyroid cartilage superiorly and the cricoid cartilage inferiorly. It can be identified 1–1.5 fingerbreadths below the laryngeal prominence (thyroid notch, or Adam's apple). It is often crossed horizontally in its upper third by the anastomosis of the left and right superior cricothyroid arteries. The membrane has a central portion known as the conus elasticus and two lateral portions, which are thinner and located directly over the laryngeal mucosa. Because of anatomic variability in the course of veins and arteries and its proximity to the vocal folds

(which are 0.9 cm above the ligaments' upper border), it is suggested that any incisions or needle punctures to the cricothyroid membrane be made in its inferior third and be directed posteriorly.

At the base of the larynx, suspended by the underside of the cricothyroid membrane, is the signet ring-shaped cricoid cartilage. This cartilage is approximately 1 cm in height anteriorly, but almost 2 cm in height in its posterior aspect as it extends in a cephalad direction, behind the cricothyroid membrane and the thyroid cartilage (Fig. 23-1). The trachea is suspended from the cricoid cartilage by the cricotracheal ligament. The trachea measures ~15 cm in adults and is circumferentially supported by 17–18 C-shaped cartilages, with a posterior membranous aspect overlying the esophagus (Fig. 23-2).

Figure 23-2. Bronchoscopic view of the adult trachea. The cartilaginous, C-shaped tracheal rings are seen anteriorly, and the membranous portion, overlying the esophagus, is posterior.

The first tracheal ring is anterior to the sixth cervical vertebrae. The tracheal cartilages are interconnected by fibroelastic tissue, which allows for expansion of the trachea both in length and diameter with inspiration / expiration and flexion / extension of the thoracocervical spine. The trachea ends at the carina at the level of the fifth thoracic vertebra, where it bifurcates into the principal bronchi (Fig. 23-3). The right principal bronchus is larger in diameter than the left, and deviates from the plane of the trachea at a less acute angle. Because it is therefore a fairly direct continuation of the trachea, aspirated materials, as well as a deeply inserted tracheal tube, tend to gain entry into the right principal bronchus. Cartilaginous rings support the first seven generations of the bronchi.

Figure 23-3. The adult tracheal carina. The cartilaginous rings of the principal bronchi are easily visualized beyond the carina.

Patient History and Physical Exam

Preoperative evaluation of the patient should elicit a thorough history of airway-related untoward events as well as related symptoms. If feasible, a search for documentation to confirm or elucidate these problems should be conducted. Signs and symptoms related to the airway should be elicited, such as snoring (e.g., obstructive sleep apnea), chipped teeth, changes in voice, dysphagia, stridor, cervical spine pain or limited range of motion, upper extremity neuropathy, temporomandibular joint pain or dysfunction, and significant or prolonged sore throat / mandible after a previous anesthetic. Many congenital and acquired syndromes are associated with difficult airway management (Table 23-2).

| Syndrome | Associated Airway Management Difficulties |
|--|---|
| Obstructive sleep apnea | Upper airway obstruction during sedation and anesthesia |
| Obesity | Reduced functional residual capacity, increased airway resistance, and difficulty with mask ventilation |
| Macroglossia | Difficulty with mask ventilation and laryngoscopy |
| Small mouth | Difficulty with mask ventilation and laryngoscopy |
| Temporomandibular joint dysfunction | Difficulty with mask ventilation and laryngoscopy |
| Cervical spine injury | Difficulty with laryngoscopy and intubation |
| Tracheomalacia | Upper airway obstruction during sedation and anesthesia |
| Tracheobronchomalacia | Upper airway obstruction during sedation and anesthesia |
| Tracheal stenosis | Difficulty with intubation and ventilation |
| Tracheal diverticulum | Difficulty with intubation and ventilation |
| Tracheal web | Difficulty with intubation and ventilation |
| Tracheal rings | Difficulty with intubation and ventilation |
| Tracheal cartilage | Difficulty with intubation and ventilation |
| Tracheal membrane | Difficulty with intubation and ventilation |
| Tracheal ligament | Difficulty with intubation and ventilation |
| Tracheal muscle | Difficulty with intubation and ventilation |
| Tracheal nerve | Difficulty with intubation and ventilation |
| Tracheal blood vessel | Difficulty with intubation and ventilation |
| Tracheal lymph node | Difficulty with intubation and ventilation |
| Tracheal tumor | Difficulty with intubation and ventilation |
| Tracheal infection | Difficulty with intubation and ventilation |
| Tracheal trauma | Difficulty with intubation and ventilation |
| Tracheal surgery | Difficulty with intubation and ventilation |
| Tracheal anesthesia | Difficulty with intubation and ventilation |
| Tracheal intubation | Difficulty with intubation and ventilation |
| Tracheal ventilation | Difficulty with intubation and ventilation |
| Tracheal oxygenation | Difficulty with intubation and ventilation |
| Tracheal perfusion | Difficulty with intubation and ventilation |
| Tracheal innervation | Difficulty with intubation and ventilation |
| Tracheal blood flow | Difficulty with intubation and ventilation |
| Tracheal temperature | Difficulty with intubation and ventilation |
| Tracheal pH | Difficulty with intubation and ventilation |
| Tracheal pO ₂ | Difficulty with intubation and ventilation |
| Tracheal pCO ₂ | Difficulty with intubation and ventilation |
| Tracheal pO ₂ /pCO ₂ ratio | Difficulty with intubation and ventilation |
| Tracheal pO ₂ /pCO ₂ gradient | Difficulty with intubation and ventilation |
| Tracheal pO ₂ /pCO ₂ difference | Difficulty with intubation and ventilation |
| Tracheal pO ₂ /pCO ₂ ratio/gradient/difference | Difficulty with intubation and ventilation |

Table 23-2. SYNDROMES ASSOCIATED WITH DIFFICULT AIRWAY MANAGEMENT

Of course, some pathology will only present on the induction of anesthesia and / or attempts at laryngoscopy (Fig. 23-4). In one landmark case, a patient who was an impossible mask ventilation, laryngoscopy, and LMA placement had an unsuspected airway mass.⁵

Figure 23-4. A 40-year-old male whose epiglottic cyst was discovered at laryngoscopy.

In general, tracheal intubation is difficult under the following conditions: (1) the presence of equally important priorities to the management of the airway (“full stomach,” “open globe,” etc.), (2) abnormal airway anatomy, (3) an emergency, or (4) direct injury to the larynx and / or trachea. Physical examination should focus on the state of dentition, the presence of a beard, mouth size, submandibular soft tissue compliance, atlanto-occipital extension, identification of the cricothyroid membrane, and the presence of pharyngeal pathology. Although the finding of abnormal anatomy is not necessarily synonymous with the difficult airway, it should kindle a heightened level of suspicion. Several investigators have identified anatomic features as having unfavorable influences on the mechanics of direct laryngoscopy; these are explainable on the basis of disproportion, distortion, decreased mobility of joints, and dental overbite. In the earliest attempt to describe anatomic correlates of difficult intubation, Cass *et al* placed emphasis on a short muscular neck with a full dentition, a receding mandible with obtuse mandibular angles, protruding maxillary incisor teeth, decreased mobility at temporomandibular joints, a long high arched palate, and increased alveolar-mental distance.⁶ Early radiographic studies showed that the posterior depth of the mandible (the distance between the bony alveolus immediately behind the third molar tooth and the lower border of mandible) was an important factor in determining the ease or difficulty of laryngoscopy.⁷ Later, the “thyromental distance,” the distance from the tip of the mentum to the thyroid notch, was described as being a crucial measure to be evaluated.⁸ A distance of less than 6 cm was determined to be predictive of a difficult laryngoscopy. This concept was expanded upon by Savva,⁹ who measured the sternomental distance with maximal head extension. This measure functionally “added” the atlanto-occipital joint into the evaluation. A measure of less than 12 cm was proposed to be a positive finding. Turning attention to the intraoral cavity, Mallampati suggested that when the tongue base is disproportionately large, it renders laryngoscopy and intubation difficult; difficulty arises not only from the anatomic overshadowing of the larynx but also from the acuity of the angle between the tongue base and larynx.¹⁰ This anatomic relationship does not allow easy exposure of the glottis. In contrast, it is logical to deduce that a proportionate tongue would not hinder exposure of laryngeal inlet, provided there are no associated factors that impede axis alignment or restrict the mobility of joints. A massive tongue not only overshadows the larynx but also masks the visibility of pharyngeal space and other structures, including soft palate, uvula, and faucial pillars. For elicitation of this clinical sign, the patient remains seated with his or her head in the neutral position, opens the mouth as widely as possible, and protrudes the tongue to the maximum extent. The Mallampati classification is based on the extent to which the base of tongue is able to mask the visibility of pharyngeal structures (Fig. 23-5). Samsoon and Young modified the Mallampati classification to include a fourth class, representing an extreme form of Mallampati’s Class III, in which the soft palate is totally masked by the tongue.¹¹ In this “Class IV,” only the hard palate is visible. Significant correlation was found between airway class and degree of ease or difficulty of exposure of glottis by direct laryngoscopy. The practical value of this method lies in its ease of application. Unfortunately, this index, as with most others, has not proven to be sensitive or specific in identifying difficult-to-intubate patients. In a trial of 675 patients, this index detected only 5 of 12 difficult airways, and gave 139 false positives.¹²

Figure 23-5. Mallampati / Samsoon–Young classification of the oropharyngeal view.¹⁰ *Class I:* uvula, faucial pillars, soft palate visible; *Class II:* faucial pillars, soft palate visible; *Class III:* soft and hard palate visible; *Class IV:* hard palate visible only (added by Samsoon and Young).

It should be noted that the traditional examinations of the airway, including the Mallampati / Samsoon and Young classes, the thyromental distance, and the sternomental distance, may reveal much about the ability to perform direct laryngoscopy, but say little about the ability to use supraglottic ventilatory devices (e.g., Laryngeal Mask Airway, Cuffed Oropharyngeal Airway [COPA], Tracheal Esophageal Combitube), or indirect vision guides (e.g., the fiberoptic bronchoscope, the Bullard laryngoscope).

CLINICAL MANAGEMENT OF THE AIRWAY

Preoxygenation

Preoxygenation (also commonly termed “denitrogenation”) should be practiced in all cases when time permits.¹³ This procedure entails the replacement of the nitrogen volume of the lung (upwards of 69% of the functional residual capacity [FRC]) with oxygen to provide a reservoir for diffusion into the alveolar capillary blood after the onset of apnea.¹⁴ Preoxygenation with 100% O₂ and spontaneous ventilation with a tight-fitting face mask for 5 minutes can furnish up to 10 minutes of oxygen reserve following apnea (in a patient without significant cardiopulmonary disease and a normal oxygen consumption).¹⁵ In one study of healthy, nonobese patients who were allowed to breathe 100% O₂ preoperatively, subjects sustained an oxygen saturation of greater than 90% for 6 ± 0.5 min, whereas obese patients experienced oxyhemoglobin desaturation to under 90% in 2.7 ± 0.25 min.¹⁶ The patient breathing room air (21% O₂) will experience oxyhemoglobin desaturation to a level of under 90% after approximately 2 min under ideal conditions. Patients in respiratory failure, or with conditions affecting metabolism or lung volumes, frequently evidence desaturation sooner owing to increased O₂ extraction, decreased FRC, or right-to-left transpulmonary shunting. The most common reason for not achieving a maximum alveolar F_{IO₂} during preoxygenation is a loose-fitting mask, allowing the entrainment of room air.¹³ Less time-consuming methods of preoxygenation have also been described. Using a series of 4 vital capacity breaths of 100% O₂ over a 30-sec period, a high arterial P_{aO₂} (339 torr) can be achieved, but the time to desaturation is consistently shorter as compared to techniques of breathing 100% O₂ for 5 min.¹⁷ A modified vital capacity technique, wherein the patient is asked to take eight deep breaths in a 60-sec period, shows promise in terms of prolonging the time to desaturation.^{13,18} I prefer the technique of applying a tight-fitting mask for 5 min or more of tidal volume breathing; the mask is placed immediately after the patient has been made comfortable on the operating room table, and remains in place during intravenous catheter insertion and application of monitors. Pharyngeal insufflation of oxygen is a technique that has been described to prolong the duration that an apneic patient sustains an oxyhemoglobin saturation of >90%. In this technique, oxygen is insufflated at a rate of 3 l · min⁻¹ via a catheter passed through the nares. This technique relies upon the phenomenon of apneic oxygenation, a process by which gases are entrained into the alveolar space during apnea, as long as there is a patent airway.¹⁹ This entrainment can provide enough oxygen to sustain hemoglobin saturation for prolonged periods. It is based upon the decrease in intrathoracic pressure, relative to atmospheric pressure, produced as approximately 210 cm³ of oxygen diffuses into the alveolar capillary bed each minute while as little as 12 cm³ of carbon dioxide diffuses into the alveolar space (the remainder of the carbon dioxide being buffered in the blood or tissues). The alveolar carbon dioxide is not removed in this situation, limiting the duration of this technique of oxygenation.

Support of the Airway with the Induction of Anesthesia

With the induction of anesthesia and the onset of apnea, ventilation and oxygenation are supported by the anesthesiologist. Traditional methods include the anesthesia face mask, and the tracheal tube. Recently, a number of supralaryngeal airway support devices have been introduced into worldwide clinical practice. Of these, the Laryngeal Mask Airway (LMA) has gained significant acceptance among anesthesiologists in the United States, with use rates as high as 35% of all general anesthesia cases, in some settings.²⁰ This device, and others that have evolved from it, are reviewed here extensively, since they represent a significant change in airway management practice.

The Anesthesia Face Mask

The anesthesia face mask is the device most commonly used to deliver anesthetic gases and oxygen as well as to ventilate the patient who has been made apneic.

The skillful use of a face mask is challenging and, despite the many advances in airway management, remains a mainstay in the delivery of anesthesia and resuscitation. When the induction of anesthesia commences, the patient’s level of consciousness changes from the awake state, with a competent and protected airway, to the unconscious state, with an unprotected and potentially obstructed airway. This is drug-induced central ventilatory drive depression with a relaxation of the musculature of the upper airway that can rapidly lead to hypercapnea and hypoxia. Thus, ventilation by face mask becomes critical to management of the airway.

Appropriate positioning of the patient is paramount to successful mask ventilation. With the patient in the supine position, the head and neck are placed in the *sniffing* position, which is discussed extensively below. Not only does this position improve mask ventilation by anteriorizing the base of the tongue and the epiglottis, but also

aligns the axes of the oral cavity, pharynx, and trachea in preparation for laryngoscopy.

The mask is gently held over the patient's face with the left hand, leaving the right hand free for other uses (Fig. 23-6). Elastic "mask straps" may be used to help secure the mask in the awake or anesthetized patient who is breathing spontaneously and without obstruction, or to complement the left-hand grip. The mask straps can be particularly helpful for the clinician with short fingers. However, prolonged use of tight-fitting mask straps has been associated with motor and sensory neuropraxias.

Figure 23-6. Holding the anesthesia mask on the face. The thumb and the first finger grip the mask in such a fashion that the anesthesia circuit (or ambu bag) connection abuts the web between these digits. This allows the palm of the hand to apply pressure to the left side of the mask, while the tips of these three digits apply pressure over the right. The third finger helps to secure under the mentum, while the fourth finger is under the angle of the mandible or along the lower mandibular ridge. Mask straps (on pillow) may be used to complement the hand grip by securing the right side of the mask.

After induction of anesthesia, a tight fit of the face mask is achieved by downward displacement of the mask between the thumb and first / second fingers with concurrent upward displacement of the mandible with the remaining fingers. This latter maneuver, commonly known as a *jaw thrust*, raises the soft tissues of the anterior airway off of the pharyngeal wall and allows for improved ventilation. In those patients who are obese, edentulous, or bearded, two hands or a mask strap may be required to ensure a tight fitting mask seal. When two hands are required for holding the face mask, a second operator will obviously be required to ventilate the patient (Fig. 23-7). If need be, the second operator can lend a third hand to the mask fitting.

Figure 23-7. When mask ventilation is difficult owing to upper airway obstruction, a second operator may be required so that (A) two or (B) three hands can be used in a jaw thrust maneuver.

It must be noted that the patient with normal lung compliance should require no more than 20–25 cm H₂O pressure to inflate the lungs. If more pressure than this is required, the clinician should reevaluate the adequacy of the airway, then adjust the mask fit, seek the aid of a second operator in order to perform two- or three-handed mask holds, and / or consider other devices that aid in the creation of an open passage for air flow through the upper airway. Both rigid oral airways and soft nasal airways create an artificial passage between the roof of the mouth, tongue, and the posterior pharyngeal wall (Fig. 23-8).

Figure 23-8. A variety of oral (A) and nasal (B) airways are available. The goal of these devices is to hold the base of the tongue forward to create an air passage.

Oral airways, which come in a wide variety of sizes, can stimulate the semiconscious patient and provoke coughing, vomiting, and / or laryngospasm. The level of anesthesia must be assessed before they are inserted. Likewise, a LMA or COPA may be used at this juncture if the anesthetic is adequate. Nasal airways, less stimulating to the patient, can cause significant nasal trauma and bleeding and should be used with extreme caution in patients with known coagulopathy or nasal deformities. These devices are contraindicated in the patient with a basilar skull fracture.

Obstruction to mask ventilation may be caused by laryngospasm, an intrinsic closure of the vocal folds. Laryngospasm occurs as a result of foreign body (e.g., oral or nasal airway), saliva, blood, or vomitus touching the glottis, or even a light plane of anesthesia. Hypoxia as well as noncardiogenic pulmonary edema can result if there is continued spontaneous ventilation against closed vocal cords. Treatment of laryngospasm includes removal of an offending stimulus (if it can be identified), continuous positive airway pressure, deepening of the anesthetic state, and the use of a rapid-acting muscle relaxant.

If there are no contraindications (e.g., a "full stomach" or other aspiration risk), mask ventilation can be the technique employed for the duration of anesthesia maintenance. Otherwise, it is commonly used to administer anesthetic gases until the anesthetic state is adequate for use of another means of airway support (e.g., tracheal tube). This decision is made after careful consideration of the patient's coexisting diseases and surgical requirements.

The Laryngeal Mask Airway

The LMA was introduced into clinical practice in the 1980s, and was approved as a substitute for the face mask during elective anesthesia by the U.S. Food and Drug Administration in 1991 (Fig. 23-9). It also was recommended as a substitute for the tracheal tube in cases where tracheal intubation was not necessary. Though initially the LMA enjoyed limited acceptance among anesthesiologists, its role has expanded in recent years, so that practicing anesthesiologists report that 23% of all cases

are being managed with the LMA.²⁰

Figure 23-9. The original LMA design: a size 1 and size 6 LMA-Classic. The two bars over the airway aperture prevent the epiglottis from obstructing the LMA barrel.

LMA Design. The LMA is composed of a small “mask” designed to sit in the hypopharynx, with an anterior surface aperture overlying the laryngeal inlet. The rim of the mask is composed of an inflatable silicone cuff which fills the hypopharyngeal space, creating a seal that allows positive pressure ventilation with up to 20 cm H₂O pressure.²¹ The adequacy of the seal is dependent on correct placement and appropriate size. It is less dependent on the cuff filling pressure. Attached to the posterior surface of the mask is a barrel (airway tube) which extends from the mask’s central aperture through the mouth and can be connected to an ambu bag or anesthesia circuit.

A range of sizes are available for use in neonates through adults. LMA size selection is critical to its successful use, and to the avoidance of minor as well as more significant complications. [Table 23-3](#) gives the recommended size for patient weight and the maximum inflation volumes.

| LMA Size | Patient Weight | Increase in Size (%) | Maximum Inflation Volume (ml) | Test Inflation Volume (ml) |
|----------|-----------------------------|----------------------|-------------------------------|----------------------------|
| 1 | Neonates/infants up to 5 kg | — | 4 | 6 |
| 1.5 | 5–10 kg | 21 | 7 | 10 |
| 2 | 10–20 kg | 21 | 10 | 15 |
| 2.5 | 20–30 kg | 18 | 14 | 21 |
| 3 | >30 kg | 15.7 | 20 | 30 |
| 4 | Small adults | 14.4 | 30 | 45 |
| 5 | Normal adults | 13.8 | 40 | 60 |
| 6 | Large adults | 8.1 | | |

Table 23-3. LMA SIZING AND INFLATION VOLUMES

The manufacturer recommends that the clinician choose the largest size that will comfortably fit in the oral cavity, then inflate to the minimum pressure that allows ventilation to 20 cm H₂O without an air leak. The intracuff pressure should never exceed 60 cm H₂O (and should be periodically monitored if nitrous oxide is used as part of the anesthetic). When an adequate seal cannot be obtained with 60 cm H₂O cuff pressure, the LMA may be malpositioned and / or sizing should be reevaluated. Light anesthesia may also contribute to poor seal or partial or complete laryngospasm.

LMA Insertion. The insertion of the LMA as described by its inventor, Dr. Archie J. I. Brain, has been modified by a number of writers. Discussion of these various alternatives is beyond the scope of this text. Dr. Brain’s initial contemplations of this unique airway considered routine and natural placement of a “foreign body” in the hypopharynx—food. It was Dr. Brain’s intent to mimic the placement of food into the hypopharynx and thereby establish the placement of a device, which could then serve as an airway.

In order to understand the insertion technique, we must therefore review the processes of deglutination: lubrication with saliva; formation of a flat oval food bolus by the tongue; initiation of the swallowing reflex by stimulation of the palate; upward pressure by the tongue flattening the food bolus against the palate; directing of the food bolus toward the posterior pharyngeal wall and into the hypopharynx by the shape of the palate and pharyngeal wall; head extension and neck flexion opening the space behind the larynx to allow passage of the food bolus into the hypopharynx; and finally, opening of the upper esophageal sphincter to allow esophageal entry of the food bolus. These functions allow the food bolus to reach its mark blindly, while avoiding the anterior pharyngeal structures and avoiding reflex responses meant to protect the airway.

Prototype insertion methods involved rotation through 180° and the early use of an introducer to prevent down-folding of the epiglottis. The currently recommended, technique illustrated in [Figure 23-10](#) has been found to be less traumatic and have a 98% success rate. In this technique the mask is lubricated with a non-silicone, non-local anesthetic-containing lubricant (simulating the saliva), and is fully deflated to form a thin, flat wedge shape (*cf.* masticated food bolus). The operator’s nondominant hand is placed under the occiput to flex the neck on the thorax and extend the head at the atlanto-occipital joint (creating a space behind the larynx; this action also tends to open the mouth). The index finger of the dominant hand is placed in the cleft between the mask and barrel. The hard palate is visualized and the superior (nonaperture) surface of the mask is placed against it. Force is applied by the index finger in an upward direction toward the top of the patient’s head. This will cause the mask to flatten out against the palate and follow the shape of the palate as it slides into the pharynx and hypopharynx. The index finger continues along this arc, always applying an outward pressure until the resistance of the upper esophageal sphincter is met. The most common error made by clinicians is applying pressure with a posterior vector. This tends to catch the tip of the LMA on the posterior pharyngeal wall, causing folding with resultant misplacement and trauma.

Figure 23-10. Insertion of the LMA. The LMA is inserted with the index finger of the dominant hand pressing with a force vector against the hard palate (A and B). The outward force vector is continued from the hard palate to the pharynx and hypopharynx (C) until the index finger meets resistance against the upper esophageal sphincter (D).

Once insertion is complete, removal of the inserting hand is facilitated by gentle stabilization of the LMA barrel with the nondominant hand. Prior to attachment of the anesthesia circuit, the LMA is inflated with the minimum amount of gas to form an effective seal. Though it is difficult to suggest a particular volume of gas to be used,

the operator should be accustomed to the feel of the pilot bulb when it is inflated to 60 cm H₂O pressure, the maximum suggested seal pressure. Accompanying the inflation, one should be able to observe a rising of the cricoid and thyroid cartilage and lifting of the barrel out of the mouth by approximately 1 cm as the mask is lifted off the upper esophageal sphincter. The mask is fixed in position by bringing the barrel down against the chin and taping in the midline while a gentle upward pressure is exerted against the hard palate. If a midline position is not possible owing to the nature of the patient position or surgical procedure, a flexible LMA (discussed below) should be considered. A bite block is recommended to prevent biting and occlusion of the LMA barrel.²²

The LMA and Gastroesophageal Reflux. Although the distal tip of the LMA's mask sits in the esophageal inlet, it does not reliably seal it. A predominant clinical perception is that the LMA does not protect the trachea from regurgitated gastric contents. As of December 1999, just 20 cases of suspected pulmonary aspiration have been reported (with an estimated 100,000,000 uses of the LMA worldwide). Of these, only 12 were verified as true aspiration events and none resulted in death, though five patients required positive-pressure ventilation. There were predisposing factors in most of the cases, including obesity, dementia, emergency surgery, upper abdominal surgery, Trendelenburg position, intraperitoneal insufflation, or a difficult airway.^{23,24,25,26,27,28,29,30,31,32} and ³³ Indeed when used in patients at low risk for regurgitation, the rate of aspiration during LMA use is similar to that in all non-LMA general anesthetics (~2 in 10,000 cases), though the incidence of gastroesophageal reflux may be increased when compared to use of the face mask.^{34,35,36,37,38,39} and ⁴⁰

Some evidence suggests that there may be more gastroesophageal reflux during LMA use with a patient in the Trendelenburg or lithotomy position.^{39,41} If regurgitated gastric contents are noted in the LMA barrel, maneuvers similar to those applied when using an ETT should be instituted: Trendelenburg position, administer 100% oxygen, leave the LMA in place and use a flexible suction device down the barrel, deepen anesthetic if necessary.

When populations of patients considered to have a full stomach are studied (in controlled trials, prospective series, or anecdotally), there is a very low incidence of aspiration noted with elective or emergency LMA use. Reports have included patients who are morbidly obese or experience frequent gastroesophageal reflux and those undergoing elective cesarean section or airway rescue during labor and those presenting to emergency departments or paramedic crews.^{42,43,44,45,46,47,48,49,50} and ⁵¹

During cardiopulmonary resuscitation, the incidence of gastroesophageal regurgitation is four times greater with a bag-valve mask than with the LMA.⁵²

Unconventional Use of the LMA. Since its introduction, a wealth of clinical data has indicated that the LMA can be safely used in the operating room in a variety of clinical situations. A large number of clinical situations traditionally managed with tracheal intubation and mechanical ventilation have been performed with the LMA. [Table 23-4](#) presents a number of these clinical situations, describes some of the advantages and precautions of LMA use, and provides appropriate references. A few of these clinical scenarios are discussed in the text.

| Clinical Situation | Advantages | Precautions | References |
|---------------------------------------|--|-----------------------------|--------------------|
| Head and neck surgery | • Improved visualization of the surgical field | • Avoidance of laryngospasm | 53, 54 |
| Obesity | • Improved ventilation | • Avoidance of aspiration | 55, 56, 57, 58, 59 |
| Emergency surgery | • Rapid placement | • Avoidance of aspiration | 60, 61, 62 |
| Upper abdominal surgery | • Improved ventilation | • Avoidance of aspiration | 63, 64 |
| Trendelenburg position | • Improved ventilation | • Avoidance of aspiration | 65, 66, 67 |
| Lithotomy position | • Improved ventilation | • Avoidance of aspiration | 68, 69, 70 |
| Difficult airway | • Improved ventilation | • Avoidance of aspiration | 71, 72, 73 |
| Cardiopulmonary resuscitation | • Improved ventilation | • Avoidance of aspiration | 74, 75, 76 |
| Obstructive pulmonary disease | • Improved ventilation | • Avoidance of aspiration | 77, 78, 79 |
| Chronic obstructive pulmonary disease | • Improved ventilation | • Avoidance of aspiration | 80, 81, 82 |
| Acute respiratory distress syndrome | • Improved ventilation | • Avoidance of aspiration | 83, 84, 85 |
| ARDS | • Improved ventilation | • Avoidance of aspiration | 86, 87, 88 |
| Severe asthma | • Improved ventilation | • Avoidance of aspiration | 89, 90, 91 |
| Severe COPD | • Improved ventilation | • Avoidance of aspiration | 92, 93, 94 |
| Severe emphysema | • Improved ventilation | • Avoidance of aspiration | 95, 96, 97 |
| Severe bronchitis | • Improved ventilation | • Avoidance of aspiration | 98, 99, 100 |

Table 23-4. REPORTED UNCONVENTIONAL USE OF THE LMA

LMA and Positive-Pressure Ventilation. Though first introduced for use with spontaneous ventilation, the LMA has proved useful for cases in which positive-pressure ventilation is either desired or preferred.^{53,54} Contrary to initial impression, positive-pressure ventilation can be safely accomplished with the LMA.^{55,56,57,58,59} and ⁶⁰ There is no difference found in gastric inflation with positive pressure (<17 cm H₂O) when comparing the LMA and the ETT.^{61,62} When using the LMA, one should limit tidal volumes to 8 ml · kg⁻¹ and airway pressure to 20 cm H₂O since this is the sealing pressure of the device under normal circumstances. The clinician should also auscultate over the throat in order to detect leak, or over the stomach to detect gastric insufflation. LMA use has been described with the supine, prone, lateral, oblique, Trendelenburg, and lithotomy positions.⁶³

Duration of LMA Use. Duration of LMA use has also been a controversial issue. Though the manufacturer recommends use for a maximum of 2–3 hours, reports of use lasting more than 24 hours can be found.⁶⁴

The LMA-flexible. The advent of the LMA-flexible ([Fig. 23-11](#)) has permitted extension of LMA use to a variety of cases in which the airway is shared with the surgical team (e.g., otolaryngologic surgery).⁶⁵ The LMA-flexible differs from the original design by virtue of a thin-walled, small-diameter, wire-reinforced (kink-resistant) barrel, which can be positioned out of the midline without affecting the hypopharyngeal position of the mask. It was designed to be used with a tonsillar mouth gag, as employed in surgery on the mouth and pharynx.^{66,67} The LMA-flexible has also proved useful when heavy drapes are placed over the head and airway, when there is movement of the head position during surgery (e.g., typanostomy tubes), or when the LMA barrel cannot be secured in the midline (e.g., mid or lateral facial surgery). The use of this mask in surgery above the level of the hypopharynx affords a number of clinically important advantages over tracheal intubation ([Table 23-5](#)).

Figure 23-11. An LMA-flexible in place with a Crow-Davis mouth gag during a tonsillectomy and uvulopharyngopalatoplasty. The uvula has been removed. The LMA mask is not visible to the surgeon when correctly placed.

- Improved protection of the airway from blood and surgical debris
- Reduced cardiovascular responses
- Reduced coughing on emergence
- Reduced laryngospasm after airway device removal
- Improved oxygen saturation after airway device removal
- Ability to administer oxygen until complete restoration of airway reflexes

Table 23-5. ADVANTAGES OF THE LMA IN SUPRAGLOTTIC SURGERY

When correctly placed, the LMA mask serves as a superb block of the airway from blood, secretions, and surgical debris above the level of the mask, as compared to the tracheal tube, which is known not to protect the trachea from liquids instilled into the pharynx^{68,69,70 and 71} (Fig. 23-12).

Figure 23-12. Following endoscopic sinus surgery, (A) the superior, pharyngeal surface of the LMA is blood-stained whereas (B) the laryngeal surface remains clean.

The LMA and Bronchospasm. As a supraglottic airway, the LMA appears to be well suited to the patient with a history of extrinsic asthma. The LMA presents a unique opportunity for the clinician to conveniently and effectively control the airway without having to introduce a foreign body into the trachea. Thus, it may be an ideal airway tool in the asthmatic patient who is not at risk for reflux and aspiration.^{72,73,74 and 75} Because the halogenated inhaled anesthetics are potent bronchodilators, it is at the time of emergence when they are discontinued that the patient at risk for bronchospasm is most likely to wheeze. In the patient managed with the LMA, there is no foreign body in the sensitive broncho-respiratory tree and the patient can be fully emerged prior to removal of the device. In the event that uncontrollable bronchospasm does occur intraoperatively (e.g., from vagal stimuli such as traction on the peritoneum), intubation can be performed through the LMA or after its removal.⁷⁶

LMA Removal. Timing of the removal of the LMA at the end of surgery is also critical.^{77,78 and 79} The LMA should be removed either when the patient is deeply anesthetized or after protective reflexes have returned and the patient is able to open the mouth on command. Removal during excitement stages of emergence can be accompanied by coughing and / or laryngospasm. Many clinicians remove the LMA fully inflated; thus, it acts as a “scoop” for secretions above the mask, bringing them out of the airway. This has been particularly useful in otolaryngologic surgery (Fig. 23-12).

Contraindications to LMA Use. The primary contraindication to elective use of the LMA is a risk of gastric-content aspiration (e.g., full stomach, hiatus hernia with significant gastroesophageal reflux, morbid obesity, intestinal obstruction, delayed gastric emptying, poor history). Other contraindications include poor lung compliance or high airway resistance, glottic or subglottic airway obstruction, and limited mouth opening (<1.5 mm).⁶³

LMA Use Complications. Apart from gastroesophageal reflux and aspiration, reported complications have included laryngospasm, coughing, gagging, retching, bronchospasm, and other events characteristic of airway manipulation. The incidence of sore throat is approximately 10%, as compared to 30% with tracheal intubation, but has been reported as 0–70%.⁶³ Also reported are hoarseness (4–47%) and dysphagia (4–24%). The LMA may cause transient changes in vocal cord function.⁸⁰ This is possibly related to cuff overinflation during prolonged procedures.

There have been several reports of nerve injury associated with LMA use. As of April 1999, 11 cases of nerve palsy have been reported: recurrent (7), hypoglossal (2), and lingual (2).⁸¹ All but one of these resolved spontaneously. In all cases, size 3 and 4 LMAs were in use and nitrous oxide was one of the inhalation agents (which can increase cuff pressures by 9–38%).⁸² Cuff pressures were not monitored in any of the cases. It is hypothesized that lingual nerve injuries occur as the nerve is trapped between the mandible and the LMA barrel lying lateral to the tongue. The hypoglossal nerve runs rostral and lateral to the hyoid bone, and may be pressed up against the bone. The recurrent nerve may be compressed between the LMA cuff and the cricoid or thyroid cartilage. Unmonitored increases in pressure due to N₂O diffusion, light anesthesia with constriction of pharyngeal musculature, tissue edema and venous engorgement from a head-down position, and lidocaine gel lubricant have been blamed for nerve injury.⁸³ To prevent such injury, the cuff of the LMA should be inflated to no more than 60 cm H₂O and should be monitored if N₂O is in use. The use of a larger LMA, with less pressure, has also been recommended.⁸⁴

One death has been associated with an LMA device. An elderly woman suffered a tear of her esophagus after use of the intubating LMA (LMA-Fastrach[®]), dying 9 weeks later from septic shock after a series of related complications.⁸⁵ Interestingly, the actual complication was most likely a small esophageal tear from an inadvertent esophageal intubation. Therefore this complication was more of a misadventure of “blind intubation” not inherently attributable to the LMA-Fastrach itself. No other deaths due to complication of LMA use have been reported in the literature. It has been estimated, though, that 600 deaths occur each year in the developed world because of complications of difficult tracheal intubation.⁸⁶

The LMA-Proseal[®]. Although the original LMA and the LMA-flexible have been used successfully for positive-pressure ventilation, they are not ideally suited to this task for two reasons: first, if poorly seated in the hypopharynx, gastric inflation may occur; second, the seal pressure is limited to approximately 20 cm H₂O. In 1994 an LMA prototype that includes a gastric drain was described.⁸⁷ It was believed that such a design would reduce both the risk of gastric inflation (by providing a low-resistance pathway for pressure transmitted to the esophagus) and the risk of aspiration of refluxed gastric contents. Subsequently, it was found that the design, which also incorporates a second, posterior cuff, could reliably allow positive-pressure ventilation with 40 cm H₂O pressure. A prototype of this mask, termed the LMA-Proseal (Fig. 23-13), has been used in patients and is now undergoing multicenter trials (personal communication with Archie Brain).⁸⁸

Figure 23-13. The LMA-Proseal: (A) Anterior view showing gastric drain passing through the bowl. (B) Lateral view showing the circumferential and posterior mask cuffs. (In the photograph, the view of the esophageal lumen is obscured by the airway lumen.) (C) The airway lumen and gastric drain, separated by an integral bite block, emerge from the patient. (D) A drop of water-soluble lubricant has been placed in the proximal aperture of the esophageal lumen in order to monitor for gas leak, which should not be present.

Another advantage of this design is that the gastric drain can be an aid in determining correct positioning of the mask, since malpositions (e.g., nasopharynx, intratracheal) are accompanied by an air leak via this lumen.^{87,88,89 and 90} This can be accentuated by filling the proximal few centimeters of the lumen with a

water-soluble surgical lubricant and observing for bubbles or movement of the meniscus (Fig. 23-13d).

The design of the LMA-Proseal also makes use of the flexible, wire-reinforced barrel pioneered with the LMA-flexible, making it less prone to displacement with head movement. The second, gastric drain is also constructed of soft silicone, mounted lateral to the airway tube. A small gastric tube can be inserted into the stomach via this lumen. A silicone bite block is cemented between the two tubes. Because of the array of components at the level of the teeth (e.g., airway barrel, gastric drain, bite block), the LMA-Proseal may be more difficult to insert into the airway. For this reason, the inventor included a surgical stainless steel insertion device which replicates the insertion technique of the LMA-Fastrach. After placement, the insertion device is removed. It is expected that this new design will improve the clinician's ability and comfort in safely using the LMA with positive-pressure ventilation and in patients at risk for gastric-contents aspiration.

The LMA and the Difficult Airway. Apart from its role as a routine anesthetic airway device, the LMA has a history of being a valuable tube in the care of the patient with the anticipated, or the unanticipated, difficult airway. This will be considered later in this chapter.

The Cuffed Oropharyngeal Airway

Another supraglottic airway device now available is the Cuffed Oropharyngeal Airway, or COPA (Mallinckrodt Medical, Athlone, Ireland). This device (Fig. 23-14) resembles a Guedel airway with an inflatable cuff along the distal half of its length and a 15-mm circuit adapter at the proximal end. The inflated cuff fills the pharynx and displaces the epiglottis and base of the tongue anteriorly. An unobstructed, sealed airway is provided. A flange around the circuit adapter has two posts for the attachment of a stabilizing head strap. The COPA was designed for airway maintenance during anesthesia with spontaneous ventilation and is in many ways comparable to the LMA in this population.^{91,92} It has been used in the difficult-to-intubate patient, also.

Figure 23-14. The COPA is inserted with the concavity in a cephalad direction. Once in the oral cavity, it is rotated into position, and inflated. A strap is used to keep the device in place.

Tracheal Intubation

Routine Laryngoscopy

PREPARING FOR LARYNGOSCOPY AND THE “BEST ATTEMPT.” Whether laryngoscopy is undertaken with the patient in an awake or unconscious state, repeated attempts often result in edema and bleeding of the anterior upper airway structures (tongue, vallecula, epiglottis, laryngeal structures), hindering subsequent attempts at visualization and causing increased airway obstruction. It is therefore important to assure that the first attempt at laryngoscopy is a “best attempt.”

First, when faced with the critically ill patient, the most skilled laryngoscopist available should be positioned to perform the laryngoscopy. In less acute situations, it is not inappropriate for a trainee, clinician extender, or other skilled personnel to assume this role. Second, the availability of all the materials needed to perform laryngoscopy and intubation should be assured, as should the availability of materials needed to manage a failed intubation. When devices are fashioned in a variety of sizes, the operator should have at hand the presumed correct size, as well as one size smaller and one size larger of each item (Table 23-6).

| |
|--|
| Oxygen source and self-inflating ventilation bag (e.g., ambu bag) |
| Face mask† |
| Oropharyngeal and nasopharyngeal airways† |
| Tracheal tubes† |
| Tracheal tube stylet |
| Syringe for tracheal tube cuff inflation |
| Suction apparatus |
| Laryngoscope handle (2), tested for working order and battery freshness |
| Laryngoscope blades: Common blades include the curved (Macintosh) and straight (Miller)† |
| Pillow, towel, blanket, or foam for head positioning |
| Stethoscope |

* Equipment that should be immediately available in the ideal clinical setting.
† Presumed size as well as one larger and one smaller should be immediately available.

Table 23-6. EQUIPMENT FOR LARYNGOSCOPY*

Other devices that complete the equipment list, but may not be uniformly available, include: end-tidal CO₂ monitoring (e.g., capnography or colorimetric device [e.g., Easy Cap II, Mallinckrodt]), pulse oximetry, LMA, transtracheal jet ventilation catheter, and a high-pressure oxygen source.

The height of the supine patient surface should be at the level of the laryngoscopist's xyphoid cartilage, with the bed or operating room table in a nonmovable mode (e.g., wheels locked). The clinician performing the intubation must have unobstructed access to the head.

DIRECT LARYNGOSCOPY. Successful laryngoscopy involves the distortion of the normal anatomic planes of the supralaryngeal airway to produce a line of direct visualization from the operator's eye to the larynx: this requires alignment of the oral, pharyngeal, and laryngeal axes. A number of criteria must be met if this is to occur:

The oral aperture has to be adequate to allow visualization (and instrumentation).

The tongue must be small (relative to the oral cavity and mandibular space) and pliable enough to allow its distortion.

The mandibular space (the area between the mentum and the hyoid bone) must be able to accommodate the tongue as it is displaced by the laryngoscope.

With the head in a neutral position—that is, with the base of the occiput on the same plane as the lower thoracic spine, the face pointed directly upward—there is no overlap of the three axes, and direct visualization cannot occur (Fig. 23-15A). To remedy this, an optimal “sniff” or Magill position should be achieved. This position, which entails a slight flexion of the neck on the thorax (35°) and severe extension of the head on the neck (an 80–85° angle between the sagittal axis of head at level of nose, and the long axis of neck) at the atlanto-occipital joint, accomplishes the best possible alignment of the oral, pharyngeal, and laryngeal axes (Fig. 23-15B).⁹³ The sniff position may be simulated by imagining or assuming the head and neck position of the long-distance runner.⁹⁴ This position maximally opens the airway, moves the epiglottis out of the visual line, and maximally reduces airway resistance.⁹⁵ The Magill position can be accomplished in the clinical setting by placing a small pillow (10 cm) under the head, while the shoulders remain flat on the patient surface (Fig. 23-15B). Failure to maintain this position during laryngoscopy is one of the most common reasons for a poor-grade laryngoscopic view.⁹⁶

Figure 23-15. (A) With the patient supine and no head support, the oral, pharyngeal, and tracheal axes do not overlap. (B) The “sniff” position maximally overlaps the three axes.

A sniff position pillow (Dupaco, Oceanside, CA) that is comfortable for the awake patient, but easily reconfigured after anesthetic induction to provide an ideal sniff position, has been developed by Dr. Kaiduan Pi ([Fig. 23-16](#)).

Figure 23-16. (A) Pi's pillow (Dupaco, Oceanside, CA) places the patient in a comfortable position prior to the induction of anesthesia and (B) in an ideal “sniff” position during airway management.

Overextension of the head on the neck and / or anterior movement of the mandible after the administration of neuromuscular relaxation can hinder the laryngeal view by moving the thyroid cartilage and larynx anteriorly.

The obese patient may need further positioning to move the mass of the chest away from the plane across which the laryngoscope handle will sweep as it is manipulated into the mouth. This may require placing a wedge-shaped lift (e.g., blankets, pillows) under the scapula, shoulders, and nape of neck, raising the head and neck above the thorax and providing a grade in order to allow gravity to take the mass away from the airway ([Fig. 23-17](#)).

Figure 23-17. (A) With the morbidly obese patient, a 10-cm pillow may not provide a position adequate for laryngoscopy. (B) A wedge-shaped lift is used to move the mass of the morbidly obese patient's chest away from the area of laryngoscopy and to improve the compliance of the thoracic cavity.

If, during the laryngoscopy, a satisfactory laryngeal view is not achieved the backward-upward-rightward pressure (BURP) maneuver may aid in improving the view. In this maneuver, a second operator displaces the larynx (a) backward against the cervical vertebrae, (b) superiorly as possible and (c) slightly laterally to the right, using external pressure over the cricoid cartilage. The BURP maneuver has been shown to improve the laryngeal view, decreasing the rate of difficult intubation in 1993 patients from 4.7% to 1.8%.^{97,98} When a left-handed operator is using a left-handed laryngoscope blade, the lateral external pressure should displace the larynx to the left. Similarly, Benumof describes “optimal external laryngeal manipulation,” which consists of pressing posteriorly and cephalad over the thyroid, hyoid, and cricoid, as improving laryngeal view by at least one Cormack and Lehane grade.^{99,100}

Once alignment has been achieved, the mouth is opened by one of two techniques ([Fig. 23-18](#)). The first accomplishes hyperextension of the atlanto-occipital joint head by the use of the dominant hand under the occiput. This maneuver tends to open the mouth, and can be accentuated by using the fifth finger of the nondominant hand (holding the laryngoscope) to apply pressure over the chin in a caudad direction ([Fig. 23-18a](#)). In the second technique, which tends to be more effective but requires contact of the (gloved) hand with the teeth and / or gum, caudad pressure is applied with the thumb of the dominant hand on the mandibular molars on the patient's same side while the first finger, crossed above or below the thumb, applies cephalad pressure to the ipsilateral maxillary molars ([Fig. 23-18b](#)). The ultimate goal of both techniques is rotation and translation of the temporomandibular joint in order to achieve the widest interincisor gap. The patient, whether conscious or not, is now ready for laryngoscopy.

Figure 23-18. Techniques of opening the mouth in preparation for laryngoscopy. (A) Hyperextension of the atlanto-occipital joint and use of the fifth finger of the

dominant hand; (B) the thumb–first finger “scissors” technique.

USE OF THE LARYNGOSCOPE BLADE. Proper use of the laryngoscope blade is vital to the success of this basic airway management technique. Two blade types are commonly available and each is applied in a unique manner (Fig. 23-19). The curved (Macintosh) blade is used to pull the epiglottis out of the line of sight by tensing the glossoepiglottic ligament, whereas the straight blade (Miller) compresses the epiglottis against the base of the tongue. Both blades include a flange along the left side of their length which is used to sweep the tongue to the left side of the mouth. Blades with a right-side flange are available for the left-handed practitioner, but they are not commonly found in practice.

Figure 23-19. Macintosh and Miller laryngoscope blades with small and regular-sized handles.

In most available systems the flange incorporates the light source, either a bulb placed near the distal blade aspect or a rigid fiberoptic cable that transmits light produced within the handle. In either case, these blades must be long enough to achieve their respective applications. Therefore, blade size needs to be chosen appropriately and, on occasion, exchanged after a failed attempt. As a generalization, the Macintosh blade is regarded as better wherever there is little room to pass an endotracheal tube (e.g., small mouth), whereas the Miller blade is considered better in the patient who has a small mandibular space, large incisor teeth or a large epiglottis.⁹⁴

With the left hand holding the laryngoscope handle, the blade is inserted into the right side of the mouth, with care taken not to compress the upper lip against the teeth. As the blade is advanced toward the epiglottis, it is swept leftward, using the flange to displace the tongue to the left as the blade compresses it into the mandibular space. Once reaching the base of the tongue (the Macintosh blade tip in the vallecula, or the Miller blade compressing the epiglottis against the base of the tongue), the operator's arm and shoulder lift in an anterior and caudad direction (Fig. 23-20).

Figure 23-20. (A) When a curved laryngoscope blade is used, the tip of the blade is placed in the vallecula, the space between the base of the tongue and the pharyngeal surface of the epiglottis. (B) The tip of a straight blade is advanced beneath the epiglottis.

Importantly, the laryngoscopist must strive to avoid rotating the wrist and laryngoscope handle in a cephalad direction, bringing the blade against the upper incisor teeth. Extending either blade style too deeply can bring the tip of the blade to rest under the larynx itself, so that forward pressure lifts the entire airway from view (Fig. 23-21).

Figure 23-21. The sequence of routine laryngoscopy. (A) With the mouth maximally opened, the laryngoscope is held in the left hand and the blade inserted on the right side of the mouth. Using the blade flange, the tongue is swept to the left as the wrist pulls in a caudad direction. (B) While visualizing the laryngeal inlet, the tracheal tube is inserted.

Special considerations apply to the technique of laryngoscopy and intubation in the infant and child. Because of the relatively larger size of the occiput in children, producing an anatomic sniffing position, elevation of the head (as done in the adult) is not needed.¹⁰¹ On occasion, one may need to elevate the thorax instead. The relatively short neck gives the impression of an anterior position of the larynx. Posterior cricoid pressure is often required to place the laryngeal inlet into view. A straight blade is more helpful in displacing the stiff, omega-shaped, and high epiglottis. Since the cricoid cartilage is the narrowest aspect of the airway until 6 to 8 years of age, the intubator must be sensitive to resistance to advancement of the ETT that has easily passed the vocal folds. Hyperextension at the atlanto-occipital joint, as done in adult, may cause airway obstruction due to the relative pliability of the trachea. In the child, there is a higher risk of endobronchial intubation or extubation with head movement owing to the short length of the trachea.

With laryngoscopy, the view of the larynx may be complete, partial, or impossible. A laryngeal view scoring system that has won general acceptance was developed by Cormack and Lehane, who described four grades of laryngeal view:¹⁰⁰ Grade I includes visualization of the entire glottic aperture; Grade II includes visualization of only the posterior aspects of the glottic aperture; Grade III is visualization of the tip of the epiglottis; Grade IV is visualization of no more than the soft palate (Fig. 23-22). This system has proved useful not only as a means of recording the laryngeal view on individual patients, but also as a clinical endpoint in the evaluation of the predictive value of preoperative airway assessments tools.

Figure 23-22. The Cormack–Lehane laryngeal view scoring system: (A) Grade 1, (B) Grade 2, (C) Grade 3, (D) Grade 4.

Once the larynx is visualized with a left side–flanged blade, the tracheal tube is inserted from the right-hand side, care being taken not to obstruct the view of the vocal folds. Whenever possible, the action of the endotracheal tube passing through the vocal folds should be witnessed by the laryngoscopist. The tracheal tube should be inserted to a depth of at least 2 cm after the disappearance of the tracheal tube cuff past the vocal folds in order to approximate placement in the mid trachea. This should present the 21-cm and 23-cm external markings at the teeth for the typical adult female and male, respectively.¹⁰² Choice of adult tracheal tube size may be made by the generalization that for women, size 7–8 id (internal diameter) may be used, and for a man, size 8–9 id. The larger tracheal tubes may be desirable if pulmonary toilet or diagnostic or therapeutic bronchoscopy is to be part of the clinical course. Pediatric laryngoscope blades and tracheal tube sizes are discussed in detail elsewhere in this chapter (Table 23-7).

| Age | Internal Diameter (mm) | Distance from Lips to Mid-trachea* (cm) | Diameter of Trachea (mm) | Length of Trachea (cm) | Distance from Lips to Carina (cm) |
|-----------|------------------------|---|--------------------------|------------------------|-----------------------------------|
| Preterm | 2.5 | 8 | | | |
| Full term | 3.0 | 10 | | | |
| 1–4 mo | 3.5 | 11 | 5 | 6 | 13 |
| 6–12 mo | 4.0 | 12 | | | |
| 2 yr | 4.5 | 13 | | | |
| 4 yr | 5.0 | 14 | | | |
| 6 yr | 5.5 | 15 | | | |
| 8 yr | 6.5 | 16 | 8 | 8 | 18 |
| 10 yr | 7.0 | 17–18 | | | |
| 12 yr | 7.5 | 18–20 | | | |
| 14 yr | 8.0–8.5 | 20–22 | 20–22‡ | 18–22‡ | 28–30‡ |

* Add 2–3 cm for nasal tubes.

 ‡ Females.

Table 23-7. SIZE AND LENGTH OF TRACHEAL TUBES RELATIVE TO AIRWAY ANATOMY

Verification of successful tracheal tube placement is made by a variety of methods. The gold standard for confirmation of placement includes visualization of placement through the vocal folds and sustained detection of exhaled carbon dioxide as measured with capnography or a disposable chemical colorimetric device such as the Easy Cap II (Mallinckrodt). Other portable techniques include auscultation over the chest and abdomen, visualization of the chest excursion, observation of condensation in the ETT, use of a self-inflating bulb (Tubecheck-B, Ambu, Linthicum, MD), lighted stylets (Trachlight, Laerdal Medical, Armonk, NY; SURCH-LITE, Aaron Medical Industries, St. Petersburg, FL), fiberoptic bronchoscope identification of the tracheal rings, chest x-ray, and a device called the SCOTI that detects the patency of the tracheal tube–tracheal lumen using a sonographic technique.^{103,104}

NPO Status and the Rapid-Sequence Induction. Induction of anesthesia in patients who have “full stomachs” or incompetent gastroesophageal sphincters can result in regurgitation and pulmonary aspiration. Individuals at risk include the morbidly obese, pregnant women, diabetics with gastroparesis, those who require emergency operations, patients with gastroesophageal reflux disease, and patients who have recently eaten. Individuals experiencing emotional stress have increased gastric acid secretions and are also at an increased risk for aspiration.¹⁰⁵ Threshold values of a pH < 2.5 or gastric volume >25 ml are widely accepted as placing the patient at risk of sequelae should aspiration occur. Although few cases occur in modern anesthetic practice, the consequences of developing an aspiration syndrome can be devastating; hence, all efforts to avoid its development should be made. Therapeutic interventions are directed toward maintaining NPO status and administering gastric antisecretory agents, including histamine-2 (H₂) blockers, prostaglandin E₁ analogs, and omeprazole. Common anesthetic practice dictates a policy of “nothing by mouth” orders for 8 hours prior to the induction of anesthesia. However, controversy exists over this guideline, and many centers allow clear liquids to be taken until hours before the operation unless delayed gastric emptying is a concern. H₂ blockers help maintain gastric pH above 2.5, thereby decreasing the severity of any chemical pneumonitis that may occur. Prostaglandin E₁ analogs (*i.e.*, misoprotol) act directly on gastric parietal cells to increase gastric pH, while omeprazole blocks the final step in the secretion of hydrochloric acid by parietal cells.¹⁰⁶ The use of metoclopramide (for its gastropropulsive effects) and nasogastric suction may reduce the volume of gastric content. The use of a nonparticulate antacid may decrease the acidity of any residual contents of the stomach by serving as a buffer. The combination of cimetidine and metoclopramide given to ambulatory patients during the preinduction phase is better than either drug alone for increasing gastric pH and decreasing gastric volume.¹⁰⁷

The technique of rapid-sequence induction is performed to gain control of the airway in the least amount of time after the ablation of protective airway reflexes with the induction of anesthesia. In the rapid-sequence technique, the administration of an intravenous anesthetic induction agent is immediately followed by a rapidly acting neuromuscular blocking drug. Direct laryngoscopy and intubation are performed as soon as muscle relaxation is confirmed. Cricoid pressure (Sellick’s maneuver) is applied by an assistant from the beginning of induction until confirmation of endotracheal tube placement. Cricoid pressure entails the downward displacement of the cricoid cartilage against the vertebral bodies (Fig. 23-23). In this manner, the lumen of the esophagus is ablated, while the completely circular nature of the cricoid cartilage maintains the tracheal lumen. Early cadaveric studies showed that correctly applied cricoid pressure was effective in preventing gastric fluids, under 100 cm H₂O pressure, from leaking into the pharynx. Cricoid pressure is contraindicated with active vomiting (risk of esophageal rupture), cervical spine fracture, and laryngeal fracture.

Figure 23-23. Cricoid pressure (Sellick’s maneuver) is applied to occlude the esophagus and prevent aspiration of gastric contents.

If during rapid-sequence induction there are difficulties in securing the airway and oxyhemoglobin desaturation occurs, gentle positive pressure ventilation may be used while maintaining cricoid pressure. This positive pressure should require <25 cm H₂O pressure. If more positive pressure is used, there is a risk of gastric distention

and regurgitation.

The Intubating Laryngeal Mask Airway. Blind, fiberoptic aided, stylet-guided, and laryngoscopy-directed intubation via the LMA has been widely reported in adults and children.^{76,108,109,110,111,112,113} and ¹¹⁴ There are several limitations to this procedure including the maximal size ETT that can be used, the minimal length of the ETT required to ensure that its cuff is within the larynx and not wedged between or above the vocal folds, and the difficulty in removing the LMA after intubation.^{76,115} In an effort to overcome these limitations, Brain introduced a version of the LMA with a large-diameter (13 mm id), short-length (14 cm) rigid stainless steel barrel curved to align the mask aperture to the glottic vestibule (Fig. 23-24).^{116,117} and ¹¹⁸

Figure 23-24. (A) The LMA-Fastrach; (B) The LMA-Fastrach used for intubation in a patient outside the operating room.

The mask incorporates a vertically oriented semirigid bar, fixed at the proximal end of the bowl aperture and positioned to sit beneath the epiglottis in the average adult. A handle at the proximal end of the barrel is used for insertion, repositioning, and removal. A secondary advantage of the handle is that the operator need never reach into the patient's mouth. This new device, the LMA-Fastrach, can accommodate up to an 8.0-mm id cuffed ETT, which can be inserted blindly or over a fiberoptic. The LMA-Fastrach is designed to be used with a straight, armored, silicone tracheal tube (Euromedics, Malaysia), although standard polyvinyl chloride tracheal tubes have been used.¹¹⁹ To date, the LMA-Fastrach has been distributed in adult sizes with cuffs equivalent to the size 3, 4, and 5 LMAs. Experience has suggested that most adults between 40 and 70 kg are best managed with a size 4 LMA-Fastrach, larger persons requiring the size 5. Pediatric sizes are not yet available.

The LMA-Fastrach is indicated for routine, elective intubation and for anticipated and unanticipated difficult intubation. Since it was designed to facilitate blind tracheal intubation, the presence of airway secretions, blood, or edema (e.g., from previous intubation attempts or trauma) does not interfere with its use. Because the design of the barrel is based upon the normal adult palate-to-glottis relationship, patients who are evaluated as being manageable with tracheal intubation based on external exam, but subsequently are found to have a high Cormack–Lehane score (due to lingual tonsil hyperplasia or cervical spine immobility, for example) should be successfully managed with the LMA-Fastrach.¹⁰⁰ In the largest trial of the LMA-Fastrach to date, ventilation was satisfactory in 95% and unsatisfactory in 1% of 500 uses, and 96% were intubated within three attempts (79.8% on first, 12.4% on second, 4% on third).¹²⁰ Patients who are assessed as grossly abnormal on preoperative airway exam may often still be managed with the LMA-Fastrach.¹²¹ The LMA-Fastrach has been demonstrated to be useful as a ventilatory and intubating device after failed rapid sequence intubation.¹¹⁹

The contraindications to the LMA-Fastrach are similar to those of the LMA. Since the goal of the LMA-Fastrach is tracheal intubation, it may prove useful for management of patients at moderate risk for gastroesophageal regurgitation and aspiration, or for high-risk patients on whom other techniques have failed.

The LMA-Fastrach is inserted with the head in a neutral position. It can be used in the unconscious or awake patient (with the use of topical anesthetics). The mask of the LMA-Fastrach is tested, deflated, and lubricated as described for the LMA. It is inserted into the mouth, with the handle held parallel to the chest, so the mask lies flat against the palate. Gentle pressure on the handle and barrel, toward the chin, reproduces the palatal pressure described for insertion of the LMA. A smooth backward rotation of the handle toward the top of the head seats the tip of the mask in the hypopharynx, posterior to the cricoid cartilage. Once seated, the LMA-Fastrach's mask is inflated via the pilot cuff. An ambu bag or anesthesia circuit is attached to the proximal end of the LMA-Fastrach barrel and ventilation is attempted. By using the LMA-Fastrach handle, the position of the device can be optimized by lateral and anterior–posterior manipulation. A seemingly common cause of airway obstruction is the downfolding of the epiglottis. This can be relieved with a smooth rotational movement of the inflated LMA-Fastrach out of the airway (6 cm along the axis of the insertion) and immediate re-placement.

After adequate ventilation is achieved, the ETT is advanced through the barrel. As the ETT exits the bowl aperture of the LMA-Fastrach, the semirigid elevating bar is pushed anteriorly, carrying the epiglottis out of the way of the airway. If positioned correctly, the ETT can freely enter the glottis.

Once intubation is achieved and confirmed (e.g., by auscultation or capnography), the ETT circuit adapter is removed and the LMA-Fastrach is withdrawn over the ETT. During this removal procedure, the ETT is stabilized by one of two methods. A silicone stabilizing rod can be held against the ETT as the LMA-Fastrach is retreated out of the mouth. The advantage of this technique is that the operator's hands do not have to enter the oral cavity. The disadvantage is that in the mid-removal position, the operator loses direct contact with the ETT. In the second technique, described by Rosenblatt and Murphy, a Magill forceps is used to hold the proximal tip of the ETT while the LMA-Fastrach is removed.¹¹⁹ In the mid-removal position, a finger is placed in the mouth to identify and stabilize the ETT, while the Magill forceps is removed and the LMA-Fastrach is fully retreated. This technique requires the hand to be placed in the mouth, but allows more control of the ETT.

Extubation of the Trachea

Though a wealth of literature is focused on the field of tracheal intubation, few reviews have well contemplated the area of extubation after completion of surgery, or prolonged ventilatory support.¹²² Indeed, the period of extubation may be far more treacherous than that of intubation (Table 23-8A).

| A. Causes of Ventilatory Compromise During Tracheal Extubation |
|--|
| Residual anesthesia |
| Excess external respiratory effort |
| Decreased respiratory effort |
| Decreased respiratory drive in response to CO ₂ |
| Decreased respiratory drive in response to O ₂ |
| Mechanical block of upper airway musculature |
| Mechanical gag and laryngeal reflex |
| Decreased threshold to laryngospasm |
| Residual airway edema |
| Vocal cord paralysis |
| Upper airway obstruction |
| Supraglottic edema with airway obstruction by the epiglottis |
| Subglottic edema with limited vocal fold abduction |
| Subglottic edema |
| Tracheomalacia (from long-standing tracheal intubation) |
| Brachycephalus |

| B. Complications of Tracheal Extubation |
|---|
| Respiratory drive failure |
| Hypoxia (e.g., desaturation) |
| Upper airway obstruction (e.g., edema, residual anesthesia) |
| Vocal fold-related obstruction (e.g., vocal cord paralysis) |
| Tracheal obstruction (e.g., subglottic edema) |
| Brachycephalus |
| Aspiration |
| Hyperinflation |
| Increased intracranial pressure |
| Increased pulmonary artery pressure |
| Increased pulmonary venous pressure (e.g., after pulmonary resection) |
| Increased ocular pressure |
| Increased abdominal wall pressure (e.g., risk of venous thrombosis) |

Table 23-8. TRACHEAL EXTUBATION

Routine Extubation. Extubation of the trachea must not be considered a benign procedure. It is not simply the elimination or reversal of tracheal intubation. Extubation is fraught with its own set of potential complications (Table 23-8B). Appropriately trained personnel and equipment should be immediately available at the time of extubation. This may range from a postanesthetic care unit nurse or respiratory therapist with a set of laryngoscopes to a surgeon prepared to perform an emergency tracheostomy.

Most adult patients are extubated after the return of consciousness and spontaneous respiration, the resolution of neuromuscular block, and the ability to follow simple commands (Table 23-9). The patient is asked to open the mouth and a suction catheter is used to remove excessive secretions and / or blood. The airway pressure is allowed to rise to 5–15 cm of H₂O to allow for a “passive cough,” and the endotracheal tube is removed after the cuff (if present) is deflated.¹²² If coughing or straining is

contraindicated or hazardous (e.g., increased intracranial pressure), extubation may be performed while the patient is in a surgical plane of anesthesia. In patients at risk for gastric contents aspiration (e.g., full stomach) or upper airway obstruction, the clinician needs to assess the relative risk of each potential morbidity. For the latter risk, and possibly the former, a maneuver has been described in which an LMA is placed posterior to the ETT, which is then removed. This obviates the problem of upper airway obstruction, and may offer some protection against regurgitation and aspiration.^{123,124} and ¹²⁵ Because of the risks of atelectasis and diffusion hypoxia, the ability to administer oxygen should be available at the time of extubation.

| Subjective Clinical Criteria: | |
|---|--|
| Follows commands | |
| Clear oropharynx/hypopharynx (e.g., no active bleeding, secretions cleared) | |
| Intact gag reflex | |
| Sustained head lift for 5 seconds, sustained hand grasp | |
| Adequate pain control | |
| Minimal end expiratory concentration of inhaled anesthetics | |
| Objective Criteria: | |
| Vital Capacity: ≥ 10 ml/kg | |
| Peak voluntary negative inspiratory pressure: >20 cm H ₂ O | |
| Tidal Volume >6 cc/kg | |
| Sustained tetanic contraction (5 sec) | |
| T ₁ /T ₄ ratio >0.7 | |
| Alveolar-Arterial Pao ₂ gradient (on Pao ₂ of 1.0): <350 mm Hg* | |
| Dead Space to Tidal Volume ratio: ≤ 0.6 * | |

*Used during weaning from mechanical ventilation in the intensive care setting.

Table 23-9. CRITERIA FOR ROUTINE “AWAKE” EXTUBATION

Difficult Extubation. The patient who presented as a difficult airway at the time of anesthetic induction must be considered a difficult airway at the time of extubation, even when corrective surgery was performed in the interim (e.g., uvulopharyngoplasty in the obstructive sleep apnea patient).

As a cause of ventilatory compromise, laryngospasm deserves special attention because of its prevalence in children and because it accounts for 23% of all critical postoperative respiratory events in adults.¹²² Laryngospasm may be triggered by respiratory secretions, vomitus, or blood in the airway; pain in any part of the body; and pelvic or abdominal visceral stimulation. The cause of airway obstruction during laryngospasm is the contraction of the lateral cricoarytenoids, the thyroarytenoid, and the cricothyroid muscles. Management of laryngospasm consists of the immediate removal of the offending stimulus (if identifiable), administration of oxygen with continuous positive airway pressure, and, if other maneuvers are unsuccessful, the use of a small dose of short-acting muscle relaxants.¹²²

Negative-pressure pulmonary edema may result from any airway obstruction in a patient who continues to have a voluntary respiratory effort. Negative intrathoracic pressure is transmitted to the alveoli, which are unable to expand owing to the more proximal obstruction. Fluid is entrained from the pulmonary capillary bed. Negative-pressure pulmonary edema is treated as any other form of noncardiogenic edema.

IDENTIFICATION OF PATIENTS AT RISK AT EXTUBATION. A number of well known clinical situations may place patients at increased risk for complication at the time of extubation. [Table 23-10](#) lists the risk factors for extubation complications. However, the clinician should evaluate every patient in terms of potential problems, in the same manner that they are prepared for the unanticipated difficult intubation.

| Paradoxical vocal cord motion (preexisting) | Directly related mechanism |
|---|--|
| Dental surgery | 4,5% recurrent laryngeal nerve injury |
| Laryngospasm (Boggs ¹²²) | Larynx edema |
| Uvulopharyngoplasty | Endotracheal tube (long-standing patient) |
| Obstructive sleep apnea syndrome (unrecognized) | Edema, laryngospasm, especially with therapy |
| Cardiac arrhythmias | Edema and airway obstruction |
| Neuroleptic analgesia | Minimal hemolysis, glottic edema, severe pain |
| Cervical vertebrae decompression | Laryngeal fracture, isolated level of consciousness, in- |
| Talbot's disease | paralysis for mandibular/masseteric atonia |
| Rheumatoid arthritis | Supraglottic and hypopharyngeal edema |
| Graves' disease | |
| Angiodysplasia | Laryngotracheal narrowing |
| Angiodysplasia | Laryngotracheal narrowing |
| Angiodysplasia | Laryngotracheal narrowing |
| Hypertrophic osteodystrophy | Laryngotracheal narrowing |
| Hypertrophic osteodystrophy | Laryngotracheal narrowing |
| Hypertrophic osteodystrophy | Laryngotracheal narrowing |
| Inadequate airway protective reflexes | Aspiration risk |

*Residual anesthetic or preoperative medications (including alcohol and illicit drugs), central sleep apnea, central hypoventilation syndrome, Guillain-Barre syndrome, myasthenia gravis, botulism, thoracic distal deformity, severe pain (with diaphragmatic spasm), morbid obesity, severe chronic obstructive pulmonary disease.
†Hypoxemia, ventilation-perfusion mismatch, bronchospasm or intrapulmonary shunting, increased oxygen consumption, severe anemia, impaired alveolar oxygen diffusion.

Table 23-10. CLINICAL SITUATIONS PRESENTING INCREASED RISK FOR COMPLICATIONS AT EXTUBATION¹²²

APPROACH TO THE DIFFICULT EXTUBATION. When there is a suspicion that a patient may have difficulty with oxygenation or ventilation after tracheal extubation, the clinician may choose from a number of management strategies. These may range from the preparation of standby reintubation equipment to the active establishment of a route or guide for reintubation and / or oxygenation. When the patient's intubation is without difficulty and there is no substantial reason to believe that an interim insult to the airway has occurred, extubation may be accomplished in a routine fashion, with a heightened state of readiness for reintubation. When there has been difficulty with intubation or there is a clinical suspicion that reintubation will be difficult, extubation over a guiding stylet may be a successful technique. Any number of devices can be used as a stylet ([Table 23-11](#)).

| Device | Advantage | Disadvantage |
|-------------------------------------|---|---------------------------------------|
| Fiberoptic bronchoscope | Visualize structures Oxygen can be insufflated through working channel | ETT cannot be exchanged |
| Eschmann catheter or similar device | Inexpensive, semi-rigid | Cannot visualize or oxygenate |
| Exchange/ventilatory catheter | Oxygen can be insufflated through central lumen | Cannot visualize, may be too flexible |

Table 23-11. DEVICES USED AS EXTUBATING STYLETS

A popular test to predict airway patency after extubation is the detection of a leak upon deflation of the ETT cuff.¹²⁶ Recent investigations have cast doubt on the reliability of this test. In this study no patient with a positive leak test (no leak around the ETT cuff) developed problems after extubation.

When using an FOB, the tracheal structures can be observed during the removal of the ETT. If extubation is tolerated, the FOB can be slowly withdrawn into the subglottic region. If secretions do not obstruct the objective lens, the vocal folds and other structures may be visualize and evaluated.

A number of obturators are available for use in trial extubation (where they may be left in place in the airway for extended periods) or endotracheal tube exchange (e.g., failure of the ETT cuff).¹²⁷ It is beyond the scope of this text to describe all the commercially available catheters. The Cook airway exchange catheters (Cook Critical Care, Bloomington, IN) are manufactured with external diameters of 2.7, 3.7, 4.7, and 6.33 mm ([Fig. 23-25a](#)). The smallest diameter catheter (which can fit within a 3.0-mm id ETT) is 45 cm long, whereas the others are 83 cm in length). They all have a central lumen and rounded, atraumatic ends. The catheters are graduated from the distal end. The proximal end is fitted with either a 15-mm or a Luer-lock Rapi-Fit adapter, which can be quickly removed and replaced for ETT removal or change. With these adapters an oxygen source can be used to provide insufflated or jet-ventilated oxygen if the patient fails extubation and / or if reintubation over the catheter

fails.

Figure 23-25. (A) The Cook airway exchange catheter fitted with a Rapifit Luer-lock adapter (Cook Critical Care, Bloomington, IN). A 15-mm Rapifit adapter for attachment to an anesthesia circuit or ambu bag is also available. (B) The Cardiomed endotracheal ventilation catheter.

The Patil two-part intubation catheter (Cook Critical Care, Bloomington, IN) is a 6.0-mm od (outer diameter), 3.4-mm id, 63-cm catheter composed of two interlocking lengths. One half can be used as a malleable stylet for blind intubation or intubation through an LMA. The second length, and / or a Rapi-fit adapter, can be added for use in oxygen insufflation or as an ETT exchange catheter.

The Cardiomed endotracheal ventilation catheter (Gromley, Ontario, Canada) designed by Richard Cooper, M.D., a Canadian anesthesiologist, is 85 cm in length, and has inner and outer diameters of 3 and 4 mm, respectively. An integral Luer-lock fitting adapter is found at the proximal end, whereas the blunted distal end incorporates eight helically arranged side holes in addition to the distal end hole (Fig. 23-25b). The arrangement of these holes is meant to center the catheter during oxygen insufflation, and prevent traumatic “whipping” within the trachea. The use of this catheter for ETT exchange, tracheal reintubation, oxygen insufflation, jet ventilation, and end-tidal CO₂ detection after extubation has been documented by the inventor.¹²²

THE DIFFICULT AIRWAY

The Difficult Airway Algorithm

In 1993, the American Society of Anesthesiologists' (ASA) Task Force on the Difficult Airway published an algorithm that has become a staple of management for clinicians (Fig. 23-26).¹²⁸ The ASA defines the difficult airway as the situation in which the “conventionally trained anesthesiologist experiences difficulty with mask ventilation (e.g., the unassisted anesthesiologist . . . unable . . . to maintain S_pO₂ greater than 90% using 100% oxygen), difficulty with tracheal intubation (e.g., unable to properly place an ETT with conventional laryngoscopy . . . with more than three attempts or more than 10 minutes), or both.” Based on available data, the incidence of failed intubation is 0.05–0.35%, whereas the incidence of failed intubation / inability to perform mask ventilation is 0.01–0.03%.^{11,129,130}

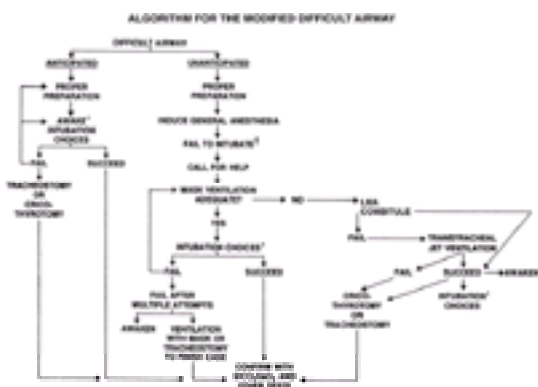

Figure 23-26. Algorithm for managing the patient with a difficult airway. (Modified from the algorithm prepared by the American Society of Anesthesiologists' Task Force on Airway Management^{94,128}.)

When writing in 1993, the Task Force was not able to anticipate the advent of new devices and techniques that would alter the basic nature of airway management. The addition of such devices as the LMA, LMA-Fastrach, COPA, and lighted stylet to routine as well as difficult airway management armamentarium has required a re-evaluation of the algorithm.^{58,131}

The ASA algorithm stands as a model for the approach to the difficult airway for nurse anesthetists, emergency medicine physicians, and prehospital personnel, as well as for anesthesiologists. Although the algorithm largely speaks for itself, its salient features are discussed here.

Entry into the algorithm is with the evaluation of the airway. Although there is some debate as to the value of particular evaluation methods and indices, the clinician must use all available data to reach a general impression as to the difficulty of the patient's airway in terms of laryngoscopy and intubation, supraglottic ventilation techniques, and ability of the patient to cooperate with awake procedures. Incorporated into this process are the history regarding previous airway management and other airway-related symptoms (e.g., snoring), the findings on physical exam, and the clinician's personal level of comfort with the situation. Paramount to the decision process is the patient's relative aspiration risk—when there is no or minimal aspiration risk (absence of recent ingestion, obesity, gastroesophageal reflux symptoms, ascites, pregnancy, excessive opioid administration). Many difficult airways may be managed with anesthesia mask or LMA ventilation, either in lieu of or during tracheal intubation or tracheostomy. If there is a significant risk of gastric regurgitation or foreign body aspiration, the patient judged to be a difficult intubation should be managed in an awake state whenever possible. The exception to this is the patient who is unable to cooperate owing to mental retardation, intoxication, anxiety, depressed level of consciousness, or age.⁹⁴

Preparation of the patient for awake intubation is discussed below. In most instances, awake intubation is successful if approached with care and patience. When awake intubation fails, the clinician has a number of options. First, one can consider cancellation of the surgical case. In this situation, specialized equipment or personnel can be assembled for a return to the operating room. Where cancellation is not an option, regional anesthetic techniques can be considered, or, if demanded by the situation, a surgical airway may be called for.

The decision to proceed with regional anesthesia because the airway has been assessed, or proven to be difficult to manage, must be considered in terms of risks and benefits (Table 23-12).

| May Consider RA | Should Not Consider RA |
|--|--|
| Superficial surgery | Cavity-invasive surgery |
| Minimal sedation needed | Significant sedation needed |
| Anesthetic may be provided with local infiltration | Extensive neuroaxial local anesthetic administration will be required, or risk of intravascular injection/absorption is high |
| Access to the airway is good | Access to the airway is poor |
| Surgery can be halted at any time | Surgery cannot be stopped once started |

Table 23-12. FACTORS TO CONSIDER IN PROCEEDING WITH REGIONAL ANESTHESIA (RA) AFTER THE PATIENT HAS BEEN JUDGED TO HAVE A DIFFICULT AIRWAY

The algorithm truly becomes useful in the unanticipated difficult airway. When induction agents (with or without muscle relaxants) have been given and the airway cannot be controlled, vital management decisions must be made rapidly. This section of the algorithm may also be applied to the uncooperative patient who is recognized to have a difficult airway. Typically, the clinician has attempted direct laryngoscopy and intubation after successful or failed anesthesia mask ventilation (unless a rapid-sequence induction is being performed). Even if the patient's oxygen saturation remains adequate throughout these efforts, the number of laryngoscopy attempts should be limited to three. As discussed earlier, significant soft tissue trauma can result from multiple laryngoscopies, thereby worsening the situation. First, mask ventilation should be reinstated if it had been successful previously. The clinician may then turn to the most convenient and / or appropriate technique for establishing tracheal intubation, if needed. This might include, but is not limited to, blind oral or nasal intubation; intubation facilitated by a fiberoptic bronchoscope, LMA, LMA-Fastrach, bougie, lighted stylet, or a retrograde wire; or a surgical airway. (The most widely regarded of these procedures will be discussed with clinical scenarios, below.) When mask ventilation fails, the algorithm suggests two noninvasive, supraglottic ventilation and oxygenation techniques (the LMA and Combitube), a minimally invasive technique (transtracheal jet ventilation), or a surgical airway. At this point, the patient can be awakened, various intubation techniques can be attempted in a stable situation, or a surgical airway can be performed if needed.

Awake Airway Management

Awake airway management remains a mainstay of the ASA's Difficult Airway Algorithm. If, after a thorough exam of the airway and review of previous anesthetics or other emergency airway events, the ability to safely control ventilation and oxygenation, without the risk of gastric content aspiration is in doubt, awake management is indicated. Airway management is not synonymous with intubation: anesthesia mask, LMA, COPA, tracheal esophageal Combitube, and other devices may provide alternatives to tracheal intubation, depending on the clinical situation. Awake intubation provides many advantages over the anesthetic state, including maintenance of spontaneous ventilation in the event that the airway cannot be secured rapidly, increased size and patency of the pharynx, relative forward placement of the base of the tongue, posterior placement of the larynx, and patency of the retropalatal space.^{132,133} The effect of sedatives and general anesthetics on airway patency may be secondary to direct effects on motoneurons and on the reticular activating system.¹³⁴ The sleep apnea patient may be particularly prone to obstruction with minimal sedation. Additionally, the awake state confers some maintenance of upper and lower esophageal sphincter tone, thus reducing the risk of reflux. In the event that reflux occurs, the patient can close the glottis and / or expel aspirated foreign bodies by cough to the extent that these reflexes have not been obtunded by local anesthesia.¹³⁵ Lastly, patients at risk for neurologic sequelae (e.g., patients with unstable cervical spine pathology) may undergo sensory-motor monitoring after tracheal intubation. In an emergent situation, there may be cautions (e.g., cardiovascular stimulation in the presence of cardiac ischemia or ischemic risk, bronchospasm, increased intraocular pressure, increased intracranial pressure)¹³⁶ but no absolute contraindications to awake intubation. Contraindications to elective awake intubation include patient refusal or inability to cooperate (e.g., child, profound mental retardation, dementia, intoxication) or allergy to local anesthetics.

Once the clinician has decided to proceed with awake airway management, the patient must be prepared both physically and psychologically. Most adult patients will appreciate an explanation of the need for an awake airway exam and will be more cooperative once they realize the importance of and rationale for any uncomfortable procedures. The full extent of the procedures need not be explained in total, or all at once. The clinician might explain that he or she is going to "examine" the airway in order to plan a course of action. This can include nasal endoscopy. Once the airway has been prepared and examined, patients will realize that they should experience no further discomfort during the intubation, which may then be discussed.

Apart from appropriate explanation, medication can also be used to allay anxiety. If sedatives are to be used, the clinician must keep in mind that producing obstruction or apnea in the difficult airway patient can be devastating and an overly sedated patient may not be able to protect the airway from regurgitated gastric contents, or cooperate with procedures. Small doses of benzodiazepines (diazepam, midazolam, lorazepam) are commonly used to alleviate anxiety without producing significant respiratory depression. These drugs may be given in iv or oral forms (when available) and may be reversed with specific antagonists (e.g., flumazenil). Opioid receptor agonists (e.g., fentanyl, alfentanil, remifentanil) can also be used in small, titrated doses for their sedative and antitussive effects, although caution must be exercised. A specific antagonist (e.g., naloxone) should always be immediately available. Ketamine and droperidol have also been popular among clinicians.

Administration of antisialagogues is important to the success of awake intubation techniques. As will be discussed below, clearing of airway secretions is essential to the use of indirect optical instruments (e.g., fiberoptic bronchoscope, rigid fiberoptic laryngoscope) because small amounts of any liquid can obscure the objective lens. The commonly used drugs atropine (0.5–1 mg im or iv) and glycopyrrolate (0.2–0.4 mg, im or iv) have other significant effects: by reducing saliva production, these drugs increase the effectiveness of topically applied local anesthetics by removing a barrier to mucosal contact and reducing drug dilution. Vasoconstriction of the nasal passages is needed if there is to be instrumentation of this part of the airway. If the patient is at risk for gastric regurgitation and aspiration, prophylactic measures should be undertaken. Often, it is also prudent to supply supplemental oxygen to the patient by nasal cannula (which can be placed over the nose or mouth).

Local anesthetics are a cornerstone of awake airway control techniques. The airway, from the base of the tongue to the bronchi, comprises an undeniably sensitive series of tissues. Topical anesthesia and injected nerve block techniques have been developed to blunt the protective airway reflexes as well as to provide analgesia. As is well known to the anesthetic practitioner, local anesthetics are both effective and potentially dangerous drugs. The clinician should have a thorough understanding of the mechanism of action, metabolism, toxicities, and acceptable cumulative doses of the drugs that he or she chooses to employ in the airway. Because much of the agent used will be within the tracheal-bronchial tree and will travel to the alveoli, there will be significant and rapid intravascular absorption.

Despite the availability of myriad local anesthetics, only those most commonly used in airway preparation will be discussed here.

Among otolaryngologists, cocaine is a popular topical agent. Not only is it a highly effective local anesthetic, but also it is the only local anesthetic that is a potent vasoconstrictor. It is commonly available in a 4% solution. The total dose applied to the mucosa should not exceed 200 mg in the adult. Cocaine should not be used in patients with a known cocaine hypersensitivity, hypertension, ischemic heart disease, pre-eclampsia, or those taking monoamine oxidase inhibitors.¹³⁷ Since cocaine is metabolized by pseudocholinesterase, it is contraindicated in patients deficient in this enzyme.

Lidocaine, an amide local anesthetic, is available in a wide variety of preparations and doses (Table 23-13). Topically applied, peak onset is within 15 minutes. Toxic plasma levels are not impossible to achieve but are not commonly reported in airway management.

| Preparation | Doses |
|-----------------------------|------------|
| Injectable/topical solution | 1%, 2%, 4% |
| Viscous solution | 1%, 2% |
| Ointment | 1%, 5% |
| Aerosol | 10% |

Table 23-13. AVAILABLE LIDOCAINE PREPARATIONS

Tetracaine is an amide local anesthetic with a longer duration of action than either cocaine or lidocaine. Solutions of 0.5%, 1%, and 2% are available. Absorption of this drug from the respiratory and GI tracts is rapid, and toxicity after nebulized application has been reported with doses as low as 40 mg, although the acceptable safe dose in adults is 100 mg.¹³⁸

Benzocaine is popular among some clinicians because of its very rapid onset (<1 minute) and short duration (~10 minutes). It is available in 10%, 15%, and 20% solutions. It has been combined with tetracaine (Hurricane[®], Beutlich Pharmaceuticals) to prolong the duration of action. A 0.5-second aerosol administration of Hurricane delivers 30 mg of benzocaine, the toxic dose being 100 mg. Another common preparation is Cetacaine spray, which combines benzocaine with tetracaine, butyl aminobenzoate, benzalkonium chloride, and cetyltrimethylethyl ammonium bromide. Benzocaine may produce methemoglobinemia, which is treated by the administration of methylene blue.

There are three anatomic areas to which the clinician directs local anesthetic therapy: the nasal cavity / nasopharynx, the pharynx / base of tongue, and the larynx / trachea. The nasal cavity is innervated by the greater and lesser palatine nerves (innervating the nasal turbinates and most of the nasal septum) and the anterior ethmoid nerve (innervating the nares and anterior third of the nasal septum). The two palatine nerves arise from the sphenopalatine ganglion, located posterior to the middle turbinate. Two techniques for nerve block have been described. The ganglion can be approached through a noninvasive nasal approach¹³⁹ cotton-tipped applicators soaked in local anesthetic are passed along the upper border of the middle turbinate until the posterior wall of the nasopharynx is reached. They are left in place for 5–10 minutes. In the oral approach, a needle is introduced into the greater palatine foramen, which can be palpated in the posterior lateral aspect of the hard palate, 1 cm medial to the second and third maxillary molars. Anesthetic solution (1–2 ml) is injected with a spinal needle inserted in a superior / posterior direction at a depth of 2–3 cm. Care must be taken not to inject into the sphenopalatine artery. The anterior ethmoid nerve can be blocked by cotton-tipped applicators soaked in local anesthetic placed along the dorsal surface of the nose until the anterior cribriform plate is reached. The applicator is left in place for 5–10 minutes.

The oropharynx is innervated by branches of the vagus, facial, and glossopharyngeal nerves. The glossopharyngeal nerve (GPN) travels anteriorly along the lateral surface of the pharynx, its three branches supplying sensory innervation to the posterior third of the tongue, the vallecula, the anterior surface of the epiglottis (lingual branch), the walls of the pharynx (pharyngeal branch), and the tonsils (tonsillar branch). A wide variety of techniques may be used to anesthetize this part of the airway. The simplest techniques involve aerosolized local anesthetic solution, or a voluntary “swish and swallow.” As long as the clinician has developed a plan to anesthetize all relevant structures, has allowed enough time for drying agents to work, and remains continually cognizant of the total dose of local anesthetics administered, most patients will be adequately anesthetized in this way.

Some patients may require a GPN block, especially when topical techniques do not adequately block the gag reflex. The branches of this nerve are most easily accessed as they transverse the palatoglossal folds. These folds are seen as soft tissue ridges which extend from the posterior aspect of the soft palate to the base of the tongue, bilaterally (Fig. 23-27).

Figure 23-27. The palatoglossal arch (arrow) is a soft tissue fold which is a continuation from the posterior edge of the soft palate to the base of the tongue. A local anesthetic-soaked swab placed in the gutter along the base of the tongue is left in contact with the fold for 5–10 minutes.

A noninvasive technique employs anesthetic-soaked cotton-tip applicators which are positioned against the inferiormost aspect of the folds, being left in place for 5–10 minutes. When the noninvasive technique proves inadequate, local anesthetic can be injected. Standing on the side contralateral to the side to be blocked, the operator displaces the extended tongue to the contralateral side and a 25G spinal needle is inserted into the membrane near the floor of the mouth. An aspiration test is performed. If air is aspirated, the needle has passed through-and-through the membrane. If blood is aspirated, the needle is redirected more medially. The lingual branch is most readily blocked in this manner, but retrograde tracking of the injectate has also been demonstrated.¹³⁵ Though providing a reliable block, this technique is reported to be painful and may result in a bothersome persistent hematoma.¹³⁹ A posterior approach to the GPN has been described in the otolaryngologic literature (for tonsillectomy). It may be difficult to visualize the site of needle insertion, which is behind the palatopharyngeal arch where the nerve is in close proximity to the carotid artery. Because of the risk for arterial injection and bleeding, the technique will not be described here; however, the reader is referred to a more authoritative text.¹⁴⁰

The internal branch of the superior laryngeal nerve (SLN), which is a branch of the vagus nerve, provides sensory innervation to the base of the tongue, epiglottis, aryepiglottic folds, and arytenoids. The branch originates from the SLN lateral to the cornu of the hyoid bone. It then pierces the thyrohyoid membrane and travels under the mucosa in the pyriform recess. The remaining portion of the SLN, the external branch, supplies motor innervation to the cricothyroid muscle. Several blocks of this nerve have been described. In many instances topical application of anesthetics in the oral cavity will provide adequate analgesia. An external block is performed with the patient supine with the head extended and the clinician standing on the side ipsilateral to the nerve to be blocked. Beneath the angle of the mandible the clinician identifies the superior cornu of the hyoid bone (Fig. 23-28). Using one hand, medially directed pressure is applied to the contralateral hyoid cornu, displacing the ipsilateral hyoid cornu toward the clinician. Caution must be taken to locate the carotid artery and displace it if necessary. The needle can be inserted directly over the hyoid cornu and then “walked” off the cartilage in an anterior-caudad direction until it can be passed through the ligament to a depth of 1–2 cm (Fig. 23-29A). Before the injection of local anesthetic, an aspiration test should be performed to ensure that one has not entered the pharynx or a vascular structure. Local anesthetic with epinephrine (1.5–2 ml) is injected in the space between the thyrohyoid membrane and the pharyngeal mucosa. The superior laryngeal nerve can also be blocked with a noninvasive block internal technique. The patient is asked to open the mouth widely, and the tongue is grasped using a gauze pad or tongue blade. A right-angle forceps (e.g., Jackson-Krause forceps) with anesthetic-soaked cotton swabs is slid over the lateral tongue and into the pyriform sinuses bilaterally. The cotton swabs are held in place for 5 minutes.

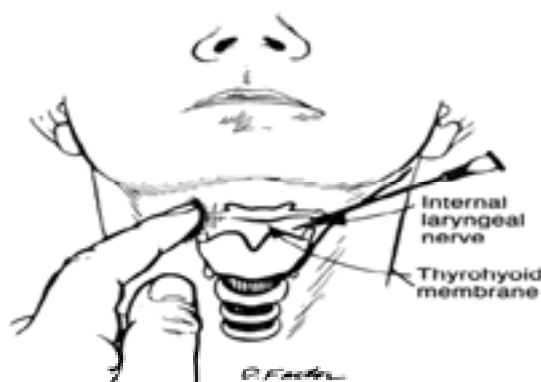

Figure 23-28. When a superior laryngeal nerve block is performed, pressure is applied to the contralateral greater cornu of the hyoid to facilitate identification of anatomic landmarks. The needle is inserted at the level of the thyrohyoid membrane just inferior to the greater cornu of the thyroid cartilage.

Sensory innervation of the vocal folds and the trachea is provided by the recurrent laryngeal nerve. Transtracheal injection of local anesthetic can easily be performed

to produce adequate analgesia, and the technique is described in detail below (see Retrograde Intubation) ([Fig. 23-29B](#)). Lidocaine, 4 ml of 2% or 4% solution, is injected.

Figure 23-29. (A) Superior laryngeal nerve block; (B) transtracheal aspiration and injection of local anesthetic (note bubble of aspirated tracheal air).

An effective and noninvasive technique of tracheal and vocal cord topical analgesia utilizes the working channel of the fiberoptic bronchoscope. A disadvantage of this technique is that solutions leaving the working channel can obscure the objective lens. This can be overcome by use of an epidural catheter, inserted through the working channel, as described by Ovassapian.¹⁴¹ Not only does this prevent the obscuring of the view, but also it allows specific “aiming” of the anesthetic stream.

Clinical Difficult Airway Scenarios

The clinician approaching the patient with a difficult airway has a vast armamentarium of techniques and instruments that can be applied to securing and maintaining oxygenation and ventilation. Although this array can be confusing, textbook authors cannot dictate specific approaches in every situation;¹⁴² moreover, the variability of patient presentation makes specific recommendations difficult. Thus, in order to discuss management, the following section presents a number of brief clinical scenarios and the author's own approach. The major alternative airway management techniques are discussed in this manner. All the clinical cases described herein have been managed by the author or a colleague. Other techniques that might be applied in each situation are also discussed, together with the author's own “decision tree” regarding their applicability. In these cases, as in actual practice, the first technique applied may not have been the best one. The principle of flexibility (and a keen eye to the need to change course quickly) will be emphasized repeatedly. In view of the critical importance of the act of airway control, the clinician must be prepared to alter his or her approach as the situation demands.

Case 1: Flexible Fiberoptic-Aided Intubation

A 50-year-old man with symptomatic cervical vertebrae disk herniation presents for disk resection and spinal fixation. He has a history of tobacco use, alcohol consumption, and gastroesophageal reflux. In the preoperative holding area 0.4 mg of glycopyrrolate is administered. Fifteen minutes later, when the patient states that his oral secretions are minimized, topical anesthesia is administered to the airway. The patient receives 4 mg of intravenous midazolam. An intubating oral airway is placed without eliciting a gag reflex and a flexible fiberoptic bronchoscope is advanced into the airway. The vocal ligaments are visualized, and 4 ml of 4% lidocaine solution is injected through the fiberscope's working channel, being seen to bathe the laryngeal and sublaryngeal structures. The distal end of the fiberscope is advanced into the larynx, and a 7.0-id endotracheal tube, which had been threaded onto the fiberscope's insertion shaft, is advanced into the trachea. The fiberscope is removed while the structures of the carina, trachea, and, finally, the tracheal tube are observed. The anesthesia circuit is attached to the tracheal tube and a steady output of carbon dioxide is detected by capnography. A brief sensory and motor neurologic exam is performed by the attending surgeon and general anesthesia is induced.

Use of the Fiberoptic Bronchoscope in Airway Management. The fiberoptic bronchoscope (FOB) is a ubiquitous instrument in anesthesia, being available to 99% of surveyed active ASA members.¹⁴² The technique of fiberoptic-aided intubation was first performed using a choledochoscope in a patient with Still's disease.¹⁴³ By the late 1980s it was recognized that the use of the flexible FOB represented such a great advancement in the management of the patient with a difficult airway that experts stated that no anesthesiologist could afford not to be facile with this technique.¹⁴⁴ It is now generally accepted that for a variety of clinical situations, the FOB is a critical tool in the armamentarium of the anesthesiologist dealing with the awake or unconscious patient who is, or appears to be, difficult to intubate.¹⁴⁵ The FOB has proven to be the most versatile tool available in this regard.¹⁴¹

There is no true or firm indication for FOB-aided intubation, as there might be with direct laryngoscopy (e.g., rapid-sequence induction for the full-stomach patient). There are, however, many clinical situations where the FOB can be of unparalleled aid in securing the airway, especially if the clinician has made an effort to master the necessary skills by using it in routine intubations.¹⁴¹ These include anticipated difficult intubation due to historical or physical exam findings, unanticipated difficult intubation (where other techniques have failed), lower and upper airway obstruction, unstable or fixed cervical spine disease, mass effect in the upper or lower airways, dental risk or damage, and awake intubation.¹⁴¹ Unlike the other devices used to intubate the trachea, the FOB can also serve to visualize structures below the level of the vocal folds. For example, it can identify the placement of the tracheal tube or aid in placement of a double lumen tracheal tube. It may be helpful in diagnosis within the trachea and bronchial tree, or in pulmonary toilet ([Fig. 23-30](#)).

Figure 23-30. The fiberoptic bronchoscope may be useful for diagnosis and therapy below the level of the vocal ligaments including bronchial segments exam and toilet (see [Fig. 23-3](#)). (A) Laryngeal web; (B) bronchial tumor.

Contraindications to FOB-aided intubation are relative, and revolve about the limitations of the device ([Table 23-14](#)).

-
- Hypoxia
 - Heavy airway secretions not relieved with suction or antisialagogues
 - Bleeding from the upper or lower airway not relieved with suction
 - Local anesthetic allergy (for awake attempts)
 - Inability to cooperate (for awake attempts)
-

Table 23-14. CONTRAINDICATIONS TO FIBEROPTIC BRONCHOSCOPY

Because the optical elements are small (the objective lens is typically 2 mm in diameter or smaller), minute amounts of airway secretions, blood, or traumatic debris can hinder visualization. Care must be taken to remove these obstacles from the airway beforehand: application of intramuscular or intravenous antisialagogues (e.g., glycopyrrolate, 0.2–0.4 mg; atropine, 0.5–1 mg) will produce a drying effect within 15 minutes, but caution should be taken in patients who may not be able to tolerate an increase in heart rate. Vasoconstriction of the nose using topical oxymetazoline, phenylephrine, or cocaine reduces the chances of bleeding should this route be chosen. If an awake intubation is planned using the FOB, the patient must be able to cooperate—a “quiet” airway, with little motion of the head, neck, tongue, and larynx, is vital to success. Finally, because FOB-aided intubation of the trachea can require significant time, especially if the clinician is not facile with the device, hypoxia or impending hypoxia is a contraindication, and a more rapid method of securing an airway (e.g., LMA or surgical airway) should be considered.

Elements of the Fiberoptic Bronchoscope. The FOB is a fragile device with optical and nonoptical elements. The fundamental element consists of a glass-fiber bundle. Each fiber is 8–12 μm in diameter, and is coated with a secondary glass layer, the cladding. The cladding aids in maintaining the image within each fiber as the light is reflected off the sidewall at a rate of 10,000 times per meter as it moves from the objective lens to the eyepiece lens in the operator’s handle. The typical intubating FOB has 10,000–25,000 such fibers encased in a 60-cm, water-impermeable insertion cord, marked every 10 cm. Though the fibers are allowed to rotate over each other throughout the length of the cord, they are fused together at the two ends in a coherent pattern; that is, the arrangement of the fibers at the eyepiece end is identical to the arrangement at the objective lens, where a diopter ring allows focusing. Therefore, one might envision that the image before the objective lens (i.e., the objective) is divided into 10,000 individual and unique pictures, which independently travel down an unwieldy cord, to be reassembled in front of the eyepiece lens. Broken fibers, which may occur because of bending of the insertion cord, entrapping the cord in other equipment, and dropping the FOB, are readily apparent and are generally no more than a nuisance until the number of broken fibers interferes with the visual field.

The insertion cord also contains a working channel: a lumen, up to 2 mm in diameter, which travels from the distal tip to the handle. It can be used for applying suction, or oxygen, and instilling lavaging fluids or drugs (e.g., local anesthetics). There is one report of gastric rupture attributed to the insufflation of oxygen through the working channel when the FOB was within the esophagus.¹⁴⁶ In general, FOBs <2 mm in external diameter (e.g., pediatric) do not have a working channel.

Two wires traveling from a lever in the handle down the length of the insertion cord control movement of the distal tip in the sagittal plane. The entire insertion cord is protected by a metal “wrap” until the level of the distal tip, which is hinged for movement. Coronal plane movement is accomplished by a combined use of the control lever and rotation of the entire FOB from handle to distal end. Because the fibers are able to move over one another, except for where they are fused at the extreme ends of the optic cord, rotational control is maximized by reducing any curves in the FOB shaft (Fig. 23-31).

Figure 23-31. Handling of the fiberoptic bronchoscope. (A) The handle is held in the nondominant hand with the tip of thumb over the sagittal plane control lever. The index finger can be used to control the working channel (e.g., suction, oxygen insufflation). The dominant hand is used for fine manipulation at the distal end. (B) The operator’s two hands should be kept maximally apart so as to keep the insertion shaft as straight as possible, maximizing coronal plane rotational control. (C) Curves introduced along the shaft reduce coronal plane rotational control.

The final element of the FOB is the light source. Illumination of the objective is provided by one or two noncoherent bundles of glass fibers which transmit light from the handle to the distal tip. The light is provided either by a “universal” cord which emerges from the handle and is inserted into a medical-grade endoscopic light source, or may be provided by a battery-operated light source on the handle.

Preparation of the Fiberoptic Bronchoscope. When approaching the FOB-aided intubation, one must ensure that the device is in working order. A series of inspections are made, as listed in Table 23-15.

| Procedure | Inspection | Significance and Action |
|--|---|--|
| Inspect piston agitator: Allow FOB to hang from the hand. | Observe distortion from “J” form | Agitation may signify damage to the insertion shaft. If loose controls are operative, the FOB may be usable. Excessive agitation or operation may make manipulation difficult. Disassembling the piston or the agitator should not be used. |
| Active agitator: The control lever is used to manipulate the distal tip. | Observe lever control move the tip in the sagittal plane smoothly and to the extent stated by the manufacturer? | There may be a damaged or entangled control wire. The device should be repaired by the manufacturer. |
| Apply suction to the working channel. | See or minimal suction at distal aperture. | Caking of secretions within channel may require clearing by the manufacturer. Copying of numbers and negative signs. |
| Visually check: Observe printed markings a few millimeters in front of the objective lens. | Rough or dirty picture | The objective lens and eyepiece lens can be cleaned with a clean face cloth. Use a commercial detergent. Prior to placing in the patient, warm water may prevent further fogging by equalizing the lens and patient temperatures. Fogging or vapor insufflation. If these are assessed, the FOB may need clearing by the manufacturer. |

Table 23-15. PREPARATION OF THE FIBEROPTIC BRONCHOSCOPE

Use of the Fiberoptic Bronchoscope. The FOB is held in the nondominant hand, the thumb over the control lever and the index finger poised over the working channel valve (see Fig. 23-31). The dominant hand will be used to steady and hold the insertion cord as it is manipulated in the patient. Many operators are tempted to “switch” hands, but the thumb of the nondominant hand should be well able to control the gross movement of the control level. Any experienced endoscopist will recognize that the fine control required to hold the shaft of the endoscope steady and make adjustments is where the art of endoscopy lies.

The insertion shaft is lubricated with a water-soluble lubricant, and it is threaded through the lumen of an ETT, the objective end emerging from the main ETT orifice. A clinically appropriate ETT should be chosen, but the larger the ratio between the internal diameter of the ETT and the external diameter of the insertion shaft, the greater the risk of “hangup” on airway structures, as occurs in 20–30% of attempts (Fig. 23-32).¹⁴¹ Hangup occurs when a cleft exists between these two devices because of the differential sizes. Hangup may involve entrapment of the epiglottis, corniculate / arytenoid cartilages, the aryepiglottic folds, or the vocal folds.¹⁴⁷ A variety of methods have been described for overcoming hangup, including use of a small ETT, rotation of the plane of the ETT bevel 90 clockwise and / or counterclockwise, the use of soft-tipped ETTs, asking the patient to inspire deeply during the ETT advancement, and the “double setup” ETT, which uses a small ETT (e.g., 5.0 id) within a clinically adequate ETT (e.g., 7.5 id) to overcome the clefts caused by size differentials.^{147,148}

Figure 23-32. The size discrepancy between the fiberoptic bronchoscope and the tracheal tube that has been threaded onto it can create a cleft that can entrap anterior anatomic structures, hindering advancement of the tracheal tube into the larynx (hang-up).

The clinician chooses the route of intubation, either oral or nasal, based on clinical requirements, surgical needs, operator experience, and other intubation techniques available should FOB-aided intubation fail. This last factor is important because should an attempt at nasal intubation fail, there may be significant bleeding hindering other indirect visualization techniques. The nasal route is considered easier by many clinicians. The differences between oral and nasal FOB-aided intubation are discussed in [Table 23-16](#).

| | Nasal | Oral |
|-----------------|---|--|
| Preparation | Antiseptics, topical decongestant, nasal dilators with soft and later rigid nasal trumpet* | Antiseptics, intubating oral airway (IOA) |
| ETT | Softened by placing in warm water. May be kept either on personal air source used (near handle) or inserted into the nose so that it is left to turn the head from the nasal cavity into the nasopharynx. | Kept either on personal insertion cord (near handle) or inserted 4-6 cm into the ETT. |
| Structures seen | Floor of nose, nasal turbinate, superior aspect of the soft palate, nasopharyngeal posterior wall, base of tongue, epiglottis (lateral tip), arytenoid cartilage, vocal folds, tracheal rings, carina | IOA (anterior or posterior depending on IOA) Soft palate, uvula Epiglottis (lateral tip), arytenoid cartilage, vocal folds, tracheal rings, carina |

*Although fiberoptic and excimer have been used to decongest the nose, evidence suggests that oxymetazoline may be the best agent.
 †The level of the ETT should follow along the nasal septum, away from the turbinates. If the ETT will not turn into the nasopharynx, it may be rotated 90° in a clockwise or counterclockwise direction and readjusted.
 ‡An obstructing base of tongue or epiglottis can be moved by extension of the atlanto-occipital joint, jaw thrust, chin lift, or sustained pulling tongue forward.

Table 23-16. TECHNIQUES OF NASAL AND ORAL FOB-AIDED INTUBATION

A variety of intubating oral airways (IOA) are commercially available. Their chief function is to provide a clear visual path from the oral aperture to the pharynx, keep the bronchoscope in the midline, prevent the patient from biting the insertion cord, and provide a clear airway for the spontaneously or mask-ventilated patient. The common characteristic of all IOAs is a channel along the length of the airway large enough to allow the passage of the endotracheal tube. The Ovassapian airway ([Fig. 23-33](#)) provides two sets of semicircular, incomplete flexible flanges which stabilize the ETT (up to size 9.0 id) in the midline but allow its removal from the airway after intubation has been accomplished so that the IOA can be removed from the mouth. The flat lingual surface of the airway gives it good lateral and rotational stability. The Patil-Syracuse endoscopic airway and the Luomanen oral airway ([Fig. 23-33](#)) were also designed for fiberoptic-aided intubation. Each has a central groove, open at the lingual (Patil-Syracuse) or palatal (Luomanen) aspect, which allows easy removal of the ETT. The flat lingual surface provides good stability. Though this style of IOA provides superb access to the pharynx, it is larger than other airways and is often uncomfortable for the patient. The Williams airway ([Fig. 23-33](#)) and the Berman airway were both designed for blind oral intubation. It is often difficult to manipulate the tip of the fiberscope when it is within these narrow airways. Both are molded plastic with a complete circular internal lumen which guides the ETT toward the larynx. These airways have a small profile and are often better tolerated by the awake patient, but tend to be less stable on the tongue. Because the internal lumen is a complete circle, the Williams airway must be retreated off the ETT if it is going to be removed after intubation. This may pose difficulty if the ETT in use has a fused circuit adapter. The Berman airway solves this problem by being split along the length of one side. The plastic of the opposite side is thin and malleable. If the interincisor gap is adequate, the airway can be opened laterally to allow removal from the ETT.

Figure 23-33. (A) Williams airway, (B) Luomanen airway, and (C) Ovassapian fiberoptic intubating airway.

After successful navigation through the supraglottic airway, the endoscopist visualizes the vocal folds. If glottic closure, gag, or coughing occur as the FOB distal tip stimulates the structures of the larynx, the operator can choose to apply local anesthetic through the working channel, administer more sedation, or withdraw the scope and reinforce preparatory procedures. The clinician might also decide to advance the FOB into the larynx without further preparation. The actions taken must be dictated by the individual clinical situation; in the elective scenario, for example, there may be time for reinforced airway analgesia, whereas in the face of impending respiratory arrest patient discomfort may need to be tolerated. Once the larynx is entered, the operator may choose a structure, such as the tracheal carina, to serve as an identifying landmark as the ETT is advanced. Simply because the FOB has entered the trachea, there is no guarantee that the intubation will be successful. As noted above, 20–30% of ETT advancements are accompanied by hangup. Therefore, a patient with a critical airway should not be induced with a general anesthetic with the assumption that the ETT will be easy to pass.

Once the ETT enters the trachea, the clinician may choose to view the ETT and a chosen anatomic landmark simultaneously (e.g., the tracheal carina) to assure correct ETT placement before the FOB is withdrawn.

There have been a number of variations and adjuncts to FOB-aided intubation. The reader is referred to the primary literature listed in [Table 23-17](#), which is not meant to be exhaustive.

| Technique | Advantage |
|---|--|
| Endoscopy mask | Control ventilation maintained during or between attempts at FOB-aided intubation |
| Laryngeal mask | Excellent view of the larynx and ability to ventilate during or between attempts at FOB-aided intubation |
| Fiberoptic-aidedretrograde intubation | Guiding of the FOB with a wire known to be entering the trachea |
| Retrograde fiberoptic intubation | Changing a tracheostomy to an oral or nasal tracheal tube when antegrade intubation is difficult or impossible |
| FOB-aided intubation with the aid of a rigid laryngoscope | Helpful with an obstructing mass or large epiglottis |

Table 23-17. AIDS TO FIBEROPTIC AIDED INTUBATION

Although FOB-aided intubation is a versatile and vital technique, there are several pitfalls, most of which have been discussed. [Table 23-18](#) lists the most common reasons for failure of FOB-aided intubation.

| |
|---|
| Lack of experience: Not practicing on routine intubations |
| Failure to adequately anesthetize the airway of the awake patient: Secretions not dried; rushed technique |
| Failure to adequately dry the airway: Underdose or rushed technique |
| Nasal cavity bleeding: Inadequate vasoconstriction; rushed technique; forcible ETT insertion |
| Obstructing base of tongue or epiglottis: Poor choice of intubating airway; require chin lift/jaw thrust |
| Inadequate sedation of the awake patient |
| Hangup: ETT too large |
| Fogging of the FOB: Suction or oxygen not attached to working channel; cold bronchoscope |

Table 23-18. COMMON REASONS FOR FAILURE DURING FIBEROPTIC-AIDED INTUBATION

Rigid Fiberoptic Intubation Devices. Rigid fiberoptic devices allow indirect views of the larynx and act as an ETT guide for intubation. More than one third of all anesthesiologists have access to these devices.¹⁴² The most commonly available of these devices include the Bullard (Circon ACMI, Stamford, CT), Wu, and Uspher laryngoscopes ([Fig. 23-34](#)). Although these laryngoscopes may be used in routine clinical situations, they are particularly useful when movement of the patient's head and neck is impossible or contraindicated, (e.g., atlanto-occipital joint disease and the spine-injured patient). They are also applicable when there is a limited oral aperture (0.64 cm in the case of the Bullard). These devices consist of a rigid, stainless steel laryngoscope-like blade which encases a fiberoptic cable with a proximal eyepiece and distal objective lens. The blades have an anatomic curve to match the neutral position of the human oral cavity:pharynx:hypopharynx relationship. Alignment of the oral, pharyngeal, and tracheal axes is not required. Illumination is provided by a second fiberoptic cable transmitting light from a battery or free-standing light source.

Figure 23-34. The Bullard laryngoscope, battery handle, and stylet.

The Bullard scope, which comes in adult and pediatric sizes, has been the best investigated. It features a fixed fiberoptic cable located on the posterior aspect of the blade. The eyepiece lens has an adjustable diopter. A working channel also runs the length of the blade. Once the larynx is visualized, the ETT is advanced using a detachable stylet, although other techniques have been described.¹⁴⁹ Recently, the advantages of the Bullard scope over traditional laryngoscope blades in managing the spine-injured patient and the obese patient have been investigated.^{150,151 and 152}

The Upsher scope (Mercury Medical, Clearwater, FL) is available in an adult size as of this writing. Instead of a stylet, the ETT is held and advanced through a C-shaped lumen in the blade. There is no working channel in this scope. The eyepiece is focusable.

The Wu scope (Pentax) differs from the other devices in that a flexible fiberoptic endoscope is fitted into a passage within a three-part stainless steel handle and blade. A second, larger lumen accepts the ETT. A working channel is positioned alongside the endoscope lumen. Two adult sizes are manufactured. Once the larynx is visualized and the ETT advanced into the trachea, the two stainless steel pieces of the laryngoscope blade are disassembled and removed from the mouth. Unlike the other two devices, the Wu scope can also be used for nasal intubation by assembling only the anterior blade portion and the handle. An ETT, previously placed in the pharynx via the nares, can be fitted into the anterior portion of the blade.

Case 2: Retrograde Wire Intubation

A 65-year-old female with a 60-pack / year history of smoking and advanced rheumatoid arthritis presents to the emergency department (ED) in respiratory distress. Her oxygen saturation with a nonrebreather oxygen mask is 85%. She has a limited oral aperture (~2.5 cm) and a thyromental distance of 6 cm. Although the cricothyroid membrane can be palpated, there is limited access to it and the tracheal rings owing to a significant cervical kyphosis. The sputum is noted to be blood-tinged and contains thickened bronchial secretions. Awake blind nasal intubation is attempted twice by the emergency department physicians, is unsuccessful, and results in epistaxis. Retrograde intubation of the airway is performed with the patient in a sitting position by percutaneous placement of an 18-gauge catheter through the cricothyroid using a saline-filled 10-ml syringe to detect bubbles associated with tracheal entry (after initial local anesthetic infiltration of the skin over the membrane). The needle is advanced over the mid-cricothyroid membrane at an angle of 45° to the chest. After the free aspiration of air is noted, the Teflon sheath of the catheter is advanced into the trachea. A 0.035-inch radiologic guide wire 110 inches in length is advanced via the catheter until the proximal end emerges from the mouth. A 7.0 ETT is placed over the wire and is guided into the trachea. The wire is removed by pushing it into the percutaneous puncture site and retrieving it from the proximal end of the tracheal tube. Breath sounds are auscultated over the lung fields as ventilation is assisted with positive pressure. Once improved oxygen saturation is noted, the patient receives sedation with intravenous midazolam.

Use of the Retrograde Wire Intubation in Airway Management. Retrograde wire intubation (RWI) involves the antegrade pulling or guiding of an ETT into the trachea using a wire or catheter which has been passed into the trachea via a percutaneous puncture through the cricothyroid membrane or the cricotracheal membrane, and blindly passed retrograde into the larynx, hypopharynx, and pharynx and out of the mouth or nose. Retrograde intubation was first described in 1960 by Butler and Cirillo, with the placement a red rubber urethral catheter via a previous tracheostomy up through the larynx and out of the mouth.¹⁵³ The percutaneous

technique used today was first described by Waters in 1963, using an epidural catheter.¹⁵⁴ In 1993 the technique was include in the ASA's Difficult Airway Algorithm.¹²⁸

The basic equipment used in the retrograde intubation technique is listed in [Table 23-19](#).

18G or larger angiocatheter
 Luer-lock syringe, 3 ml or larger
 Guide wire:
 • Preferably J-type end
 • Length: at least 2.5 times the length of a standard ETT (typically 110–120 cm)
 • Diameter: capable of passing via angiocatheter being chosen
 Other: Scalpel blade, nerve hook, Magill forceps, 30° silk suture, epidural catheter

Table 23-19. EQUIPMENT FOR RETROGRADE WIRE INTUBATION

Retrograde wire intubation has been described in a number of clinical situations as a primary intubation technique (elective or urgent) and after failed attempts at direct laryngoscopy, fiberoptic-aided intubation, and LMA-guided intubation.¹⁵⁵ The most common indications are inability to visualize the vocal folds owing to blood, secretions, or anatomic variations, unstable cervical spine, upper airway malignancy, and mandibular fracture. Contraindications include lack of access to the cricothyroid membrane or the cricotracheal ligament (due to severe neck deformity, obesity, mass), laryngotracheal disease (stenosis, malignancy, infection), coagulopathy, and skin infection.

The anatomic relationships to be considered in RWI have been described elsewhere in this chapter. Typically, the procedure requires 5 minutes to perform.¹⁵⁶ Because most clinicians are not facile with the technique, it may take several minutes in inexperienced hands; therefore, RWI is relatively contraindicated in the hypoxic patient. RWI has been used in elective and emergent situations, in adults and infants, in the operating room, ED, and the prehospital environment. Complications reported with RWI are listed in [Table 23-20](#).

Bleeding (11)
 Subcutaneous emphysema (4)
 Pneumomediastinum (1)
 Breath-holding (1)
 Catheter traveling caudad (2)
 Trigeminal nerve trauma (1)
 Pneumothorax (1)

Table 23-20. COMPLICATIONS ASSOCIATED WITH RETROGRADE WIRE INTUBATION

In the current patient (as in Case 1), RWI was chosen in a setting where the patient was not apneic and was therefore supporting her own ventilation and oxygenation, albeit poorly. The two cases differ in impending respiratory failure (Case 2) versus FOB-aided intubation undertaken in an stable situation (Case 1). In many situations, where awake intubation is an obvious initial approach to securing the airway, there is little time for patient preparation (e.g., the administration of antisialagogues, topical anesthetics, and / or sedation). In this regard, RWI does not require a clear visual field or significant patient cooperation and can often be performed with little analgesia of the airway.

Performing Retrograde Wire Intubation (Fig. 23-35). RWI is generally performed with the patient in a supine position, although the sitting position is often used for patients in respiratory distress. Extension of the head or the neck displaces the cricoid and tracheal cartilages anteriorly and displaces the sternocleidomastoid muscles laterally, though, as in Case 2, this may not always be possible. The skin should be prepared. If the patient is conscious, a local anesthetic skin wheal is made over the puncture site. Local anesthesia of the airway should be administered to prevent discomfort and airway reflexes as time permits. In general, topical anesthesia of the trachea, larynx, pharynx, and nasal passages is desirable. Translaryngeal anesthesia is a particularly convenient technique since a percutaneous entry of the trachea is required during the RWI. Structures above and below the vocal folds are anesthetized during the ensuing patient cough if a local anesthetic-filled syringe is used to facilitate the recognition of appropriate placement (with tracheal air bubbles) and then is injected to provide airway anesthesia¹⁵⁷ (see [Fig. 23-33](#)).

Figure 23-35. The sequence of retrograde wire intubation after the cricothyroid or cricotracheal ligament is identified and a percutaneous puncture is performed with air aspiration (see [Fig. 23-29B](#)). (A) The retrograde device (twisted wire, Cook Critical Care) is advanced until it emerges from the mouth or nose. (B) The wire is clamped at the entrance site (arrow) and the endotracheal tube is advanced over the wire in an antegrade fashion. [In the picture, the wire has been threaded through the ETT Murphy eye (see [Table 23-21](#)).] (C) The wire is removed, leaving the tracheal tube in place.

| Technique | Advantage | Disadvantage |
|--|--|--|
| Wire travels through entire mouth lumen of the ETT | Standard technique | Margin of error equal distance from cuff folds to puncture site No angle distal removal of wire "Backsliding" can occur Cannula can enter below |
| Wire placed into ETT lumen via Murphy eye | Increased margin of error Decreased intubating | Margin of error equal distance from cuff folds to puncture site Cannula can enter below |
| Wire enters distal end of ETT and exits via Murphy eye | Decreased intubating | Margin of error equal distance from cuff folds to puncture site Cannula can enter below |
| ETT "inchworm" style is placed over skin, then placement of ETT | Decreased intubating Can use stylet to create distal margin of error once wire is removed | Cue |
| Flexipipe bronchoscope is placed over wire prior to placement of ETT | Decreased intubating Can use stylet to create distal margin of error once wire is removed | Cue |
| 30° suture | Facilitates No intubating Margin of error never reduced | May be difficult to place silk suture |
| Lead ETT | Facilitates intubating | May not be clinically adequate |

¹ Margin of error refers to the distance between the vocal folds and the endotracheal tube remains at the time that the guidewire is removed. If this distance is not adequate, there is a risk of immediate ventilation.
² Intubating refers to the differential size of the guidewire and the tracheal lumen. If large discrepancy in size allows for a leak which may enter the epiglottis, aryepiglottic folds, or vocal folds, facilitating distal airway passage.

Table 23-21. TECHNIQUES OF ETT ADVANCEMENT OVER A RETROGRADE WIRE

As noted earlier, the cricothyroid membrane (CTM) and cricotracheal ligament (CTL) are both potential sites for translaryngeal puncture. Although the CTM has the advantage of being directly anterior to the large posterior surface of the cricoid cartilage, thereby protecting the esophagus from a puncturing needle, it places the needle in close proximity (0.9–1.5 cm) to the vocal folds and hence allows for a somewhat smaller margin of error at the time of the intubation.

Although classically performed with a Tuohy needle and epidural catheter, the advent of smaller-diameter, stiffer wires with atraumatic “J” tips has made the guidewire modification popular. These guidewires are typically 0.032–0.038 inches in diameter, being able to pass through an 18G intravenous catheter. The typical length is between 110 and 120 cm. The only requirement for length is that the wire be more than twice as long as the tracheal tube to be used, so that no matter where in its course along the wire the tracheal tube should be, both ends of the wire are always accessible to the operator. Kits that conveniently incorporate all the necessary equipment are available (Cook Critical Care).

The needle / catheter approaches the trachea at 90° to the coronal and sagittal planes if possible (as it was not in Case 2). In this orientation, the needle is likely to impact the posterior aspect of the cricoid cartilage if advanced too far, and not puncture the esophagus. Additionally, this angle will help to avoid trauma to the near-lying vocal folds.

After the percutaneous puncture is made and the trachea identified by free air aspiration, the catheter is angled cephalad and the wire is advanced (J-tip) into the trachea until it emerges from the mouth or nose. The wire may need to be retrieved from the mouth with a “sweeping” finger, Magill forceps, or nerve hook. Any obstruction to advancement of the wire should prompt re-evaluation of the angle of the catheter and the position of the head and neck (e.g., catheter directed posterior and / or caudad, neck flexed). Coughing typically heralds caudad traveling of the wire. If the wire is retracted and found to be bent, it is prudent to procure a new one. When complaints of pain are encountered above the level of the larynx, it is typically due to the wire passing into an inadequately prepared nasal cavity. Options include retracting the wire modestly and asking the patient to open the mouth and maximally protrude the tongue during the readvancement, reaching into the oropharynx to retrieve the wire, or patiently re-preparing the nasal passages. Once the wire is satisfactorily retrieved, placement of the tracheal tube may be performed using the wire in a number of fashions, depending on the operator's preference and previous experience. [Table 23-21](#) lists common techniques, together with their advantages and disadvantages. Details of these techniques have been described elsewhere.¹⁵⁸

In the case reported, other techniques may have been considered. Although indirect visual devices (flexible fiberoptic bronchoscope, rigid fiberoptic laryngoscope) may have also been helpful in this case, three elements worked against their use: (1) tissue trauma from repeated attempts at blind nasal intubation produced a bloody airway, frustrating the use of these devices; (2) the patient was unable to cooperate owing to her respiratory distress; (3) because of the impending respiratory failure, there was little time for adequate airway analgesia. A coughing, gagging, conscious patient makes fiberoptic techniques nearly impossible. Straining and coughing during fiberoptic intubation attempts have resulted in Mallory-Weiss tears of the esophagus, resulting in significant hemorrhage.

Blind nasal intubation was the first technique attempted in this patient. Until recently, blind nasal intubation has been a staple of airway control, especially in the emergency department, where it has been largely supplanted by rapid-sequence intubation.¹⁵⁹ This technique requires significant analgesia of the nasal passages in the awake patient. Success is far more likely in the spontaneously breathing patient. With the head in the Magill position, the ETT is advanced into the nares, nasal passage (keeping the ETT bevel alongside the nasal septum), and into the pharynx. Breath sounds are auscultated from the ETT, and its position adjusted keep them maximized. The patient's head and larynx can be manipulated externally as necessary.

Case 3: Esophageal Tracheal Combitube

A 55-year-old male with a history of cirrhosis and esophageal varices requires airway control due to acute, recurrent upper gastrointestinal bleeding. Apart from fresh blood in the airway, physical exam of his external airway is consistent with a routine laryngoscopy. Furthermore, he had been intubated for similar events in the past. After a rapid sequence induction, the larynx cannot be visualized on three laryngoscopies owing to fresh blood emanating from the esophagus. On all three attempts, the ETT is advanced blindly, and the absence of breath sounds over the thorax together with the presence of copious blood in the ETT leads to the diagnosis of esophageal intubation. A large adult-sized esophageal tracheal Combitube (Kendall, Mansfield, NY) is requested, blindly inserted into the airway, and the pharyngeal and distal cuffs are inflated. Ventilation through the pharyngeal perforations lumen (blue) produces bilateral breath sounds to auscultation, and the oxygen saturation increases to >90%. Copious blood is suctioned from the esophageal lumen. The patient is transported to the angiography suite where his esophageal varices are embolized. The esophageal tracheal Combitube is removed and the patient is intubated with direct laryngoscopy.

History of the Tracheal Esophageal Combitube. The tracheal esophageal Combitube was developed from the concept of the esophageal operator airway (ESO), which was introduced in 1968.¹⁶⁰ The ESO consisted of a tracheal-like tube, 34 cm in length, with an inflatable cuff at its sealed, distal end. It was inserted blindly into the esophagus, so that the cuff lay at a level caudad and posterior to the tracheal carina. Sixteen holes communicating with the central lumen were positioned so as to be in the hypopharynx when inserted to the proper depth. A face mask at the proximal end was used to “seal” the airway. Ventilation was achieved by applying positive pressure to the proximal open aperture, where it emerged from the face mask. Unfortunately, significant problems / complications became apparent as the ESO came into common practice ([Table 23-22](#)).

Difficulty in obtaining a tight face mask fit, especially during pre-hospital transportation. Often, two hands were needed to produce an adequate fit, especially in the bearded or edentulous. Inadvertent or unrecognized tracheal intubation with the blind/cuffed distal end, resulting in complete airway obstruction. Esophageal or gastric rupture, possibly due to the length

Table 23-22. PROBLEMS ASSOCIATED WITH THE ESOPHAGEAL OBTURATOR AIRWAY

These shortcomings of the ESO were addressed by Dr. Michael Frass, a critical care physician in Vienna, Austria in 1986.¹⁶¹ The face mask of the ESO was replaced by an oropharyngeal balloon, sealing the upper airway and anchoring the device against the hard palate. As with the ESO, perforations at the hypopharyngeal level allowed egress of air near the level of the larynx, while the distal (esophageal) tip remained occluded and was still included in a cuff. These modifications of the ESO did not solve the problem of complete airway obstruction if the device was accidentally introduced into the trachea. To solve this problem Dr. Frass's final modification included a second lumen, patent from proximal to distal end, without perforations. This design, named the tracheal esophageal Combitube, is functional if introduced into the esophagus (ventilation being achieved through the esophageal lumen, via the hypopharyngeal perforations) or in the trachea (ventilation being achieved through the tracheal lumen, via distal aperture). In either case, the proximal balloon seals both the oral and nasal passages, and the distal conventional tracheal tube cuff isolates the respiratory system from the gastrointestinal system. The device is available in two sizes: the 41Fr size is used for larger adults (height > 5.5 feet) and the 37Fr size is used for adults 4–6 feet tall ([Fig. 23-36](#)).

Figure 23-36. The esophageal tracheal Combitube.

Use of the Esophageal Tracheal Combitube. The esophageal tracheal Combitube is inserted blindly. The operator lifts the lower jaw and tongue anteriorly with one hand, and the esophageal tracheal Combitube is inserted with a downward, caudad-curved motion until the proximal depth indicator (two black rings printed on the double lumen tube) come to rest at the level of the teeth. The oropharyngeal balloon is inflated with 100 ml of air through a blue plastic pilot balloon (85 ml in the small adult size) while the distal cuff is inflated with 5–15 ml (via a white pilot balloon). An ambu bag or anesthesia circuit is attached to the proximal end of the esophageal lumen (constructed of blue polyvinyl chloride), and ventilation is confirmed by auscultation or other means. Because 90% of esophageal tracheal Combitube placements result in an esophageal position, ventilation occurs via this lumen's hypopharyngeal perforations. If no breath sounds are auscultated and / or gastric inflation is noted, the esophageal tracheal Combitube has been positioned in the trachea. Without repositioning, ventilation is changed to the distal end of tracheal lumen (clear polyvinyl chloride). If no maneuver improves ventilation, the device is most likely in the esophagus, but has been advanced too deeply, with the oropharyngeal cuff obstructing the airway.¹⁶² In this case, the cuffs should be deflated, the device withdrawn 2 cm and the ventilation sequence repeated.

Advantages of the esophageal tracheal Combitube include rapid airway control, airway protection from regurgitation, ease of use by the inexperienced operator, no requirement to visualize the larynx, and being able to maintain the neck in a neutral position. It has been shown to be useful in the patient with massive upper gastrointestinal bleeding or vomiting, cervical spine injury or deformity (though the presence of a rigid cervical collar may make insertion difficult or impossible), and as a rescue device in failed rapid-sequence induction or unanticipated difficult intubation. It is also useful in the grossly obese, in acute bronchospasm, during cardiopulmonary resuscitation, and for prolonged ventilation after airway rescue.^{163,164,165,166,167,168,169,170,171,172,173} and ¹⁷⁴ Several series have demonstrated the esophageal tracheal Combitube's value in prehospital management of the airway.^{175,176} and ¹⁷⁷

Techniques for exchange of the esophageal tracheal Combitube for an endotracheal tube have been described.¹⁷⁸

Contraindications to esophageal tracheal Combitube use include esophageal obstruction or other abnormality, ingestion of caustic agents, upper airway foreign body or mass, lower airway obstruction, height less than 4 feet, and an intact gag reflex. Since the esophageal tracheal Combitube includes latex in its construction, it should not be used in patients with latex allergy.

Complications associated with the esophageal tracheal Combitube have included lacerations to the pyriform sinus and esophageal wall resulting in subcutaneous emphysema, pneumomediastinum, pneumoperitoneum, and esophageal rupture.^{179,180} and ¹⁸¹

Case 4: Failed Rapid-Sequence Induction and the LMA

A 39-year-old male presents for elective uvulopharyngopalatoplasty. He has no previous surgical history. His maximal incisor gap is 5 cm, thyromental distance is 7 cm, and his oropharyngeal view is a Samssoon–Young Class 2. There is no limitation in head and neck flexion and extension. During a sleep apnea study, he had had 15 apneic events each hour. The patient has a significant history of gastroesophageal reflux, and rapid-sequence induction is planned. After the administration of pentothal, succinylcholine, and cricoid pressure (Sellick maneuver), direct laryngoscopy with a Macintosh number 3 laryngoscope blade reveals a large epiglottis obscuring the view of the vocal folds (Cormack–Lehane Grade 3).¹⁰⁰ Significant hyperplasia of the base of the tongue, which prevents its full displacement, is also noted. The BURP maneuver does not improve the view.⁹⁷ A Macintosh 4 and Miller 3 blades are used and do not improve the view. Oxygen saturation, which was 100% prior to induction, is now 92%, and face-mask ventilation is initiated with the Sellick maneuver in place. Complete obstruction to ventilation is encountered, despite chin and / or jaw lift, two-person ventilation, and a reduction in the degree of cricoid pressure. The oxygen saturation falls to 85% and a size 5 LMA (which had been prepared prior to the induction of anesthesia) is inserted with the technique as described by the inventor. Immediately, a clear airway is established, and the Sellick pressure remains in place. A second dose of pentothal is administered, and the patient is intubated by the blind passage of a 7.0-id ETT via the LMA. The LMA is then removed using a Cook airway exchange catheter (Cook Critical Care, Bloomington, IN) as a stylet, and the surgical case proceeds.

The LMA in the Failed Airway. One clear advantage of LMA use is in the failed airway. There have been many reported (and unreported) cases of failed intubation and failure to ventilate by mask in which the airway was rescued with an LMA.^{182,183} Parmet *et al* estimate that 1:800,000 patients cannot be managed with an LMA, providing an 80-fold increase in margin of safety over the oft-noted 1:10,000 patients who cannot be ventilated by mask nor intubated by traditional means.¹⁸⁴ Likewise, a wealth of literature describes the use of the LMA in elective difficult airway management in awake and unconscious patients, in anticipated and unanticipated situations, in cervical spine injury, and in pediatric dysmorphic syndromes.^{183,184,185,186,187,188,189,190,191,192,193,194,195,196,197,198} and ¹⁹⁹ The characteristics of the LMA that underlie its superiority as a tool in the difficult airway armamentarium are that it is well tolerated by the patient, simulating the natural distension of the hypopharyngeal tissues by food, and that its insertion follows an intrinsic pathway, requiring no tissue distortion (as with laryngoscopy), which may not be possible in all patients. Finally, it is a blind technique not hindered by blood, secretions, debris, and edema from previous attempts at laryngoscopy.²⁰⁰ Because the LMA's ease of insertion is not dependent on anatomy that can be assessed on routine physical exam, typical airway assessment measures do not apply to its application.²⁰¹ The major disadvantage of the LMA in resuscitation is the lack of mechanical protection from regurgitation and aspiration. Lower rates of regurgitation during CPR (3.5%) than with the bag-valve mask ventilation (12.4%) have been shown.^{52,202,203,204} and ²⁰⁵ Even in the face of regurgitation, pulmonary aspiration is a rare event with the LMA.^{205,206} and ²⁰⁷ Unfortunately, the use of the Sellick maneuver may prevent proper seating of the LMA in a minority of instances.^{208,209} and ²¹⁰ This may require the brief removal of the cricoid pressure until the LMA has been properly seated. Cricoid pressure is effective with an LMA *in situ*. Had it been available, the Fastrack-LMA would also have been an ideal device in this scenario.

Case 5: Deviation from the Difficult Airway Algorithm

Thirteen hours after admission to the intensive care unit, a 76-year-old female who had sustained trauma to the face, head, and neck in a motor vehicle accident is noted to have progressive decline in her consciousness and respiratory effort. On examination, there appears to be an adequate interincisor gap and thyromental distance. The oropharyngeal view and range of motion of the head and neck cannot be evaluated. Owing to the inability to fully evaluate the airway with respect to ease of intubation, an awake procedure is chosen. Fiberoptic devices are not considered usable because of the presence of fresh and clotted blood in the mouth as a result of continued epistaxis. Other airway techniques that require significant patient preparation are not considered because of the rapid progression of the patient's respiratory failure. Additionally, the presence of fresh blood in the oral and pharyngeal cavities will hinder adequate drying and analgesia. Blind nasal intubation is considered contraindicated based upon the obvious facial trauma and the risk of cribriform plate disruption. Neither equipment for retrograde intubation nor the tracheal esophageal Combitube is readily available. A lighted stylet intubation guide is available, but no clinician present is experienced with this technique. Although the mental status change is believed to reflect an intracranial process (*e.g.*, intracranial hypertension), the risk of complete loss of the airway is judged to be the primary clinical hazard. Awake direct laryngoscopy is attempted with manual in-line stabilization of the neck. After clearing fresh blood from the pharynx with a Yankauer suction catheter, a Cormack–Lehane Grade 3 laryngeal view is obtained; but because of patient resistance (biting on the laryngoscope and movement), tracheal intubation is not achieved. The decision is made to proceed with rapid-sequence induction and intubation, with preparations made for an emergency tracheostomy. After surgical preparation of the neck and preoxygenation, intravenous succinylcholine and etomidate are administered, direct laryngoscopy is undertaken, the larynx is easily visualized, and the trachea is intubated.

Muscle Relaxants and Direct Laryngoscopy. In the case described above, the use of muscle relaxants significantly improved the ability to visualize the larynx.^{211,212} and ²¹³ In a recent study, the use of muscle relaxants during a direct laryngoscopy increased the success rate of intubation and was associated with fewer incidents of airway trauma, intubation attempts, esophageal intubations, aspiration, and even death.²¹⁴ Intubating conditions with and without muscle relaxation have been investigated in few well controlled trials because the superior intubating conditions achieved with muscle relaxants has discouraged inclusion of control groups.²¹⁵ Muscle relaxation actions that improve laryngoscopic view include allowing complete temporomandibular joint relaxation and opening, anterior movement of the epiglottis, and widening of the laryngeal vestibule and laryngeal sinus.⁹⁵ In addition, the finding that laryngoscopic stimulation of the pharyngeal musculature causes the

upper airway lumen to appear small is offset by the use of relaxants.

Leaving the Algorithm. The situation described in Case 5 is unusual in that rapid-sequence induction was attempted because the clinical situation had deviated from the ASA Difficult Airway Algorithm owing to the progressive nature of the airway compromise. The situation was more akin to the “crash” airway described by Walls *et al.*¹⁵⁹ In this case, the institution of muscle relaxation, which might be considered contraindicated in the apparently difficult-to-intubate patient, allowed for full visualization of the larynx. Knowing that failure to intubate in this case would result in probable loss of the airway, the clinician was prepared for cricothyroidotomy. Although the ASA's Difficult Airway Algorithm is a valuable tool in the process of approaching the difficult airway, the clinician must always be prepared for the case that does not fit the mold. As stated earlier, adaptability in a rapidly changing clinical situation is critical to the success of airway management. Also of interest in this case was the availability of a lighted stylet for use in similar difficult airway scenarios. Although this device may have been useful in the current case, no clinician present was familiar with its operation. A critical situation is not an occasion for trying an unfamiliar technology.

Other Devices

An ever increasing number of airway management devices are commercially available. Although encyclopedic coverage of these tools is beyond the scope of this chapter, a review of the more established of this equipment follows.

Lighted Stylets

These devices rely on transillumination of the airway. A light source introduced into the trachea will produce a well circumscribed glow of the tissues over the larynx and trachea. The same light placed in the esophagus will produce no or a diffuse light. A number of devices have become available, including disposable, partly disposable, and fully reusable systems. Although there are many reports of successful intubation using these devices, some common problems have been noted: In general, the operating theater lights must be dimmed to best appreciate the circumscribed glow; a stylet tip successfully placed in the trachea, but not pointing in an anterior direction, may give a false-negative impression; it is often difficult to remove the semirigid stylet from the ETT after intubation.

Airway Bougie

These encompass a series of solid or hollow, semimalleable stylets that maybe be blindly manipulated in to the trachea. An ETT is then “threaded” over the bougie and into the trachea. These bougies are generally low in cost and highly portable. The Eschmann introducer (Eschmann Health Care, Kent, England) was introduced in 1949. It is 60 cm long, 15Fr-gauge, and angled 40 degrees 3.5 cm from its distal end (Fig. 23-37). It is constructed from a woven polyester base, which is malleable. It can be very helpful when the larynx cannot be visualized with laryngoscopy. The introducer (also known as the gum elastic bougie) can be manipulated under the epiglottis, its angled segment directed anteriorly towards the larynx. Once it has entered the larynx and trachea, a distinctive “clicking” feel is elicited as the tip passes over the cartilaginous structures.

Figure 23-37. The Eschmann introducer.

Minimally Invasive Transtracheal Procedures

When access to the airway from the mouth or nose fails or is unavailable (*e.g.*, maxillofacial, pharyngeal, or laryngeal trauma, pathology, or deformity), emergency access via the extrathoracic trachea is a feasible route to the airway. The clinician must be familiar with these alternative techniques of oxygenation and ventilation. The decision to proceed with an invasive procedure can be difficult, and most clinicians will hesitate at potentially grave risk to the patient. One should consider becoming facile with at least one of these techniques in elective situations, such as transtracheal aspiration for airway analgesia or elective retrograde intubation. (Consider, for example, assisting a surgical colleague on a tracheostomy). Although tracheostomy and cricothyroidotomy are beyond the scope of this chapter, percutaneous techniques will be considered.

Cricothyroidotomy, cricothyrotomy, coniotomy, and minitracheostomy are synonyms for establishing an air passage through the cricothyroid membrane. The anatomy of this structure and those surrounding it was discussed earlier in this chapter. Although cricothyrotomy is the procedure of choice in an emergency situation, it may also apply to an elective situation when there is limited access to the trachea (*e.g.*, severe cervical kyphoscoliosis). Cricothyrotomy is contraindicated in neonates and children under 6 years of age, and in patients with laryngeal fractures.

Percutaneous Transtracheal Jet Ventilation (TTJV)

Percutaneous transtracheal jet ventilation (TTJV), as a form of cricothyroidotomy, is the most familiar to anesthesiologists.²¹⁶ The ASA Difficult Airway Algorithm lists transtracheal jet ventilation as an option in the cannot-mask ventilate, cannot-intubate situation.¹²⁸ TTJV is a simple and relatively safe means to sustain the patient's life in this critical situation.²¹⁷ An intravenous catheter of 12, 14, or 16 gauge, attached to a 5-ml or larger, empty or partially fluid-filled (saline or local anesthetic) syringe, should be used to enter the airway. The patient is positioned supine, with the head midline or extended on the neck and thorax (if not contraindicated by the clinical situation). After aseptic preparation, local anesthetic is injected over the cricothyroid membrane (if the patient is awake and time permits). The right-handed clinician stands on the right side of the patient, facing the head. The clinician can use his or her nondominant hand to stabilize the larynx. The catheter-needle is advanced at right angles to all planes in the caudad third of the membrane. From the moment of skin puncture there should be constant aspiration on the syringe plunger. Free aspiration of air confirms entrance into the trachea. Unless there is significant pulmonary fluid (*e.g.*, blood, aspirated gastric contents, or water from drowning), the aspiration of tracheal air should be incontrovertible. The needle-catheter assembly should be advanced slightly, and subsequently the catheter advanced fully into the airway alone. Although this technique has been described with common angiocatheters, dedicated devices made of kink-resistant materials and with accessory ports are available (Fig. 23-38).

Figure 23-38. The Cook Critical Care transtracheal ventilation catheter with Luer-locking end (*two-headed arrow*) and oxygen hose friction fitting (*single-headed arrow*).

Once the catheter has been successfully placed in the airway, an oxygen source is attached. The clinician may have several options in this regard. If a high-pressure system is available—for example, a metered and adjustable oxygen source with a hand-controlled valve (Fig. 23-39) and a Luer-lock connector—25–30 psi of oxygen (central hospital supply or regulated tank) can be delivered directly through the catheter, with insufflations of 1–1.5 seconds at a rate of 12 insufflations per minute. If a 16-gauge catheter has been placed, this system will deliver a tidal volume of 400–700 ml. Manual closure of the mouth and nose may be needed during the insufflation (but *not* exhalation) phase if there is significant air leak through the upper airway. If such a system has not been preassembled, the fresh gas outlet of the anesthesia machine (15-mm internal-diameter female adapter) can also be used to provide high pressure (Fig. 23-40).

Figure 23-39. System for regulation of a high-pressure oxygen source for transtracheal jet ventilation.

Figure 23-40. When a dedicated system is not available, the fresh gas flow outlet (15-mm diameter) of the anesthesia machine can be fitted with a tracheal tube adapter and oxygen tubing. The Oxygen Flush button is used to deliver “breaths” (*inset*).

Low-pressure systems cannot provide enough flow to expand the chest adequately to allow for ventilation, but should be able to provide oxygen while a more definitive airway is secured. A simple connection to the tracheal catheter can be achieved by placing a cuffed ETT into the barrel of a 5–10-ml syringe, inflating the cuff to provide a seal, using the distal end of the syringe to engage the catheter, while the 15-mm adapter of the ETT is fitted to an anesthesia circuit or ambu bag (Fig. 23-41).

Figure 23-41. A simple system for low-pressure transtracheal oxygenation can be rapidly constructed using an angiocatheter, a syringe, and a cuffed tracheal tube.

Specialized percutaneous cricothyroidotomy systems have been developed which improve the ease of this technique while providing all necessary equipment. These devices generally provide a large-bore access which is adequate for oxygenation and ventilation with low-pressure systems. The Melker emergency cricothyroidotomy catheter set (Cook Critical Care, Bloomington, IN) uses a Seldinger—a catheter-over-a-wire technique—familiar to most anesthesia practitioners (Fig. 23-42). The set comes in a variety of cannula sizes (3.5-, 4-, and 6-mm internal diameter). Preparation and positioning of the patient are the same as with needle cricothyroidotomy. A 1–1.5-cm vertical incision of the skin only is made over the lower third of the cricothyroid membrane. Aiming 45° caudad, a percutaneous puncture of the subcutaneous tissue and cricothyroid membrane is made with the provided 18-gauge needle-catheter assembly and syringe. After air is aspirated, the catheter is advanced into the trachea. The provided guidewire is inserted through the catheter and into the trachea. The catheter is removed and the tracheal cannula, fitted internally with a curved dilator, is threaded onto the wire. The dilator is advanced through the membrane using firm pressure. Significant resistance to its advancement may indicate that the skin incision needs to be extended. Once the cannula-dilator has been fully inserted, the dilator and wire are removed. The 15-mm circuit adapter end of the cannula is now attached to an ambu bag or anesthesia circuit.

Figure 23-42. The Melker cricothyroidotomy cannula and curved dilator (Cook Critical Care, Bloomington, IN). The guidewire is not shown.

Other percutaneous systems include Nu-Trake (Weiss Emergency Airway System; International Medical Devices) and the QuickTrach® transtracheal catheter (VBM Medizintechnik GmbH). Non-needle puncture techniques are beyond the current discussion.

CONCLUSION

Apart from monitoring, the management of the routine patient airway is the most common task of the anesthesiologist—even during the administration of regional anesthesia, the airway must be monitored and possibly supported. Unfortunately, routine tasks often become neglected tasks in terms of the care and vigilance that is afforded each event. But the consequences of a lost airway are so devastating that the clinician can never afford a lackadaisical approach.

Although the ASA's Task Force on the Difficult Airway has given the medical community an immensely valuable tool in the approach to the patient with the difficult

Positioning a patient for a surgical procedure is frequently a compromise between what the anesthetized patient can tolerate, both structurally and physiologically, and what the surgical team requires for access to their anatomic targets.^{1,2} Physiologic instability resulting from disease or injury may be magnified by rapidly moving a seriously ill patient from bed to transport cart, through corridors and elevators, and onto the operating table. Induction of anesthesia and positioning may need to be delayed until that patient is hemodynamically stable, or establishment of the intended surgical posture may need to be modified to match the patient's tolerance. This chapter presents the physiologic significance of various positions in which a patient may be placed during an operation, briefly describes the techniques of establishing the positions, and discusses the potential complications of each posture.

It is very important for clinicians to understand the physiologic and potential pathologic consequences of patient positioning. Although considerable information is available on the physiologic effects of various positions, there is a paucity of information on the complications of positioning. Until recently, there have been few studies, either retrospective or prospective, that provided epidemiologic evidence of the frequency and natural history of many of the perioperative positioning complications. Why? In decades preceding the 1990s, catastrophic perioperative outcomes, such as death or hypoxic brain injury from either the delivery of inadequate oxygen or failure adequately to ventilate patients, were infrequent but potentially avoidable consequences of the delivery of anesthesia. The development of pulse oximetry and end-tidal respiratory monitoring in the 1980s, and the subsequent acceptance of monitoring standards of care by the anesthesia community, contributed to a dramatic decline in the frequency of these major events. Less catastrophic, yet still disabling, perioperative complications, such as neuropathies, consequently increased in importance and priority for study.

In the 1990s, a number of studies of large surgical populations provided new information on the frequency and natural history of rare perioperative events such as neuropathies and vision loss. These studies occasionally provided sufficient data to allow speculation on potential mechanisms of injury. Based on the findings of these studies, investigators are seeking to confirm mechanisms of injury and the efficacy of novel interventions to decrease the frequency of or to prevent these perioperative events. For now, however, the mechanism and even the onset of many potential positioning-related complications often are unknown.

The lack of solid scientific information on basic mechanisms of positioning-related complications often leads to medicolegal entanglements. Attempts to determine the etiology of complications alleged to be caused by patient positioning are often unconsciously biased. Notations on anesthesia and operating room records may be absent or uninformative. On some occasions, medicolegal conclusions have been shaped by assumptions and assertions made by people having no understanding of the case in question and no personal familiarity with proceedings in an operating room. Careful, but laconic, descriptive notations about positions used during anesthesia and surgery, as well as brief comments about special protective measures such as eye care and pressure-point padding, are useful information to include on the anesthesia record. In potentially complicated or contentious circumstances, a brief resume in the progress notes is advisable. Only in this manner can subsequent inquiries be properly answered on behalf of either the patient or the anesthesiologist. When credible, expanded knowledge that further delineates mechanisms of positioning-related complications is available, these issues and the care of patients will be improved.

DORSAL DECUBITUS POSITIONS

Physiology

Circulatory

In the horizontal supine position ([Fig. 24-1A](#)), the influence of gravity on the vascular system is minimal. Intravascular pressures from head to foot vary little from mean pressures at the level of the heart; therefore, almost no perfusion gradient exists between the heart and arteries in either the head or the lower extremities. Similarly, venous gradients from the periphery to the right atrium consist principally of the cyclic intrathoracic pressure changes that occur with respiration.

Figure 24-1. (A) Supine adult with minimal gradients in the horizontal vascular axis. Pulmonary blood volume is greatest dorsally. Viscera displace the dorsal diaphragm cephalad. Cerebral circulation is slightly above heart level if the head is on a small pillow. (B) Head-down tilt aids blood return from lower extremities but encourages reflex vasodilation, congests vessels in the poorly ventilated lung apices, and increases intracranial blood volume. (C) Elevation of the head shifts abdominal viscera away from the diaphragm and improves ventilation of the lung bases. According to the gradient above the heart, pressure in arteries of the head and

neck decreases; pressure in accompanying veins may become subatmospheric.

If the patient in the dorsal decubitus position is tilted head high or head low, the effects of gravity on blood flow in the head or the feet can become quite significant as the gradient to or from the heart increases. Pressures have been shown to change by 2 mm Hg for each 2.5 cm that a given point varies in vertical height above or below the reference point at the heart.³

When the lower extremities are below the level of the heart, blood pools in distensible dependent vessels, causing a reduction in effective circulating volume, cardiac output, and systemic perfusion. If the head is high and blood pressure measured at the level of the heart is low, the blood pressure in the brain is decreased further according to the magnitude of the head elevation.

The *tilt test*, which is the cardiovascular response to a head-up tilt of 75 degrees maintained for 3 minutes, can be a useful indicator of the magnitude of acute blood loss.⁴ If sustained tilt causes an increase in heart rate of more than 25 beats · min⁻¹ but does not produce hypotension or syncope, the blood volume deficit is 9–14 ml · kg⁻¹. If syncope occurs on tilting, the deficit is likely to be as much as 20 ml · kg⁻¹. Hypotension without tilting indicates a deficit in excess of 20 ml · kg⁻¹.

If the head is tilted down (see [Fig. 24-1B](#)), pressure in the cerebral veins increases in proportion to the gradient upward to the heart. Many alert patients so positioned complain of a rapidly occurring, pounding vascular headache. Congestion develops in the nasal mucosa and conjunctivae. In the presence of an intracranial pathologic process, such as a head injury or a stroke, elevations of cerebral venous pressure resulting from head-down tilt can provoke or intensify cerebral edema and dangerously raise intracranial pressure. Head-down tilt also increases cerebrospinal fluid pressure in the cranial vault, adding its effect to the total intracranial pressure elevation.

Kubal *et al*⁵ have shown that myocardial oxygen consumption can increase in awake patients scheduled for coronary artery bypass grafting when they are placed in mild degrees of head-down tilt as a means of distending jugular vessels and facilitating the percutaneous introduction of pulmonary artery catheters. Measurements suggested that an acute volume loading of the heart had occurred with the onset of the head-down tilt. Angina recurred in some patients, and one showed electrocardiographic changes indicative of myocardial ischemia.

Head-down tilt has been used to treat hypotension. A well entrenched practice that was based on the suggestions of physiologist Walter Cannon during World War I,⁶ this maneuver has been shown to be counterproductive.⁷ Although it does increase central blood volume by recovering pooled blood from caudad portions of the body, and although cardiac output is increased transiently, the enlarged central blood mass activates baroreceptors on the great vessels of the chest and neck.⁸ The result is rapid peripheral vasodilation, unchanged or reduced cardiac output, and decreased organ perfusion. In a study of patients in intensive care units, Sibbald *et al*⁷ found that head-down tilt caused an unpredictable further decrease in mean arterial pressure in a significant number of patients who were already hypotensive.

In the microcirculation, natural and spontaneous fluctuations in blood flow serve the nutritive requirements of the tissues.⁹ When an awake human is supine and motionless, the spontaneous fluctuations weaken progressively until they disappear in approximately 1 hour. The subject then becomes uncomfortable. Although tissue blood flow continues to decrease if immobility is enforced, a normal flow pattern returns if the subject becomes restless and moves about.¹⁰

In the absence of hypocarbia, hypovolemia, or hypothermia, a similar impairment of changes in microcirculatory distribution of blood flow occurs after the induction of anesthesia, despite early augmentation of tissue flow owing to the vasodilative properties of the anesthetic agents. Normal tissue perfusion is re-established by awakening movements of the patient at the end of anesthesia.¹⁰

West *et al*¹¹ have identified three separate perfusion zones in the pulmonary circulation, based on the interrelationship among pressures in the alveoli, arterioles, and venules.

In Zone 1, alveolar pressure exceeds either arterial or venous pressure and perfusion of the lung unit is prevented. Although it is rarely present in a normal lung, Zone 1 can be produced by pulmonary hypotension, excessive positive end-expiratory pressure, or overdistention of alveolar units from large tidal volumes during positive-pressure ventilation.

In Zone 2, arterial pressure exceeds alveolar pressure, whereas alveolar pressure remains higher than venous pressure. This relationship is found in nondependent portions of the lung, and perfusion is the result of a fluctuating balance between arterial and alveolar pressures.

In Zone 3, hydrostatic forces in the dependent portion of the lung produce venous congestion, and perfusion is determined by the difference between arterial pressure and venous pressure.

In the dorsal recumbent positions, the pulmonary circulation tends to be most congested along the dorsal body wall and least congested substernally. When the patient is tilted head high, Zone 3 moves toward the lung bases as better ventilatory mechanics improve gas exchange. If the tilt is head down, Zone 3 shifts cephalad into the poorly ventilated lung apices, and abnormal ventilation–perfusion ratios can be expected to intensify.

Respiratory

In the supine position, mobile abdominal viscera gravitate toward the dorsal body wall and press the dorsal parts of the diaphragm cephalad. The displacement lengthens muscle fibers in that portion of the diaphragm and increases the strength and effectiveness of its contractions during spontaneous ventilation. The benefit is improved aeration of the congested, compacted, and less compliant lung bases. With head-up tilt (see [Fig. 24-1C](#)), the visceral weight shifts away from the diaphragm and ventilation is enhanced. In the head-down position, the visceral mass, its weight potentially increased by the presence of abdominal fat, fluid, or tumors, can cause significant respiratory embarrassment by impeding caudad excursions of the contracting diaphragm and preventing adequate expansion of the lung bases.

In the supine position, gravity-induced vascular congestion forces the dorsal portions of the lung to function as a Zone 3.¹¹ Consequently, the compliance of the area is reduced, and passive ventilation tends to distribute gas preferentially to more easily distensible substernal units where pulmonary blood volume is less. To prevent development of a clinically significant ventilation–perfusion imbalance during use of controlled ventilation, tidal volumes must be used that are greater than the average amount that is sufficient for the spontaneously breathing, conscious patient.¹²

Variations of the Dorsal Decubitus Position

Supine

Horizontal. In the traditional horizontal supine position (dubbed “lying-at-attention”), the patient lies on the back with a small pillow beneath the head (see [Fig. 24-1A](#)). The arms are either comfortably padded and restrained alongside the trunk or abducted on well padded arm boards. Either arm (or both) may be extended ventrally and the flexed forearm secured to an elevated frame in such a way that perfusion of the hand is not compromised, no skin-to-metal contact exists to cause electrical burns if a cautery is used, and the brachial neurovascular bundle is neither stretched nor compressed at the axilla (see the left arm arrangement in [Fig. 24-15](#)). The lumbar spine may need padded support to prevent a postoperative backache (see [Complications of the Dorsal Decubitus Positions](#)). Bony contact points at the occiput, elbows, and heels should be padded.

Although the horizontal supine posture has a long history of widespread use, it does not place hip and knee joints in neutral positions and is poorly tolerated for any length of time by an immobilized, awake patient.

Figure 24-15. The semisupine position with dorsal pads supporting the torso, the extended arm padded at the elbow, and the elevated arm restrained on a well cushioned, adjustable overhead bar (A). Axillary contents (B) are not under tension and are not compressed by the head of the humerus, and a pulse oximeter ensures that the digital circulation is not compromised. The position is safe only if the arm does not become a hanging mechanism to support the torso. (Reproduced with permission from Collins VJ [ed]: Principles of Anesthesiology, 3rd ed. Philadelphia, Lea & Febiger, 1993.)

Contoured. A contoured supine posture (Fig. 24-2C) has been termed the *lawn chair position*.¹³ It is established by arranging the surface of the operating table so that the trunk–thigh hinge is angulated approximately 15 degrees and the thigh–knee hinge is angulated a similar amount in the opposite direction. The patient of average height then lies comfortably with hips and knees flexed gently. Quite often a person who has been required to lie motionless on a rigid horizontal table and then is changed to the contoured supine position offers an almost involuntary expression of relief and appreciation.

Figure 24-2. Establishment of the contoured supine (“lawn chair”) position. (A) Traditional flat supine table top. (B) Thighs flexed on trunk. (C) Knees gently flexed in final body position. (D) Trunk section leveled to stabilize floor-supported arm board. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

As in the horizontal supine position, the patient should have a pad or pillow beneath the occiput, elbows, and heels. Arms can be positioned as described for the horizontal supine posture.

Frog-Leg. On occasion, a pelvic surgeon may wish to place a supportive hand or instrument in the patient's vagina at some point during a laparotomy or laparoscopy. Placing the patient supine with the knees bent and the soles of the feet together (the frog-leg position, Fig. 24-3) separates the thighs sufficiently to permit access to the perineum and vagina for the surgeon standing at the patient's flank. If the patient's skeleton is stiff, lateral spread of the knees may seriously stress the hips or stretch branches of the obturator nerves; a pad of sufficient size should be used to support each knee (1) to minimize the opportunity for postoperative hip and back pain, and (2) to prevent a dislocated hip or fracture of an osteoporotic femur during the operation.

Figure 24-3. The frog-leg position for simultaneous access to the abdomen and vagina. See text. (Reproduced with permission from McLeskey CH [ed]: Geriatric Anesthesiology. Baltimore, Williams & Wilkins, 1997.)

Lateral Uterine Displacement. With a patient in the supine position, a mobile abdominal mass, such as a very large tumor or a pregnant uterus, can rest on the great vessels of the abdomen and compromise circulation. This is known as the *aortocaval syndrome* or the *supine hypotensive syndrome*. A significant degree of perfusion can be restored if the compressive mass is rolled toward the left hemiabdomen by manual compression, by a mechanical device producing leftward displacement, by leftward tilt of the table top, or by a wedge under the right hip.¹⁴ In some quarters, this modification of the dorsal decubitus position is referred to as *semisupine*.

Lithotomy

Standard. In the standard lithotomy position (Fig. 24-4), the patient lies supine with arms crossed on the trunk or with one or both arms extended laterally to less than 90 degrees on arm boards. Each lower extremity is flexed at the hip and knee, and both limbs are simultaneously elevated and separated so that the perineum becomes accessible to the surgeon. For most gynecologic procedures, the patient's thighs are flexed approximately 90 degrees on the trunk and the knees are bent sufficiently to maintain the lower legs nearly parallel to the floor. More acute flexion of the knees or hips can threaten to angulate and compress major vessels at either joint.

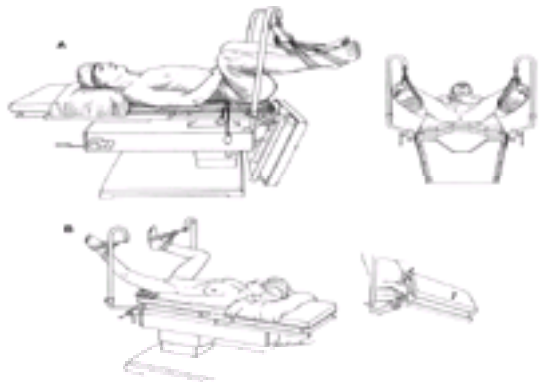

Figure 24-4. Standard lithotomy position with “candy cane” extremity support. (A) Thighs are flexed approximately 90 degrees on abdomen; knees are flexed enough to bring lower legs grossly parallel to the torso section of the table top. Arms are retained on boards, crossed on the abdomen, or snugged at the sides of patient. An inflatable bladder (blood pressure cuff bulb and manometer visible) placed under the lumbar spine helps retain lumbar curvature and may minimize postoperative backache. (B) Note the possibility for a scissoring injury to fingers as the leg section of the angulated table top is returned to horizontal. Towel-wrapping the hands helps keep the digits out of the hinge. (Modified with permission from Figures 6-5, 6-14, and 6-15 of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Numerous devices are available to hold legs that are elevated during delivery or operation. Each should be fitted to the stature of the individual patient. Care should be taken to ensure that angulations or edges of the padded holder do not compress the popliteal space or the upper dorsal thigh. Compartment syndromes of one or both lower extremities have resulted from prolonged use of the lithotomy position with some types of support devices.¹⁵

When the legs are to be lowered to the original supine position at the end of the procedure, they should first be brought together at the knees and ankles in the sagittal plane and then lowered slowly together to the table top. This minimizes torsion stress on the lumbar spine that would occur if each leg were lowered independently. It also permits gradual accommodation to the increase in circulatory capacitance, thereby avoiding sudden hypotension.¹⁶

Low. For most urologic procedures and for many procedures that require simultaneous access to the abdomen and perineum, the degree of thigh elevation in the lithotomy position is only approximately 30–45 degrees (Fig. 24-5). This reduces perfusion gradients to and from the lower extremities and improves access to a perineal surgical site for members of the operating team who may need to stand at the lateral aspect of either leg.

Figure 24-5. Low lithotomy position for perineal access, transurethral instrumentation, or combined abdominoperineal procedures.

High. Some surgeons prefer to improve access to the perineum by suspending the patient's feet from high poles. The effect is to have the patient's legs almost fully extended on the thighs (Fig. 24-6) and the thighs flexed 90 degrees or more on the trunk. The posture produces a significant uphill gradient for arterial perfusion into the feet, requiring careful avoidance of systemic hypotension. Less mobile patients may tolerate this posture poorly because of angulation and compression of the contents of the femoral canal by the inguinal ligament (see Fig. 24-6A), or stretch of the sciatic nerve (see Fig. 24-6B), or both.

Figure 24-6. High lithotomy position. Note potential for angulation and compression/obstruction of contents of femoral canal (A, insert) or stretch of sciatic nerve (B). (A reproduced with permission from McLeskey CH [ed]: Geriatric Anesthesiology. Baltimore, Williams & Wilkins, 1997. B reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Exaggerated. Transperineal access to the retropubic area requires that the patient's pelvis be flexed ventrally on the spine, the thighs almost forcibly flexed on the trunk, and the lower legs aimed skyward so as to be out of the way (Fig. 24-7). The result places the long axis of the symphysis pubis almost parallel to the floor. This exaggerated lithotomy position stresses the lumbar spine, produces a significant uphill gradient for perfusion of the feet, and may restrict ventilation because of abdominal compression by bulky thighs. It can be tolerated under anesthesia but can rarely be assumed by an awake patient. Control of ventilation is usually necessary. If painful lumbar spine disease exists, an alternative surgical position may need to be chosen beforehand to avoid severely accentuating the lumbar distress after surgery. This position has been associated with a very high frequency of lower extremity compartment syndrome.¹⁷ Maintenance of adequate perfusion pressure in the legs is important.

Figure 24-7. The exaggerated lithotomy position. Shoulder braces, usually needed to stabilize the torso, are placed over the acromioclavicular area to minimize compression of the brachial plexus and adjacent vessels. (Reprinted with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Tilted. Frequently, some degree of head-down tilt is added to one of the lithotomy positions. If the tilt is great enough, and particularly in the instance of the exaggerated lithotomy position, the patient may slide cephalad. Care must be taken to avoid this situation; there are several anecdotes from medicolegal actions involving patients who slid off operating tables with resulting head injuries.

Depending on the degree of head depression, the addition of tilt to the lithotomy position combines the worst features of both the lithotomy and the head-down postures. The weight of abdominal viscera on the diaphragm adds to whatever abdominal compression is produced by the flexed thighs of an obese patient or of one placed in an exaggerated lithotomy position. Ventilation should be assisted or controlled. Because elevation of the lower extremities above the heart produces an uphill perfusion gradient, systemic hypotension and compressive leg wrapping should be avoided because they are potential contributors to the development of compartment syndromes in the legs of lithotomized patients.¹⁵ This perfusion gradient often is unpredictable and exaggerated, potentially increasing the risk of compartment syndrome.¹⁸

Head-Down Tilt—The Trendelenburg Position. Sometime during the mid-1800s, Bardenhauer, an innovative German surgeon in Cologne, began to elevate the hips of patients to gravitate the viscera cephalad and help expose lesions deep within the pelvis.¹⁹ Others may have used the posture at about the same time. That unique maneuver, tilting a patient 30–45 degrees head down (Fig. 24-8), was adopted and popularized by Friedrich Trendelenburg of Bonn and Leipzig before 1870. However, its publication apparently awaited an article by Meyer, an American pupil of Trendelenburg, in 1885.²⁰

Figure 24-8. Head-down tilt. Foreground figure shows traditional steep (30- to 45-degree) tilt described by Trendelenburg. Leg restraints and knee flexion stabilize the patient, avoiding the need for wristlets or shoulder braces that threaten the brachial plexus. Upper figure shows 10 to 15 degrees of head-down tilt (the Scultetus position), which is more common in modern surgical procedures. (Reprinted with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

During World War I, Walter Cannon, the eminent physiologist, espoused the notion that the Trendelenburg position was advantageous in the treatment of shock. He believed that it improved circulatory return from the lower extremities and improved cerebral circulation.⁶ Although he repudiated that opinion in 1923,²¹ the use of the “Trendelenburg” position to treat shock remained a common practice for many years. Reports of Cole in 1952,²² Weil in 1957,²³ Guntheroth *et al* in 1964,²⁴ Taylor and Weil in 1976,²⁵ and Sibbald’s group in 1979⁷ have carefully detailed the disadvantages of the Trendelenburg position as a means of treating shock.

An alternate position that is useful for treating supine patients with perfusion deficits, such as moderate hypovolemia from blood loss or vasodilation from spinal anesthesia, is mild elevation of the lower extremities with the trunk remaining horizontal (see Fig. 24-2D). The blood volume in the legs is thought to be “autotransfused” into the central circulation by the maneuver. With the thorax level and a small pillow placed under the patient’s head, changes in pulmonary function should be minimal and cerebral blood volume should be relatively unchanged.

Because of vasocompensation, whatever increase in mean arterial pressure accompanies elevation of the legs may be transient. In most instances, however, the rational therapy for the perfusion deficits described earlier is volume infusion rather than postural adjustment.

Reich and associates,²⁶ studying well instrumented, anesthetized patients, have compared circulatory variables in the level supine position with those recorded after 3 minutes of marked (60-degree) elevation of the lower extremities or after 3 minutes of 20 degrees of head-down tilt. They found that head-down tilt only minimally increased cardiac output and mean arterial pressure, whereas leg raising slightly increased mean arterial pressure without affecting cardiac output. In each posture, there was evidence of deteriorating pulmonary function and right ventricular stress. They urged caution in the use of either maneuver in patients with pulmonary disease or right ventricular compromise.

Cephalad displacement of the diaphragm and obstruction of its caudad inspiratory stroke accompany the Trendelenburg position because of gravity-shifted abdominal viscera. Consequently, the work of spontaneous ventilation is increased for an anesthetized patient in a posture that already worsens the ventilation–perfusion ratio by gravitational accumulation of blood in the poorly ventilated lung apices. During controlled ventilation, higher inspiratory pressures are needed to expand the lung.

Intracranial vascular congestion and increased intracranial pressure can be expected to result from head-down tilt. For patients with known or suspected intracranial disease, the position should be used only in those rare instances in which a surgically useful alternate posture cannot be found. Maintenance of the position should then be as brief as possible, and the need for postoperative neurologic intensive care should be anticipated.

The classic Trendelenburg position used 30–45 degrees of head-down tilt and required some means of preventing the patient from sliding cephalad out of position. Anklets and bent knees are a satisfactory method of retaining the tilted patient in position (see Fig. 24-8) if the anklets are not excessively tight and if the flexed knee joints are placed sufficiently caudad of the leg–thigh hinge of the table top so that the adjacent firm edge of the depressed leg section of the table cannot indent either proximal calf. Should indentation occur, compressive ischemia and phlebitis or a compartment syndrome are likely to result.

Historically, shoulder braces also have been used to prevent cephalad sliding. These braces are best tolerated if placed over the acromioclavicular joints, but care must be taken to see that the shoulder is not forced sufficiently caudad to trap and compress the subclavian neurovascular bundle between the clavicle and the first rib. If the braces are placed medially against the root of the neck, they may easily compress neurovascular structures that emerge from the area of the scalene musculature.

Head-Down Tilt—The Scultetus Position. The usual amount of head-down tilt now used in most surgical suites is probably approximately 10–15 degrees (see Fig. 24-8, insert). This corresponds not to the position of Trendelenburg (see Fig. 24-8), but to one referred to as the Scultetus position. The name appears to be derived from that of the German surgeon, Johann Schultes (1595–1645), who was known as Scultetus.

Although the Scultetus position does not threaten to dislodge the patient cephalad, its minimal head-down tilt has been shown to cause an increase in myocardial oxygen consumption in spontaneously ventilating patients.⁵ The use of head-down tilt as a method of increasing the caliber of veins in the superior caval circuit to assist in the insertion of central catheters should be seriously questioned in patients with impaired myocardial perfusion. It should be avoided in the presence of increased intracranial pressure.

In a study of 34 premedicated adults whose hearts were initially in sinus rhythm, Keusch and associates²⁷ compared the electrocardiographic effects of introducing a pulmonary artery catheter with a self-sealing diaphragm through the right internal jugular vein with each patient first in 5–10 degrees of head-down tilt (posture A) and then in 5 degrees of head-up tilt with right tilt (posture B, semisupine). Access to the pulmonary artery was equally swift in either position. Although the overall incidence of dysrhythmias was similar in both groups (A: 29/34, B: 26/34), during head-up right tilt the patients had only half as many malignant dysrhythmias (8/26) as they did when head down (17/29). In most instances, head-down tilt malignant dysrhythmias changed to benign ones when the patient was placed in the head-up right tilt

position, further confirming the head-down position as an unnecessary choice to facilitate pulmonary artery catheter insertion.

Complications of the Dorsal Decubitus Positions

Postural Hypotension

Depending on the resilience of the patient's vasocompensatory mechanisms, postural hypotension may be seen when a head-elevated position is being established. On a statistical basis, it can be presumed to be the most frequent complication of a head-elevated posture. If mean arterial pressure at the circle of Willis remains above 60 mm Hg in a patient who is not hypertensive, the postural hypotension may require little treatment other than to appropriately decrease the concentration of anesthetic drugs to preserve compensatory reflexes. If the degree of hypotension encountered is more severe, further head elevation should be delayed until the level of anesthetic is decreased; in addition, judicious use of fluids and vasopressors can re-establish effective perfusion.

Postural hypotension may also appear in the presence of inadequately replaced blood loss when the intravascular space has been functionally increased either by lowering the legs to horizontal at the termination of the lithotomy position or by returning a head-down tilt to horizontal. Volume repletion is the indicated therapy, although judiciously small doses of vasopressors may sometimes be needed initially.

Pressure Alopecia

Prolonged compression of hair follicles can produce hair loss. Abel and Lewis²⁸ described patients who had pain, swelling, and exudation where the occiput had been supporting the weight of the head for long periods in the Trendelenburg position. Alopecia occurred between the 3rd and 28th postoperative day; regrowth was complete within 3 months. Use of tight head straps to hold anesthetic face masks and prolonged hypotension and hypothermia have also been associated with compression alopecia.²⁹ Frequently turning the patient's head during long operations³⁰ and use of padded, soft head supports are recommended to reduce the risks of this complication.

Pressure Point Reactions

Weight-bearing bony prominences can produce ischemic necrosis of overlying tissue unless proper padding is applied. Hypothermia and vasoconstrictive hypotension may enhance the process. The heels, the elbows, and the sacrum are particularly vulnerable and should be carefully padded as a prophylactic routine. This is particularly important when patients are thin or when the operation will be prolonged.

BRACHIAL PLEXUS AND UPPER EXTREMITY INJURIES

Brachial Plexus Neuropathy

Root Injuries. Shoulder braces placed tight against the base of the neck can compress and injure the roots of the brachial plexus. Braces, if needed at all, are considered less harmful when placed more laterally over the acromioclavicular joint.

The dorsal decubitus positions do not usually threaten structures in the patient's neck unless considerable lateral displacement of the head occurs. In that position, the roots of the brachial plexus on the side of the obtuse head-shoulder angle can be stretched and damaged. If the upper extremity is fixed at the wrist, the stretch injury of the plexus can be accentuated as the head moves laterally away from the anchoring point of the wrist. Similarly, exaggerated rotation of the head away from an extended arm can be associated with a brachial plexus injury.

Sternal Retraction. Frequently, the patient undergoing a median sternotomy has both arms padded and secured alongside the torso. An alternative is to have both arms abducted.³¹ Vander Salm *et al*^{32,33} described first rib fractures and brachial plexus injuries associated with median sternotomies. They related the extent of the injury to the amount of retractor displacement of the rib, with the most severe injury being caused by displacement sufficient to produce a first rib fracture. Roy and associates,³⁴ in a study of 200 consecutive adults scheduled for cardiac surgery via a median sternotomy, positioned the left arm either abducted and padded on an arm board with the palm supinated or secured by a draw sheet alongside the trunk; the right arm was always placed alongside the trunk. They found a 10% incidence of upper extremity nerve injury that was not influenced by internal mammary artery harvest, internal jugular vein catheterization, or left arm position. Surgical manipulation was more contributory than extremity positioning in producing trauma to the brachial plexus. Jellish *et al*³¹ reported that there is less slowing of somatosensory evoked potentials (SSEPs) of the ulnar nerve during sternotomy when both arms are abducted instead of tucked at the sides. However, they found no differences in perioperative symptoms between patients in the arm-abducted vs. arm-at-side groups.

Compromised Retroclavicular Space. If the shoulder is allowed to move dorsally, or if the supine patient shifts cephalad while the shoulder mechanism is anchored at the levels of the hip or shoulder, the retroclavicular space is diminished or obliterated and the clavicle may be pressed forcibly against the underlying first rib. In the process, the subclavian neurovascular bundle can be compressed and its structures injured. Occasionally, a dampened pulse at the wrist identifies this situation in the sitting position; support under the elbow is required to lift the shoulder and relieve the obstruction.

Long Thoracic Nerve Dysfunction

Several lawsuits have centered on postoperative serratus anterior muscle dysfunction and winging of the scapula (Fig. 24-9) alleged to be the result of position-related injuries to the long thoracic nerve of Bell, which arises from nerve roots C5, C6, and C7. Because C5 and C6 fibers of the nerve course through the middle scalene muscle and emerge from its lateral border to join the fibers from C7, it has been proposed that neuropathies of the long thoracic nerve are traumatic in origin.³⁵ Johnson and Kendall³⁶ described the widely variable etiology of serratus anterior muscle paralysis in a review of 111 cases and found only 13% occurring after either a surgical procedure or an obstetric delivery. Because the nerve is not routinely involved in a stretch injury of the brachial plexus and because the plexus is not routinely involved when long thoracic nerve dysfunction occurs, the relationship between postoperative long thoracic nerve palsy and patient positioning remains speculative. Based on evidence of Foo and Swann³⁷ plus data from litigations, Martin³⁸ concluded that in the absence of demonstrable trauma, postoperative dysfunctions of the long thoracic nerve were quite likely the result of coincidental neuropathies, possibly of viral origin.

Figure 24-9. mScapular winging. The serratus anterior muscle (*upper right*) is supplied solely by the long thoracic nerve that branches immediately from C5, C6, C7, and sometimes C8 (*left figure*). Arising on the lateral ribs and inserting on the deep surface of the scapula, the muscle keeps the shoulder girdle approximated to the dorsal rib cage. Long thoracic nerve palsy allows dorsal protrusion of the scapula (*lower right*). See text. (Reproduced with permission from Martin JT: Postoperative isolated dysfunction of the long thoracic nerve: A rare entity of uncertain etiology. *Anesth Analg* 69:614, 1989.)

Axillary Trauma from the Humeral Head

Excessive abduction of the arm on an arm board may thrust the head of the humerus into the axillary neurovascular bundle. The bundle is stretched at that point and its neural structures may be damaged. In the same manner, vessels can be compressed or occluded and perfusion of the extremity can be jeopardized.

Radial Nerve Compression

The radial (musculospiral) nerve, arising from roots C6–8 and T1, passes dorsolaterally around the middle and lower portions of the humerus in the musculospiral groove. At a point on the lateral aspect of the arm, approximately three fingerbreadths proximal to the lateral epicondyle of the humerus, the nerve can be compressed against the underlying bone and injured. Pressure from the vertical bar of an anesthesia screen or a similar device against the lateral aspect of the arm³⁹ and excessive cycling of an automatic blood pressure cuff⁴⁰ have been implicated in causing damage to the radial nerve. Postoperative radial nerve dysfunction is a relatively rare reason for malpractice litigation.^{41,42}

Clinical manifestations of a radial nerve lesion include wrist drop, weakness of abduction of the thumb, inability to extend the metacarpophalangeal joints, and loss of sensation in the web space between the thumb and index finger.⁴³ Radial nerve function can be rapidly assessed by noting the patient's ability actively to extend the distal phalanx of the thumb.

Median Nerve Dysfunction

Isolated injuries to the median nerve allegedly owing to positioning are uncommon and the mechanism is obscure.^{41,42} A more likely source of injury is iatrogenic trauma to the nerve during access to vessels in the antecubital fossa, as might occur during venipuncture. Anecdotally, this problem appears to occur primarily in men 20–40 years of age who cannot easily extend their elbows completely. Forced elbow extension after administration of muscle relaxants and while positioning the arms has been suggested as one potential mechanism for this problem. A quick check of sensation over the dorsal and palmar surfaces of the distal phalanges of the first and second fingers identifies an acute injury.

Ulnar Neuropathy

Improper anesthetic care and patient malpositioning have been implicated as causative factors in the development of ulnar neuropathies since reports by Budinger⁴⁴ and Garriques⁴⁵ in the 1890s. These factors likely play an etiologic role for this problem in some surgical patients. Other factors, however, may contribute to the development of postoperative ulnar neuropathies. In a series of 12 inpatients with newly acquired ulnar neuropathy, Wadsworth and Williams⁴⁶ determined that external compression of an ulnar nerve during surgery was a factor in only 2 patients. A prospective study at Mayo Clinic found that ulnar neuropathies develop in medical as well as surgical patients during inpatient and outpatient care.⁴⁷ It is clear that ulnar neuropathies may develop in both surgical and medical patients during or after an episode of care. The mechanisms of the neuropathy, however, are unclear.

Typically, anesthesia-related ulnar nerve injury is thought to be associated with external nerve compression or stretch caused by malpositioning during the intraoperative period. Although this implication may be true for some patients, three findings suggest that other factors may contribute. First, a retrospective study found male sex, high body mass index (³³⁸), and prolonged postoperative bed rest to be associated with these ulnar neuropathies.⁴⁸ Of these, male sex is the factor most commonly associated with perioperative ulnar neuropathy. Various reports suggest that 70–90% of patients who have this problem are male.^{41,42,46,47} and ⁴⁸ Second, many patients with perioperative ulnar neuropathies have a high frequency of contralateral ulnar nerve conduction dysfunction.⁴⁹ This finding suggests that many of these patients likely have asymptomatic but abnormal ulnar nerves before their anesthetics, and these abnormal nerves may become symptomatic during the perioperative period. Finally, many patients do not notice or complain of ulnar nerve symptoms until more than 48 hours after their surgical procedures.^{48,49} A prospective study of ulnar neuropathy in 1502 surgical patients found that none of the patients had symptoms of the neuropathy during the first 2 postoperative days.⁵⁰ It is not clear whether onset of symptoms indicates the time that an injury has occurred to the nerve. Prielipp *et al*⁵¹ found that 8 of 15 awake volunteers who had notable alterations in their ulnar nerve SSEP signals from direct ulnar nerve pressure did not perceive a paresthesia, even when the P waveforms decreased as much as 72%.

Elbow flexion can cause ulnar nerve damage by several mechanisms. In some patients, the ulnar nerve is compressed by the aponeurosis of the flexor carpi ulnaris muscle and cubital tunnel retinaculum when the elbow is flexed by more than 110 degrees^{52,53} (Fig. 24-10). In other patients, this fibrotendinous roof of the cubital tunnel is poorly formed and can lead to anterior subluxation or dislocation of the ulnar nerve over the medial epicondyle of the humerus during elbow flexion. This displacement has been observed in approximately 16% of cadavers in whom the flexor muscle aponeurosis and supporting tissues have not been dissected.^{54,55} Ashenurst⁵⁵ has speculated that the ulnar nerve may be chronically damaged by recurrent mechanical trauma as the nerve subluxates over the medial epicondyle.

Figure 24-10. Medial-to-lateral view of right elbow. The cubital tunnel retinaculum (CTR) is lax in extension (A) as it stretches from the medial epicondyle (ME) to the olecranon (OI). The retinaculum tightens in flexion (B) and can compress the ulnar nerve (arrow). (Reprinted with permission from O'Driscoll SW, Horii E, Carmichael SW *et al*: The cubital tunnel and ulnar neuropathy. *J Bone Joint Surg Am* 73:613, 1991.)

External compression in the absence of elbow flexion also may damage the ulnar nerve.⁵⁶ Although compression within the medial epicondylar groove may be possible if the groove is shallower than normal, the bony groove usually is deep and the nerve is well protected from external compression.⁵⁷ More likely, external compression may occur distal to the medial epicondyle, where the nerve and its associated artery are relatively superficial. In an anatomic study, Contreras *et al*⁵⁸ observed that the ulnar nerve and posterior recurrent ulnar artery pass posteromedially to the tubercle of the coronoid process, where they are covered only by skin, subcutaneous fat, and a thin distal band of the aponeurosis of the flexor carpi ulnaris.

Patients in whom perioperative ulnar neuropathies develop are predominantly male.^{41,42,46,47} and ⁴⁸ Alvine and Schurrer⁴⁹ found that 15 of the 17 patients they prospectively identified to have perioperative ulnar neuropathies were men. In an earlier retrospective study of this problem, Warner *et al*⁴⁸ found the male-to-female ratio to be 2:1. Why are men more likely to have this complication? One can speculate that there are several anatomic differences between men and women that increase the likelihood of perioperative ulnar neuropathy developing in men. First, two anatomic differences may increase the chance of ulnar nerve compression in the region of the elbow. The tubercle of the coronoid process is approximately 1.5 times larger in men than women.⁵⁸ In addition, there is less adipose tissue over the medial aspect of the elbow of men compared with women of similar body fat composition.^{58,59} and ⁶⁰ Second, men may be more likely to have a well developed cubital tunnel retinaculum than women, and the retinaculum, if present, is thicker. A thicker cubital tunnel retinaculum may increase the risk of ulnar nerve compression in the cubital tunnel when the elbow is flexed.

Clinical manifestations of ulnar nerve dysfunction vary with the location and extent of the lesion.⁶¹ Nearly all patients have numbness, tingling, or pain in the sensory distribution of the ulnar nerves once they become symptomatic. However, there can be considerable ulnar nerve dysfunction before symptoms appear. Prielipp *et al*⁵¹ found that only 8 of 15 male volunteers with significant ulnar nerve conduction slowing noted any symptoms. More studies are needed to understand better the mechanism and natural history of ulnar neuropathy.

Ulnar nerve injury is relatively common.^{41,42,50} Also, a significant proportion of patients have symptoms of bilateral ulnar nerve dysfunctions both before and after surgery.⁴⁹ Therefore, some have speculated it might be helpful during the preanesthetic interview to inquire about a history of ulnar neuropathies (“crazy bone” problems) or previous surgery at the elbow. If such a history is indicated, the finding must be recorded and a discussion with the patient or family should present the possibility of a postoperative recurrence despite special precautions of padding and positioning.

The time of recognition of digital anesthesia associated with ulnar nerve dysfunction may be quite important in establishing the origin of the postoperative syndrome. If

ulnar hypesthesia or anesthesia is noted promptly after the end of anesthesia, as in the recovery facility, the condition is likely to be associated with events that occurred during anesthesia or surgery. If the recognition is delayed for many hours, the likelihood of cause shifts from the intra-anesthetic period to postoperative events. In a review of closed claims, Kroll and associates⁴¹ commented that postoperative ulnar dysfunction can occur as a result of events in the postanesthetic period and that nerve injury may develop in certain susceptible patients “despite conventionally accepted methods of positioning and padding.”

Opioids may mask postoperative dysesthesias and pain, but even strong analgesics cannot mask a loss of sensation due to nerve dysfunction. It may be helpful to assess ulnar nerve function and record these observations before discharging the patient from the recovery room.

Carpal Tunnel Syndrome Mimicking Ulnar Neuropathy

The prospective study of ulnar neuropathy from Mayo Clinic found 47 of 1502 patients had symptoms of numbness and tingling in the fourth and fifth fingers during the perioperative period.⁵⁰ On close assessment, 38 of these patients had transient carpal tunnel syndrome mimicking ulnar neuropathy. In 36 of these 38 patients, the symptoms resolved within 5 days of onset. Why does this syndrome develop in patients after procedures? The authors speculate that interstitial edema from perioperative fluid administration and decreased mobility may transiently increase pressure in a limited wrist compartment. As patients begin to use their arms, ambulate, and diurese in the days after their procedures, this edema and pressure in the wrist compartment may decrease and the symptoms should resolve. Further study is needed to determine the true cause for this phenomenon. Transient carpal tunnel syndrome should be considered, however, when evaluating postoperative patients for possible ulnar neuropathy.

Arm Complications

An arm that is hyperabducted, whether intentionally or by inadvertent pressure from the hip of a surgical assistant, can force the head of the humerus into the axillary neurovascular bundle and damage nerves and vessels to the arm. Abduction of the arm to more than 90 degrees from the trunk should be avoided. An arm board should be securely attached to the operating table to prevent its accidental release. An arm that is not properly secured can slip over the edge of the table or arm board, resulting in injury to the capsule of the shoulder joint by excessive dorsal extension of the humerus, fracture of the neck of an osteoporotic humerus, or injury to the ulnar nerve at the elbow. Conversely, in the unlikely event that the retaining strap is excessively tight across the supinated forearm (Fig. 24-11), the potential exists for pressure to compress the anterior interosseous nerve, a branch of the median nerve in the upper forearm that courses with its artery along the volar surface of the tough interosseous membrane. The result is an ischemic injury to the distribution of the nerve and artery that resembles a compartment syndrome in the lower extremity and may require prompt surgical decompression.⁶²

Figure 24-11. Arm restraint, if excessively tight, can compress the anterior interosseous nerve and vessel against the interosseous membrane in the volar forearm to produce an ischemic neuropathy. (Reproduced with permission from McLeskey CH [ed]: Geriatric Anesthesiology. Baltimore, Williams & Wilkins, 1997.)

Backache

Lumbar backache can be worsened by the ligamentous relaxation that occurs with general, spinal, or epidural anesthesia. Loss of normal lumbar curvature in the supine position is apparently the issue. Several folded towels or an inflatable bladder of a blood pressure cuff (see Fig. 24-4A) placed under the lumbar spine before the induction of anesthesia may help retain lordosis and make a patient with known lumbar distress more comfortable. An exception to this is the patient with palpable tender points in the lumbar area; the pressure of the pad may create enough distress for the patient to object strongly to its presence.

Elevation of the legs can worsen the pain of a herniated nucleus pulposus. When the lithotomy position is contemplated for a patient with a history of low back pain or a herniated lumbar disk, gentle passive attempts to have the patient assume the posture before anesthesia may be helpful in determining whether the position can be tolerated.

Perineal Crush Injury

The supine patient who is placed on a fracture table for repair of a fractured femur usually has the pelvis retained in place by a vertical pole at the perineum (Fig. 24-12), with the foot of the injured extremity fixed to a mobile rest. A worm gear on the rest lengthens the distance between the foot and the pelvis so that the bone fragments can be distracted and realigned. Unless the pole is well padded, severe pressure can be exerted on the pelvis, and damage can occur to the genitalia and the pudendal nerves. Complete loss of penile sensation has been reported after use of the fracture table.^{63,64} The correct position for the pole is against the pelvis between the genitalia and the uninjured limb.⁶³

Figure 24-12. Traction table with perineal post stabilizing patient while leg is elongated to reposition bone ends. Elevated leg risks hypoperfusion; pelvic post threatens genitalia. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Compartment Syndrome

If, for whatever reason, perfusion to an extremity is inadequate, a compartment syndrome may develop. Characterized by ischemia, hypoxic edema, elevated tissue pressure within fascial compartments of the leg, and extensive rhabdomyolysis, the syndrome produces extensive and potentially lasting damage to the muscles and nerves in the compartment. Because the pathologic process is at tissue level, distal pulses and capillary refill may remain intact while a compartment syndrome is developing in an extremity; thus, they are not useful indicators of the ongoing process. Ferrihemate, resulting from myoglobin destruction, exerts a direct toxic effect on renal tubular epithelium, and renal failure is likely.⁶⁵ Circulating debris from infections in the involved extremities is apt to be filtered by pulmonary microvasculature with injurious consequences for the lung.

Causes of a compartment syndrome while a patient is in any of the dorsal decubitus positions include (1) systemic hypotension and loss of driving pressure to the

extremity (augmented by elevation of the extremity); (2) vascular obstruction of major leg vessels by intrapelvic retractors, by excessive flexion of knees or hips, or by undue popliteal pressure from a knee crutch; and (3) external compression of the elevated extremity by straps or leg wrappings that are too tight, by the inadvertent pressure of the arm of a surgical assistant, or by the weight of the extremity against a poorly supportive leg holder.^{15,66} A tight strap on an arm board has been alleged to have compressed the anterior interosseous neurovascular bundle and created a forearm compartment syndrome.

Several clinical characteristics seem to be associated with perioperative compartment syndrome. Prolonged lithotomy posture in excess of 5 hours has been a common factor in literature anecdotes of postlithotomy compartment syndromes. For lengthy procedures in the lithotomy position, well padded holders that immobilize the limb by supporting the foot without compressing the calf or popliteal fossa seem to be the least threatening choice. There is considerable variability in the perfusion pressure of the lower extremity in elevated legs. Halliwill *et al*¹⁸ found significant blood pressure variation at the ankle in volunteers placed in various lithotomy positions. Several volunteers had mean pressures of less than 20 mm Hg when positioned in the high lithotomy position. This pressure is less than intracompartment pressures commonly measured in many lithotomy positions.

Usually, decompressive fasciotomies are the only means of terminating the cycle of ischemia and compartment edema. Alkalinizing the urine and promoting diuresis may reduce the degree of renal damage.

Finger Injury

In 1968, Courington and Little⁶⁷ described the amputation of a young woman's fingers that were caught between the leg and thigh sections of the operating table as the leg section was returned to the horizontal position at the termination of an operation during which the patient was in the lithotomy position (see Fig. 24-4B). A towel used to create a boxing-glove-like wrap on the hands of lithotomized patients may prevent such a tragic misadventure.⁶⁸ Carefully removing the patient's hands from the risky position before raising the foot of the table is less troublesome and probably as safe.

LATERAL DECUBITUS POSITIONS

Physiology

Circulatory

In the lateral decubitus position, the patient is turned onto one side of the trunk and stabilized to prevent accidental rolling toward either the supine or the prone posture. It is of practical and legal importance to note that the side of the body that rests on the table is the side that determines the name of the position (left side down = left lateral decubitus position).

If the legs are maintained in the long axis of the body, almost no pressure gradients exist along the great vessels from head to foot. Small hydrostatic differences are detected between the values recorded simultaneously by blood pressure cuffs placed on the two arms.

If the lower extremities are flexed laterally at the hips and allowed to remain below the level of the heart, blood pools in the distensible vessels of the dangling legs because of gravity-induced increases in venous pressure and resultant venous stasis. Wrapping the legs and thighs in compressive bandages is a common method to combat venous pooling. Marked flexion of the lower extremities at knees and hips can partially or completely obstruct venous return to the inferior vena cava either by angulation of vessels at the popliteal space and inguinal ligament or by thigh compression against an obese abdomen. A small support should be placed just caudad of the down-side axilla to lift the thorax enough to relieve pressure on the axillary neurovascular bundle and prevent disturbed blood flow to the arm and hand.

In the low-pressure pulmonary circuit, hydrostatic gradients occur between the two hemithoraces. Although the degree of gravity-induced lateral displacement of the heart is different in the two lateral decubitus positions, it is generally true that most of the down-side lung lies below the level of the atrium and that the up-side lung lies above it. Vascular congestion of the down-side lung resembles a Zone 3 of West *et al*,¹¹ whereas the relative hypoperfusion of the up-side lung resembles a Zone 2. Kaneko *et al*⁶⁹ found that the transition between Zone 3 and Zone 2 occurred at approximately 18 cm above the most dependent part of the lung.

If the cervical spine of the patient who is placed in a horizontal lateral decubitus position is carefully maintained in alignment with the thoracolumbar spine, almost no gradient occurs between pressures in the mediastinum and those in the head. However, if the head is improperly supported and sufficient lateral angulation of the neck occurs in either direction, obstruction of jugular flow may be produced.

Respiratory

In the presence of a supple chest, the lateral decubitus position can decrease the volume of the down-side hemithorax. The weight of the chest may force the down-side rib cage into a less expanded conformation. Gravity-induced shifts of mediastinal structures toward the down-side chest wall tend further to reduce the volume of the dependent lung. Abdominal viscera force the down-side diaphragm cephalad if the long axis of the trunk is horizontal or head down.

Spontaneous ventilation can partially compensate for the diaphragmatic stretching in the dependent hemithorax because the contractile efficiency of the elongated diaphragmatic muscle fibers is increased. The compacted lung base and Zone 3 vascular congestion decrease compliance and interfere with the distribution of gas during positive-pressure ventilation. An elevated kidney rest placed against either the down-side rib margin or flank, or that migrates into that position as the patient shifts on it, further interferes with movement of the down-side hemidiaphragm and passive ventilation of the dependent lung.

The up-side hemithorax is much less compressed than the dependent side, and because the lung lies above the level of the atria, it has less vascular congestion than the down-side lung. As a result, unless contralateral flexion has stretched the up-side flank muscles to the point of rigidity and limited excursions of the costal margin, positive-pressure ventilation is directed preferentially to the more compliant up-side lung. The result can easily be excessive ventilation of the underperfused up-side lung and hypoventilation of the congested down-side lung. The potential for a clinically significant ventilation-perfusion mismatch is obvious, particularly in the presence of pulmonary disease.

Variations of the Lateral Decubitus Positions Standard (Horizontal) Lateral Position

In the horizontal lateral decubitus position (Fig. 24-13), the patient is rolled onto one side on a flat table surface and stabilized in that posture by flexing the down-side thigh to almost 90 degrees on the trunk. The down-side knee is bent to retain the leg on the table and improve stabilization of the trunk. The peroneal nerve of that side is padded to minimize compression damage caused by the weight of the legs. The up-side thigh and leg are extended comfortably, and pillows are placed between the lower extremities. The head is supported by pillows or a head rest so that the cervical and thoracic spines are properly aligned. A small pad (usually referred to incorrectly as an axillary roll), thick enough to raise the thorax and prevent excessive compression of the shoulder, is placed just caudad to and out of the down-side axilla. It should ensure adequate perfusion of the down-side hand and minimize circumduction of the dependent shoulder, which might stretch its suprascapular nerve.

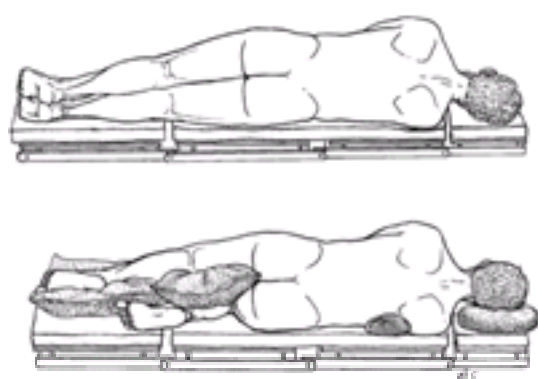

Figure 24-13. The standard lateral decubitus position. Proper head support, axillary roll, and leg pillow arrangement are shown on lower figure. Down-side leg is flexed at hip and knee to stabilize torso. Retaining straps and pad for down-side peroneal nerve are not shown. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Arms may be extended ventrally and retained on a single arm board with suitable padding between them, or they may be individually retained on a padded two-level arm support that can also help to stabilize the thorax (Fig. 24-14A). An alternate method of arm arrangement is to flex each elbow and place the arms on suitable padding on the table in front of the patient's face (see Fig. 24-14B).

Figure 24-14. Lateral position with arms (A) arranged on two-tiered arm supports or (B) positioned in front of the patient's head either on pillows or on the table surface. Note the location of the stabilizing strap(s) between the iliac crest and the head of the up-side femur (B, lower right) rather than on the head of the femur. Potential ventral relocation of the torso can threaten the down-side axillary neurovascular bundle (B, upper left). (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

The patient is stabilized in the lateral position by the use of one or more retaining tapes stretched across the hip and fixed to the underside of the table top. Care must be taken to see that the hip tapes lie safely between the iliac crest and the head of the femur rather than over the head of the femur in a compressive manner that could result in its aseptic necrosis (see Fig. 24-14B, lower insert). An additional restraining tape may be used across the thorax if needed; it is functional and safe if placed just caudad of the axilla, where it has little effect on thoracic expansion, but it can be dangerous if placed across the costal margins, where it inevitably restricts ventilation.

Semisupine and Semiprone

The semilateral postures are designed to allow the surgeon to reach anterolateral (semisupine) and posterolateral (semiprone) structures of the trunk. The semiprone position is commonly used in the postoperative management of patients who have had surgical procedures in the upper airway and in the postanesthesia care of children.

In the semisupine position, the up-side arm must be carefully supported so that it is not hyperextended and no traction or compression is applied to the brachial and axillary neurovascular bundles (Fig. 24-15). The supporting bar should be well wrapped to prevent electrical grounding contact (see Fig. 24-15A). Sufficient noncompressible padding should be placed under the dorsal torso (see Fig. 24-15, large figure) and hip to prevent the patient from rolling supine and stretching the anchored extremity. The pulse of the restrained wrist should be checked to ensure adequate circulation in the elevated arm and hand (Fig. 24-15B).

If the patient in the semiprone position is rolled more than approximately halfway between lateral and prone positions, the down-side arm is usually placed dorsal to the torso to avoid stress on that shoulder (Fig. 24-16). The down-side lower extremity is straight, whereas the up-side lower extremity is flexed at the hip and knee to prevent further pronation.

Figure 24-16. The semiprone position with the down-side leg extended and the up-side leg flexed at the knee, permitting moderate ventral rotation of the trunk. The down-side arm should be just behind the trunk to prevent axillary compression, as shown in the inset. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Sims' Position

In 1857, the prominent New York City gynecologist J. Marion Sims began to use a modification of the lateral position for operations on the perineum, rectum, vagina, and bladder⁷⁰ (Fig. 24-17). Subsequently, it became widely used as a birthing posture. It resembles the semiprone position in that the down-side lower extremity is extended, the up-side is flexed at the hip and knee to expose the perineum, and the patient rolls slightly ventrad.

Figure 24-17. The Sims position, used as a means of access to the structures of the perineum. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Flexed Lateral Positions

Lateral Jackknife. The lateral jackknife position places the down-side iliac crest over the hinge between the back and thigh sections of the table (Fig. 24-18). The table top is angulated at that point to flex the thighs on the trunk laterally. After the patient has been suitably positioned and restrained, the chassis of the table is tipped so

that the uppermost surface of the patient's flank and thorax becomes essentially horizontal. As a result, the feet are below the level of the atria, and significant amounts of blood may pool in distensible vessels in each leg.

Figure 24-18. The lateral jackknife position, intended to open intercostal spaces. Note the properly placed restraining tapes (*large figure*) thrusting cephalad to retain the iliac crest at the flexion point of the table and prevent caudad slippage, which compresses the down-side flank (*insert*). (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

The lateral jackknife position is usually intended to stretch the up-side flank and widen intercostal spaces as an asset to a thoracotomy incision. However, in terms of lumbar stress, restriction by the taut flank of up-side costal margin motion, and pooling of blood in depressed lower extremities, its physiologic price is high. Actually, its usefulness to the surgeon is brief, and its use should be limited. Once the rib-spreading retractor is placed in the incision, the position is of no value for the rest of the operation.⁷¹

Kidney. The kidney position (Fig. 24-19) resembles the lateral jackknife position, but it adds the use of an elevated rest (the “kidney rest”) under the down-side iliac crest to increase the amount of lateral flexion and improve access to the up-side kidney under the overhanging costal margin. Unlike the lateral jackknife position, the kidney position does not have a useful alternative for a flank approach to the kidney. Thus, the physiologic insults associated with the posture need to be limited by vigilant anesthesia and rapid surgery. Strict stabilizing precautions should be taken to prevent the patient from subsequently shifting caudad on the table in such a manner that the elevated rest relocates into the down-side flank and becomes a severe impediment to ventilation of the dependent lung.

Figure 24-19. The flexed lateral (kidney) position. Upper panels show improper locations of the elevated transverse rest, the flexion point of the table, in the flank (A) or at the lower costal margin (B) to impede ventilation of the down-side lung. The iliac crest at the proper flexion point (C), allowing the best possible expansion of the down-side lung. Restraining tapes deleted for clarity. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Complications of the Lateral Decubitus Positions

Eyes and Ears

Injuries to the dependent eye are unlikely if the head is properly supported during and after the turn from the supine to the lateral position. If the patient's face turns toward the mattress, however, and the lids are not closed or the eyes otherwise protected, preventable abrasions of the ocular surface can occur. Direct pressure on the globe can displace the crystalline lens or, particularly if systemic hypotension is present, cause retinal ischemia.

In the lateral position, the weight of the head can press the down-side ear against a rough or wrinkled supporting surface. Careful padding with a pillow or a foam sponge is usually sufficient protection against contusion of the ear. The external ear should also be palpated to ensure that it has not been folded over in the process of placing support beneath the head.

Neck

Lateral flexion of the neck is possible when the head of a patient in the lateral position is inadequately supported. If the cervical spine is arthritic, postoperative neck pain can be troublesome. Pain from a symptomatic protrusion of a cervical disk can be intensified unless the head is carefully positioned so that lateral or ventral flexion, extension, or rotation is avoided. Patients with unstable cervical spines can be intubated while awake and turned gently into the operative position while repeated neurologic checks, with which the patient cooperates and responds, are accomplished to detect the development of a positioning injury.⁷²

Suprascapular Nerve

Ventral circumduction of the dependent shoulder can rotate the suprascapular notch away from the root of the neck (Fig. 24-20). Because the suprascapular nerve is fixed both paravertebrally and at the notch, circumduction can stretch the nerve and produce troublesome, diffuse, dull shoulder pain. The diagnosis is established by blocking the nerve at the notch and producing pain relief. Treatment may require resecting the ligament over the notch to decompress the nerve. A supporting pad placed under the thorax just caudad of the axilla and thick enough to raise the chest off the shoulder should prevent a circumduction stretch injury to the nerve.

Figure 24-20. Circumduction of the arm displacing the scapula and stretching the suprascapular nerve between its anchoring points at the cervical spine and the suprascapular notch. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders,

Long Thoracic Nerve

Instances of postoperative winging of the scapula (see [Fig. 24-9](#)) have followed use of the lateral decubitus position.³⁸ Although coincidental viral neuropathies of the long thoracic nerve may play a major etiologic role in postoperative appearances of scapular winging in patients for whom only a dorsal decubitus position was used, the possibility of trauma to the nerve while establishing the lateral position is difficult to refute. Lateral flexion of the neck may stretch the long thoracic nerve in the obtuse angle of the neck. A firm head pillow pressed firmly against the down-side thoracic outlet in theory can traumatize either the long thoracic nerve or the root of the brachial plexus.

Aseptic Necrosis of the Up-side Femoral Head

Compression of the head of the femur into the acetabulum by pressure from a misplaced restraining tape in the lateral decubitus position can result in aseptic necrosis of the hip. Obstruction of the nutrient artery to the femoral head is the assumed cause, and the incidence of the complication is not known. Nevertheless, the tapes that stabilize the patient should be carefully placed across the up-side hip on the soft tissue in the space between the head of the femur and the crest of the ilium to avoid direct pressure on the femoral head (see [Fig. 24-18](#)).

Unstable Spine

Turning a patient with an unstable vertebral column into the lateral position requires careful teamwork and a sufficient number of personnel to ensure gentle handling. Bivalve frames such as the Foster and Stryker are rarely used. If the trachea is intubated while the patient is awake, neurologic evaluations can be accomplished while the slow turn is in progress as well as after the final position is established.⁷² Use of SSEP recordings before and after the turn may also be helpful. Having the responsible surgeon present and involved in establishing the desired position is prudent. Final support of the head and extremities should be accomplished before release of the patient by members of the turning team. Resumption of the supine position and movement of the patient to a bed or a transport cart require equally meticulous attention.

Peroneal Nerve

Pressure from weight of the down-side knee against the mattress may compress the common peroneal nerve as it courses laterally around the neck of the fibula. The patient's inability to dorsiflex the foot and loss of sensation over the dorsum of the foot indicate dysfunction of the nerve.⁷³ Padding the area of the head of the fibula is usually a sufficient precautionary measure.

VENTRAL DECUBITUS (PRONE) POSITIONS

Physiology

Circulatory

In the prone position, the circulatory dynamics vary according to the postural modification in use. If the legs remain essentially horizontal, pressure gradients in the blood vessels are minimal. If the patient is kneeling, or if the table chassis is rotated head high, significant pooling of venous blood in distensible dependent vessels is likely to occur.

With the patient lying on the soft abdominal wall, pressure of compressed viscera is transmitted to the dorsal surface of the abdominal cavity. Mesenteric and paravertebral vessels are compressed, causing engorgement of veins within the spinal canal. Obstruction of the inferior vena cava can produce immediate, visible distention of vertebral veins.⁷⁴ Because bleeding from incised vessels about the spine is increased under these circumstances, numerous modifications of the prone position have been created to free the abdomen from pressure, reduce the congestion of intraspinal veins, and facilitate surgical hemostasis.⁷⁴

If the head of a prone patient is below the level of the heart, venous congestion of the face and neck becomes evident. Turning the patient's head can alter arterial perfusion and venous drainage in both extracranial and intracranial vessels. Conjunctival edema is usual and reflects the influence of gravity on accumulation of extravascular fluid.

If the head is above the level of the heart, mean vascular pressures are decreased according to the distance above the heart, air entrainment in open veins is possible, and conjunctival edema is less evident or absent.

Kaneko *et al.*⁶⁹ described the perfusion of the entire lung of prone subjects in terms that subsequently fit the Zone 3 of West *et al.*¹¹ Backofen and Schauble⁷⁵ found that even the carefully established and supported prone position caused a significant fall in stroke volume and cardiac index, despite the development of increased vascular resistance in both the systemic and pulmonary circuits. No significant changes were detected in mean arterial pressure, right atrial pressure, or pulmonary artery occlusion pressure. On the basis of these observations, they recommend that, in patients whose cardiovascular status is precarious, invasive hemodynamic monitors be introduced to detect otherwise unrecognizable deterioration of cardiac function caused by positioning.

Respiratory

Using computed tomography, Gattinoni's group⁷⁶ found a dramatic redistribution of computed tomographic densities from the dorsal (paravertebral supine) to the ventral (substernal) portions of the lungs when subjects were turned from the supine to the prone position. The original areas of compression atelectasis reopened when those parts of the lung became nondependent, whereas fresh areas of compression atelectasis formed rather promptly in newly dependent areas of the lung. In their study group, they found no change in oxygenation or shunting when pronation occurred.

If the thorax is supple or compliant, the body weight of an anesthetized, prone patient compresses the anteroposterior diameter of the relaxed chest to a degree that is real but poorly defined. If the particular prone posture in use allows the pressure of the abdominal viscera to be sufficient to force the diaphragm cephalad, the lung is shortened along its long axis. With both the dorsoventral and the cephalocaudal dimensions of the lung decreased, and in the presence of the relative vascular congestion of a Zone 3 of West *et al.*,^{11,69} the compliance of the compacted prone lung can be anticipated to decrease. The result of decreased pulmonary compliance in a poorly positioned, prone, anesthetized patient is either an increased work of spontaneous ventilation or the need for higher inflation pressures during positive-pressure ventilation.

Proper positioning can retain more nearly normal pulmonary compliance by minimizing the cephalad shift of the diaphragm caused by compressed abdominal viscera. If the patient is arranged so that the abdomen hangs free, the loss of functional residual capacity is less in the prone position than in either the supine or the lateral position.⁷⁷ Rehder *et al.*⁷⁸ noted that the weight of the freed abdominal contents had an "inspiratory effect on the diaphragm" when the pronated patient was properly supported by pads under the shoulder girdle and pelvis.

Variations of the Ventral Decubitus Position

Full (Horizontal) Prone

In the so-called *full*, or *horizontal prone position* ([Fig. 24-21](#)), the requirement to elevate the trunk off the supporting surface so that the ventral abdominal wall is freed of compression almost always results in the head and lower extremities being below the level of the spine. If the table top is angulated at the trunk-thigh hinge to remove the lumbar lordosis and separate the lumbar spinous processes, and if the chassis is then rotated head-up sufficiently to level the patient's back, a significant perfusion gradient may develop between the legs and the heart. Wrapping the legs in compressive bandages, or the use of full-length elastic hosiery, minimizes pooling of blood in distensible vessels and supports venous return.

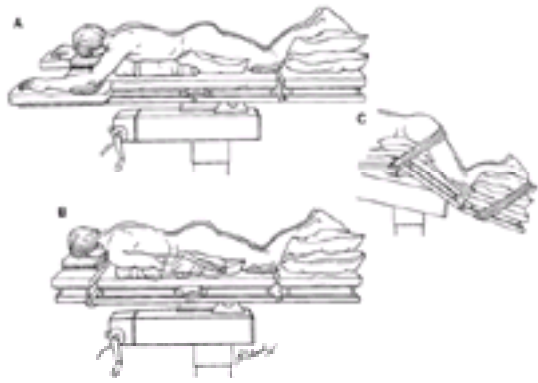

Figure 24-21. The classic prone position. (A) Flat table with relaxed arms extended alongside patient's head. Parallel chest rolls extended from just caudad of clavicle to just beyond inguinal area, with pillow over pelvic end. Elbows and knees are padded, and legs are bent at the knees. Head is turned onto a C-shaped foam sponge that frees the down-side eye and ear from compression. (B) Same posture with arms snugly retained alongside torso. (C) Table flexed to reduce lumbar lordosis; subgluteal area straps placed after the legs are lowered to provide cephalad thrust and prevent caudad slippage. (Reproduced with permission from Martin JT [ed]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Various ventral supports, including parallel rolls of tightly packed sheets, padded and adjustable metal frames, and four-pillar frames, have been devised to free the abdomen from compression.^{73,74} Each has merit, and no specific unit is unquestionably superior to all others. The choice is based on the physique of the patient, the requirements of the surgical procedure, and the available equipment.

Pronated patients with limited mobility of the neck, a history of postural neck pain, or a history suggesting a symptomatic cervical disk should have their heads retained in the sagittal plane, either with a skull-pin head clamp⁷⁹ or with a rocker-based face rest. If the neck is pain free and its mobility is satisfactory, the head can be turned laterally and supported on one of several soft sponge devices that prevents pressure on the down-side eye and ear.⁸⁰ However, forced rotation of the pronated head should be carefully avoided lest it induce postoperative neck pain.

When a patient is scheduled to be pronated after induction of anesthesia, it is worthwhile during the preanesthetic interview to obtain and record information about any limitations that may exist in his or her ability to raise the arms overhead during work or sleep.⁷⁴ If the patient is symptomatic, it may be prudent to place the arms alongside the torso after pronation (see the discussion of the [Thoracic Outlet Syndrome](#), later). If the arms are placed alongside the head (*i.e.*, extended ventrally at the shoulder, flexed at the elbow, and abducted onto arm boards), the musculature about the shoulders should be under no tension, neither humeral head should stretch or compress its axillary neurovascular bundle, ulnar nerves at the elbow should be padded, and the pulses at the wrists should remain full.

Prone Jackknife

The prone jackknife posture is used to provide access to the sacral, perianal, and perineal areas as well as to the lower alimentary canal ([Fig. 24-22](#)). The thighs are flexed on the trunk more than is usual in the full prone position, with the table surface hinges determining the degree of flexion achievable.⁷⁴

Figure 24-22. The prone jackknife positions. (A) Low jackknife position with the trunk–thigh hinge of the table used as the flexion position and augmented by a pillow under the pelvis. (B) Full jackknife position with the thigh–leg hinge of the table used as the flexion point to achieve more acute angulation of the hips on the torso. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Prone Kneeling

Kneeling positions have been used to improve operative conditions in the lumbar and cervico-occipital areas ([Fig. 24-23](#)). Numerous frames have been constructed to support the weight of a kneeling patient, and their usefulness again depends on local use and the physique of the patient. If the vertebral column is unstable, kneeling frames are not as useful as parallel longitudinal supports because kneeling risks application of shearing forces at the fracture site, with the potential for damage of the contents of the spinal canal. In massively obese patients who must be operated on in the prone position, kneeling frames tend to prevent pressure on the abdomen more successfully than longitudinal frames.

Figure 24-23. The Andrews kneeling frame with Wiltse's thoracic jack in use. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Complications of the Ventral Decubitus Positions

Eyes and Ears

The eyes and ears are at risk in the prone position even when the head is turned to one side. The eyelids should be closed, and each eye should be protected in some manner so that the lids cannot be accidentally separated and the cornea scratched. Instillation of lubrication in the eyes should be considered. Lightweight protective goggles have proved effective in this circumstance, although pressure injury from the goggle rims can occur. The eyes should also be protected against the head turning medially after positioning as well as against pressure being exerted on the globe. Monitoring wires and intravenous tubing should be checked after pronation to

see that none has migrated underneath the head. If the head is retained in the sagittal plane, the eyes should be checked after positioning to ensure that they are safe from compression by the head rest.

Conjunctival edema usually occurs in the eyes of the pronated patient if the head is at or below the level of the heart. It is usually transient, inconsequential, and requires only reestablishment of the normal tissue perfusion gradients of the supine position, or of a slight amount of head-up tilt, to be redistributed.

Blindness. Permanent loss of vision can occur after nonocular surgical procedures, especially those performed in a ventral decubitus position.^{81,82,83,84,85,86,87,88,89} and ⁹⁰ Visual loss after neurovascular and cardiopulmonary bypass procedures is well recognized and may be related to embolic events produced by the surgical intervention itself.^{91,92} and ⁹³ Visual loss after noncardiac, non-neurovascular procedures may initially be noticed by a loss of acuity (implying a pathologic process of the optic nerve or retina), a loss of visual field (implying a cortical, or, less likely, optic nerve pathologic process), or both. Although permanent postoperative visual loss is thought to be unusual under such circumstances, there is little information beyond anecdotal speculation regarding the frequency of this event.

Reported causes of significant permanent postoperative visual loss usually involve compromise of oxygen delivery to elements of the visual pathway and include ischemic optic neuropathy (anterior or posterior), retinal artery occlusion (central or branch), and cortical blindness.⁹⁴ No case series exists to provide information regarding the frequency of these events after nonocular, noncardiac surgery in a general surgical population. Roth *et al*⁸³ surveyed approximately 61,000 patients undergoing nonocular surgery (including cardiac surgery) over a 4-year period and identified 34 ocular injuries (mostly corneal abrasions), including one case of permanent postoperative visual loss from ischemic optic neuropathy after lumbar spinal fusion. In a review of 3450 spinal surgeries, Stevens *et al*⁸⁹ identified 3 patients who had permanent postoperative visual loss. Brown *et al*⁹⁵ identified three patients in whom postoperative ischemic optic neuropathy developed after noncardiac surgery over a 10-year period in one institution.

Positioning appears to be a risk factor for some of these events. Studies noting a relative high frequency of postoperative visual loss in spinal surgery patients have implicated positioning as one causative factor.^{84,85,86} and ^{87,90,93} Use of the knee–chest position,⁸⁴ the prone position,^{85,90,96} and the horseshoe head rest⁸⁶ have been cited as potential causes of visual loss, perhaps by direct pressure on the globe increasing the intraocular pressure beyond the perfusion pressure of the retina. Other reports, including those of spinal surgery patients, describe visual loss after intraoperative hypotension and massive blood loss,^{81,82} and ^{83,88,89} which may prevent adequate oxygen delivery to the visual apparatus. For example, all patients with ischemic optic neuropathy in the series of Brown *et al*⁹⁵ experienced periods of significant anemia (hemoglobin concentration <18 g/dl) and intraoperative hypotension. It is possible that venous congestion in the head associated with the prone position may be a contributing factor.

Neck Problems

Anesthesia impairs reflex muscle spasm that protects the skeleton against motion that would be painful if the patient were alert. Lateral rotation of the head and neck of an anesthetized, pronated patient, particularly one with an arthritic cervical spine, can stretch relaxed skeletal muscles and ligaments and injure articulations of cervical vertebrae. Postoperative neck pain and limitation of motion can result. The arthritic neck is usually best managed by keeping the head in the sagittal plane when the patient is prone.

Extremes of head and neck rotation can also interfere with flow in either the ipsilateral or contralateral vessels to and from the head. Excessive head rotation can reduce flow in both the carotid⁹⁷ and vertebral systems.⁹⁸ Impaired cerebral perfusion is the obvious consequence.

Brachial Plexus Injuries

Stretch injuries to the roots of the brachial plexus (Fig. 24-24A) on the side contralateral to the turned face are possible if the contralateral shoulder is held firmly caudad by a wrist restraint. If an arm is placed on an arm board alongside the head, care must be taken to ensure that the head of the humerus is not stretching and compressing the axillary neurovascular bundle (see Fig. 24-24B, Fig. 24-24C).

Figure 24-24. Sources of potential injury to the brachial plexus and its peripheral components when the patient is in the prone position. (A) Neck rotation stretching roots of the plexus. (B) compression of the plexus and vessels between the clavicle and first rib. (C) Injury to the axillary neurovascular bundle from the head of the humerus. (D) Compression of the ulnar nerve before, beyond, and within the cubital tunnel. (E) Area of vulnerability of the radial nerve to lateral compression proximal to the elbow. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

When an arm is placed on an arm board alongside the head, the forearm naturally pronates. As a result, the ulnar nerve, lying in the cubital tunnel (the groove between the olecranon process and the medial epicondyle of the humerus), is vulnerable to being compressed by the weight of the elbow (see Fig. 24-24D). Consequently, the medial aspect of the elbow must be well padded and its weight borne principally on the medial epicondyle.

Repetitious and prolonged inflations of automated blood pressure cuffs may result in injurious compression of either the radial nerve in the musculospiral groove above the elbow or the ulnar nerve before it enters the cubital tunnel¹⁰ (see Fig. 24-24E).

Thoracic Outlet Syndrome

Some patients complain of paresthesias in their arms after working with items on an overhead shelf, changing an overhead light bulb, or sleeping with one or both arms elevated alongside the head. The most likely explanation for the distress is the presence of a thoracic outlet syndrome with compression of the brachial plexus and subclavian vessels near the first rib.

As noted previously, it is recommended that all patients scheduled to be pronated should be questioned in the preanesthetic interview about their ability to work or sleep with arms elevated overhead, and their responses should be recorded on the charts.⁷⁴ A useful technique of inquiry if the history is in question is to have the patient clasp hands behind the occiput during the interview (Fig. 24-25). If the patient describes dysesthesias caused by having the arms overhead, or if dysesthesias occur while the patient is clasping hands on his or her occiput during the interview, it may be prudent to keep the arms alongside the trunk in the prone position. Agonizing, debilitating, and unremitting postoperative pain has been known to follow overhead arm placement in pronated patients who have had prior discomfort in their arms in that position.⁷⁴

Figure 24-25. Assessment of a potential thoracic outlet syndrome. (A) The patient has a history of distress when trying to work or sleep with arms over head. (B) Interview was carried out with patient's hands clasped over occiput and radial pulses checked for damping. (Reproduced with permission from McLeskey CH [ed]: *Geriatric Anesthesiology*. Baltimore, Williams & Wilkins, 1997.)

Breast Injuries

Average-sized breasts of a pronated woman, if forced laterally by ventral chest supports, can be stretched and injured along their sternal borders. Medial and cephalad displacement seems better tolerated. Massive breasts of a very large patient, if forced laterally, may not cause distress to the patient; however, if the arms are retained alongside of the torso, the huge breasts may force each arm far enough laterally to cause the surgical team difficulty in reaching the depths of an incision in the dorsal midline. Direct pressure on breasts containing enhancement prostheses can rupture the prosthesis. Tense skin grafts over mastectomy sites require considerable soft padding to prevent pressure necrosis and loss of the graft during a lengthy procedure in the prone position. No information has been located that pertains to gynecomastia and the prone position.

Coronary Artery Grafts

Mediastinal contents shift somewhat ventrad when a patient assumes the prone position. Apparently, the degree to which the ventrodorsal dimension of a stable chest is compressed by pronation can vary with the patient and the type of ventral supporting system used. Weinlander *et al*⁶⁹ reported a patient who had received a coronary artery bypass graft 8 years previously and who had, in the interim, been successfully anesthetized for a lumbar laminectomy done in the prone position on longitudinal chest rolls. For a repeat laminectomy, he was anesthetized and placed on a kneeling frame. The sternum was elevated by a pad to relieve venous congestion of the head and neck. Electrocardiographic evidence of myocardial ischemia followed placement of the sternal pad, was not relieved by drug therapy, and necessitated intra-aortic balloon pump support for emergency coronary artery revascularization after the laminectomy. Although a number of questions remain unanswered, Weinlander's group believed that sternal compression resulting from the pad adversely affected the previously functional coronary artery grafts and probably caused the ischemia. The implication that a sternal pad compresses the chest more than does a longitudinal frame is interesting, but further proof is needed.

The Unstable Spine

Pronating the patient whose spine is unstable requires skillful teamwork. (See also the previous discussion of [lateral decubitus positions](#).) Enough people should be part of the turning team to control the weight being lifted without allowing sudden shifts of the patient's posture. Participation of the principal surgeon should be a requirement if stabilizing traction must be removed during positioning. Keeping the patient sedated but awake during tracheal intubation in the supine position permits multiple neurologic evaluations during pronation and final positioning to ensure that the maneuvers caused no new deficits.⁷²

Use of bivalve nursing frames, such as the Foster or Stryker, allows anesthesia and intubation to be accomplished with the patient on the dorsal shell of the frame while traction is unchanged. Depending on the position of the neck in traction and the mobility of the mandible, fiberoptic or "blind" techniques may be needed for tracheal intubation. Addition of the ventral shell to the frame provides firm fixation of the patient during pronation. Removal of the dorsal shell after the turn permits the operation to be carried out on the remaining ventral shell without further risk from positioning torsion and without removing the corrective traction. Once the patient is pronated, care must be taken to ensure the stability of transoral anesthesia devices and the safety of the eyes and face.

Abdominal Compression

Compression of the abdomen by the weight of the prone patient's trunk can cause viscera to force the diaphragm cephalad enough to impair ventilation. If intra-abdominal pressure approaches or exceeds venous pressure, return of blood from the pelvis and lower extremities is reduced or obstructed. Because the vertebral venous plexuses communicate directly with the abdominal veins, increased intra-abdominal pressure is transmitted to the perivertebral and intraspinal surgical field in the form of venous distention and increased difficulty with hemostasis. All of the various supportive pads and frames, when properly used, are designed to remove pressure from the abdomen and avoid these problems.⁷⁴

Viscerocutaneous Stomata

Stomata that drain visceral contents into containers affixed to the abdominal wall are at risk in the prone position if they lie against a part of the ventral supporting frame or pad ([Fig. 24-26](#)). Compressive ischemia of the stomal orifice can cause it to slough.

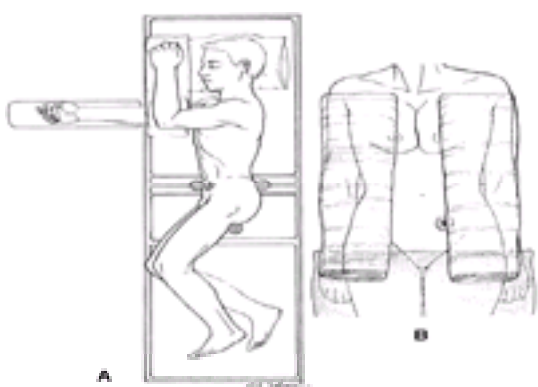

Figure 24-26. Postural supports compromising visceral stoma. Both the vertical abdominal support of a device designed to maintain a patient in the lateral position (A) and the longitudinal chest rolls supporting a pronated patient (B) can cause ischemic compression of a viscerocutaneous anastomosis and subsequent necrosis. Surgical repair of the stoma may be needed. (Reproduced with permission from McLeskey CH [ed]: *Geriatric Anesthesiology*. Baltimore, Williams & Wilkins, 1997.)

Knee Injuries

Extremely heavy patients, or those who have a pathologic condition of the knees, can have their knee joints injured in the kneeling position if the supportive ledges are not heavily padded (see [Fig. 24-23](#)). Often there is no suitable alternative position for these patients, and the possibility of postoperative knee problems caused by the kneeling prone position should be carefully discussed in the preanesthetic interview.

HEAD-ELEVATED POSITIONS

Physiology

Circulatory

Coonan and Hope¹⁰⁰ have reviewed circulatory changes that occur in alert humans with the change from the supine to the erect position. As the head is raised above the level of the heart, pressure gradients develop and increase with the degree of elevation. Blood shifts from the upper body toward the feet. Atrial filling pressures decrease, sympathetic tone increases, parasympathetic tone decreases, the renin-angiotensin-aldosterone system is activated, and fluid and electrolytes are retained by the kidneys.^{101,102} Intrathoracic blood volume decreases as much as 500 ml, pulmonary vascular resistance can double, and left atrial pressure falls more than right atrial pressure.¹⁰³ Cardiac output decreases 20–40%, and stroke volume falls by as much as 50%. Heart rate can increase by 30%. The arterial tree constricts, and systemic vascular resistance increases 30–60% to maintain a steady or increased mean arterial pressure, but the venous capacitance system is essentially unaffected.^{104,105} Oxygen consumption by the tissues is unchanged; therefore, the reduced oxygen supply (reduced cardiac output) causes an increased arteriovenous oxygen content difference.¹⁰⁶

Cerebral blood flow decreases by approximately 20% with high head elevation. Renal blood flow decreases as much as 30% (as much as 76% in massively obese patients in the sitting position), glomerular filtration decreases, and reduced secretion of antidiuretic hormone and aldosterone results in retention of water and sodium.¹⁰⁷

Albin *et al*.^{108,109} and Dalrymple¹¹⁰ noted similar alterations in cardiovascular parameters when the head-elevated position was established after patients were anesthetized. Although significant changes were not encountered with less than 60 degrees of head-up tilt, the magnitude of changes was often greater than the awake patient values presented previously. The alterations increased progressively for more than 1 hour after the final posture was achieved. The question arose as to whether an impaired circulatory system could or should adjust to these stresses.

The presence of an intracranial pathologic process can be expected to exacerbate potentially harmful reductions in cerebral blood flow associated with head elevation.¹¹¹ In the anesthetized, seated patient, mean arterial pressure should be measured at the level of the circle of Willis because that site is more reliable as an indicator of cerebral perfusion pressure in the head-elevated posture than is measurement at the level of the arm or wrist.¹⁰⁰

Respiratory

As the patient becomes more upright in the head-elevated dorsal decubitus position, the inspiratory stroke of the diaphragm becomes less impeded by the bulk of abdominal viscera. Spontaneous chest wall motion requires less effort, and less pressure is needed to inflate the lungs during passive inspiration. Functional residual capacity increases in the head-elevated positions.¹¹² Age-related increases in shunting are less in the head-elevated position than in the supine position.¹¹² Gurtner¹¹³ found that the diffusing capacity for oxygen was reduced in the sitting position as a result of the gravity-related decreases in perfusion of the upper portions of the lungs. Slutsky *et al*.¹¹⁴ however, found no difference between the supine position and the sitting position when measuring the ventilatory responses to hypoxia in volunteers.

Variations of the Head-Elevated Positions

Sitting

The full sitting position, characterized by the patient sitting upright in a chair, is uncommon in current practice. In the past it was used for instillation of air in the lumbar spine before pneumoencephalography, but now it is rarely chosen as a surgical position. It has disappeared as well in modern dental offices.

The classic sitting position for surgery places the patient in a semireclining posture on an operating table, with the legs elevated to approximately the level of the heart and the head flexed ventrally on the neck (Fig. 24-27). Head flexion should not be sufficient to force the chin into the suprasternal notch (see section on [Midcervical Tetraplegia](#), later). Elastic stockings or compressive wraps around the legs reduce pooling of blood in the lower extremities. The head is held in place by some type of a face rest or by a three-pin skull fixation frame.

Figure 24-27. (A) Conventional neurosurgical sitting position. The legs are at approximately the level of the heart and gently flexed on the thighs; the feet are supported at right angles to the legs; subgluteal padding protects the sciatic nerve. The frame of the head holder is *properly* clamped to the side rails of the back section in the event of hemodynamically significant air embolism. (B) *Improper* attachment of the head frame to the table side rails at the thigh section. In this position, the patient's head could not be quickly lowered because it would require disengaging the skull clamp. (Reproduced with permission from Martin JT, Warner MA [eds]: *Positioning in Anesthesia and Surgery*, 3rd ed. Philadelphia, WB Saunders, 1997.)

Supine—Tilted Head Up

A dorsal recumbent position with the head of the patient elevated somewhat is used for many operations involving the ventral and lateral aspects of the head (Fig. 24-28) and neck and occasionally, with the neck flexed, for transcranial access to the top of the brain. Its purpose is to improve access to the surgical target for the operating team as well as to drain blood and irrigation solutions away from the wound. The back section of the surgical table can be elevated as needed to produce a low sitting position (see Fig. 24-28A), or the entire table can be rotated head-high with the patient's extended legs supported by a foot rest (see Fig. 24-28B). Although the degree of tilt involved is not great, small pressure gradients are created along the vascular axis that can pool blood in the lower extremities or entrain air in patulous vessels that are incised above the level of the heart.

Figure 24-28. Head-elevated positions often used for operations about the ventral and ventrolateral aspects of the head, face, neck, and cervical spine. (A) The legs are at approximately heart level and the gradient into the head is appreciable but slight. (B) The flat table and foot rest are useful when a thyroidectomy is planned under regional anesthesia. (Reproduced with permission from Martin JT, Warner MA [eds]: *Positioning in Anesthesia and Surgery*, 3rd ed. Philadelphia, WB Saunders, 1997.)

Vidabaek¹¹⁵ has described a position (Fig. 24-29) that uses a modest degree of head elevation along with a carefully arched thoracolumbar spine to improve access to the organs of the upper abdomen. In a small series, he noted its usefulness to the surgeon as well as its associated difficulties for patients with precarious cardiovascular systems.

Figure 24-29. The xiphoid-high posture of Vidabaek used to gain access to the upper abdomen. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

For operations around the shoulder joint, the patient is often placed in a head-elevated semisupine position, with the upper torso rotated toward the nonsurgical shoulder and supported by a firm roll or pad (Fig. 24-30). The upper trunk is moved laterally until the raised surgical shoulder extends beyond the edge of the operating table. The torso is supported so that the hips are on the table, the surgical shoulder is off and above the table edge, and the head rests on either a pillow (see Fig. 24-30A) or a horseshoe head rest (see Fig. 24-30B). Access is thereby provided to both the dorsal and ventral aspects of the shoulder girdle. The surgical arm remains on the ventral torso and is prepared and draped to be mobile in the surgical field.

Figure 24-30. (A) The barber chair position for surgery around the shoulder joint. (B) The upper torso is rotated toward the nonsurgical shoulder and supported with a firm roll or pad. (Reproduced with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Lateral—Tilted Head Up

The lateral decubitus position with the head somewhat elevated, a means of access to occipitocervical lesions, has also been referred to as the park bench position.¹¹⁶ All the stabilizing requirements needed for the usual lateral decubitus position apply. The head is held firmly in a three-pin skull fixation holder, which can be readjusted as needed during surgery. Although the degree of head elevation used is mild, the position does not completely remove the threat of air embolization. The anesthesiologist has good access to the patient's face and ventral thorax for purposes of monitoring, manipulation, and resuscitation. Considerable attention should be directed to avoiding compression of neck veins, which can lead to an increase in intracranial pressure and to edema of the tongue.

Prone—Tilted Head Up

The ventral decubitus posture with the table rotated head high (Fig. 24-31) has become a widely used replacement for the sitting position as a means of access to dorsal structures of the head and neck. Usually the perceived advantage of the position is the avoidance of air embolization. Although the pressure gradients for air entrainment into patulous veins are less than in the full sitting position, the hazard is not eliminated. As a result of the positive-pressure inflation cycle of passive ventilation, a bothersome recurrent flux of cerebrospinal fluid into and out of the exposed wound may be encountered. The posture also severely restricts resuscitative access to the ventral thorax.

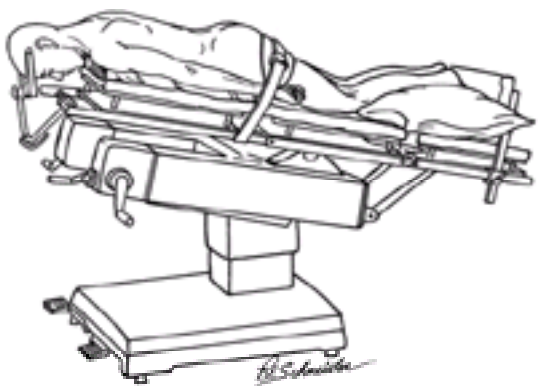

Figure 24-31. The skull-pin head rest used to stabilize a patient in the head-elevated prone position. Note the chest rolls used to free the abdomen from compression and the gluteal strap to minimize caudad slippage after head-up tilt. Complications of the Head-Elevated Positions

Postural Hypotension

In the anesthetized patient, establishing any of the head-elevated positions is frequently accompanied by some degree of reduction in systemic blood pressure. The normal protective reflexes are inhibited by drugs used during anesthesia. Measuring mean arterial pressures at the level of the circle of Willis is recommended to assess cerebral perfusion pressures more accurately. Treatment of hypotension consists of temporarily delaying the elevation of the head as the patient is positioned; reducing the concentration of anesthetic drugs; infusing crystalloids or colloids to increase effective circulating volume; and using appropriately small amounts of a

vasopressor as a temporary expedient.

Air Embolus
